fat sources (e.g., fish oil, olive oil, borage oil, etc.). In the United States, the current standard of care for both enteral and parenteral fat administration features significant components of fats that have been shown to encourage inflammation, most notably omega-6 fatty acids. Alternative fat sources have become the standard of care in Europe and are anticipated to receive U.S. Food and Drug Administration (FDA) approval in this country shortly. While there are still insufficient data to declare these alternatives superior to the standard of care, there is certainly sufficient evidence to warrant future study. As our understanding of the unique advantages and disadvantages of different fat sources matures, a reexamination of the role of fat alimentation in burn nutrition is sure to come due.[24]

Protein

Proteolysis is the metabolic hallmark of the hypermetabolic response to thermal injury. As much as 150 g of skeletal muscle is lost per day in the absence of adequate nutritional support.[6] If not attenuated, ongoing systemic proteolysis leads to immune dysfunction and retarded wound healing. Protein requirements of 1.5–2 g/kg per day in burned adults and 2.5–4 g/kg per day in burned children is well accepted in clinical practice. Unfortunately there are limits to the rate of effective protein assimilation as well. Increasing protein intake above these values will often increase urea load and azotemia, with limited additional impact on muscle wasting.[25–27]

Amino acids alanine, arginine, and glutamine play a key role in wound healing in burn patients. Glutamine plays an important role in the function of enterocytes and lymphocytes, and low plasma glutamine concentrations have been associated with increased bowel permeability and increased rates of infection. Copious studies in animal models of trauma and shock have shown distinct roles for these particular amino acids in recovering enteral and immunologic competence.[28] Glutamine supplementation and other "immunotrition" formulas featuring these key amino acids have been associated with decreased incidents of infection, shorter hospital stays, and decreased mortality in the setting of traumatic injury.[29–31] While the appropriateness and even safety of glutamine supplementation has recently been called into question by the results of a large, international randomized controlled trial in critically ill patients, showing an increased mortality risk in patients randomized to receive high-dose parenteral glutamine supplements, how these results should be interpreted remains in question (Fig. 28.5). (See further discussion in the section on formulas.)

Nutritional Support

In the face of the metabolic storm associated with acute burn injuries, provision of effective nutritional support is critical to wound healing, avoidance of complications and, ultimately, survival. Failure to provide sufficient calories superimposes starvation over a state of hypercatabolism, resulting in devastating loss of lean body mass and depletion of the protein-energy pool available to meet the pressing needs of wound healing, mucosal integrity, and basic immunologic defenses.[30,32–34]

ENTERAL NUTRITION

Benefits of Enteral Nutrition

In addition to serving as a means for systemic delivery of nutrients, enteral nutrition (EN) performs a critical function in supporting the alimentary tract itself. Enteral feeds provide direct high-concentration nutrients (e.g., glutamine, alanine), stimulate enteric blood flow, maintain barrier function by preserving tight-junction integrity, and induce production and release of mucosal immunoglobulin and critical endogenous growth factors. These functions are not replaced with parenteral nutrition (PN).[35] After dietary ingestion, polysaccharides such as fiber and starch undergo bacterial fermentation in the colonic lumen. Bacterial fermentation provides two functions crucial to intestinal health: (1) it supports the normal flora of the gut lumen, which in turn prevents colonization and subsequent infection (e.g., *Clostridium difficile*) and (2) it produces acetoacetate, propionate, and butyrate (a short-chain fatty acid). Butyrate appears to be the preferred fuel of colonic mucosa cells and is therefore essential for mucosal integrity. Both animal and human studies show that the presence of enteral feeds (in addition to or in place of PN) is associated with increased mucosal mass, mucosal oxygenation, brush-border enzyme synthesis, and villus height when compared to PN alone.[35,36] Clinically enteral feeding has frequently been found to associate with improved clinical outcomes both in terms of gastrointestinal and total patient morbidity and mortality.

Initiation of Feeds

Early Initiation. Copious data support the safety and benefit of initiating EN early in the context of traumatic injury and in burns specifically.[37,38] In both clinical and animal studies of thermal injury and shock, early EN has consistently been shown to result in improved survival and function of the enteric mucosa and decreased bacterial translocation. Perhaps most importantly, early enteral feeding represents one of the most effective means of metabolic modulation in thermal injury, with a significant blunting of the catabolic response to thermal injury associated with early feeding protocols.[39–46]

Full feeds should not be delivered in the setting of marked hemodynamic instability and/or high-dose vasopressor requirements because this runs the risk of inducing or exacerbating nonobstructive mesenteric ischemia. However complete EN can be delivered safely to patients on low to moderate doses of vasopressors with stable or decreasing vasopressor requirements.[1,17,47]

In patients without hemodynamic compromise, feeding should be initiated rapidly. While the traditional practice has long been to gradually titrate enteric feeds up to a goal rate over time, there is reason to suspect that a more aggressive approach may be warranted. Pilot studies have suggested that restarting feeds immediately and at full-goal postoperatively (rather than titrating) is well tolerated in burn patients undergoing excision and grafting. The approach of gradually restarting feeds results in significant calorie deficits accumulating over the course of care. In patients still in the midst of resuscitation, though, foregoing the process of gradually increased feeding rates may increase the rates of gastric ileus.[48,49]

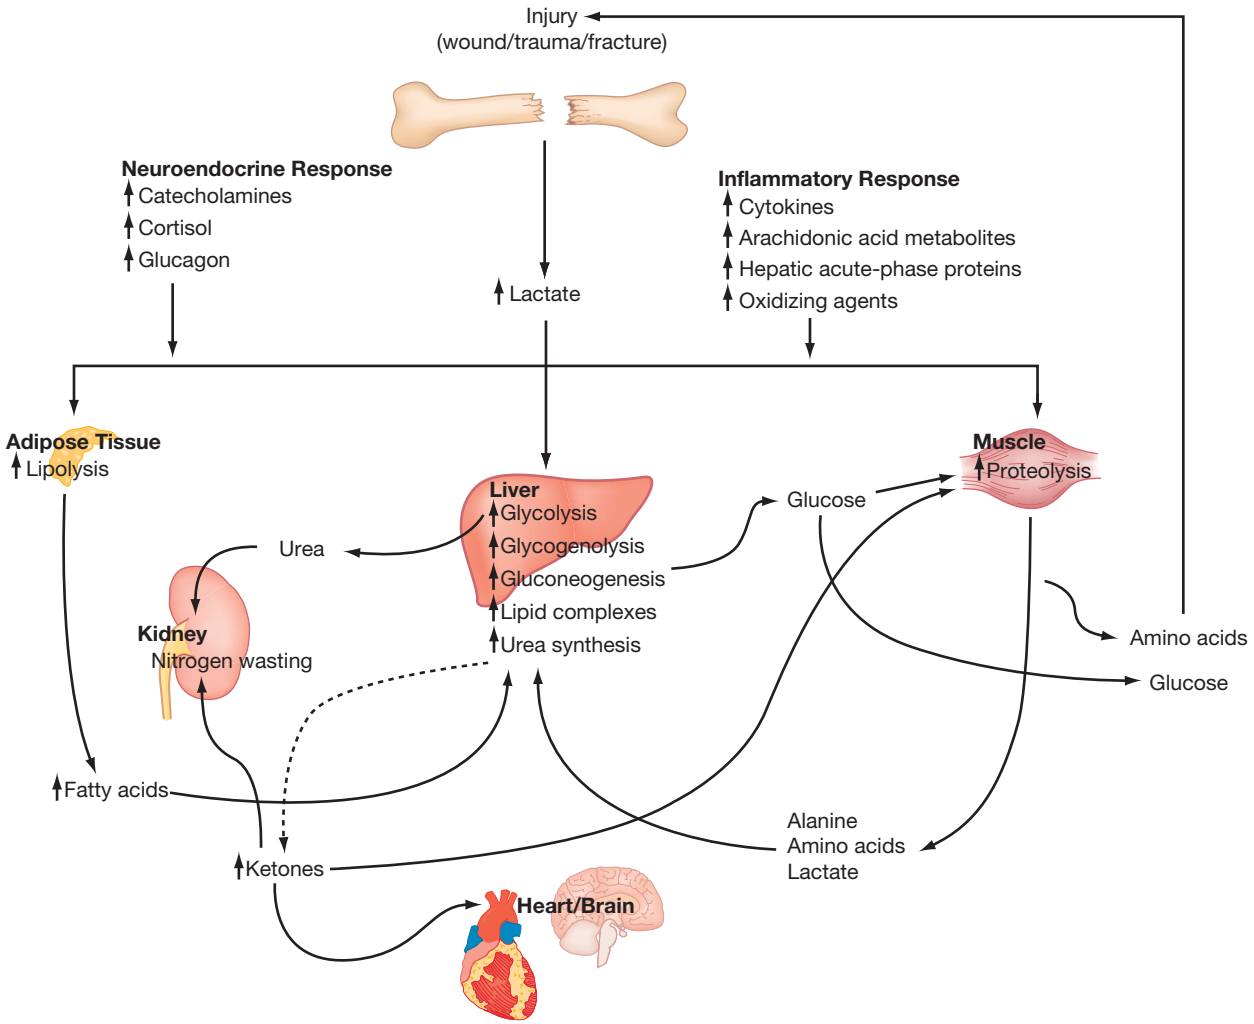

Fig. 28.5 Schematic representation of thermal-injury-induced shifts in substrate metabolism.

DELIVERING ENTERAL FEEDS

PO Feeding

For the conscious patient with an intact appetite and swallowing function, direct oral intake is the preferred feeding modality. When prescribing a patient an oral diet, it is essential that the physician continuously monitor for adequate intake. In the acute surgical setting, patients may fail to take in adequate calories due to decreased appetite, depressed mental status, pain, or any other practical obstacle to eating. Should a patient consistently fail to meet estimated caloric needs with a PO diet, consideration should be given to supplemental feeds via nasoenteric tube.

In those patients continuing to take food orally, careful monitoring should be maintained to ensure appropriate nutrition. Left unchecked, patients may frequently undereat or take in a disproportionate amount of calories as sugar or fat. A simple nutritional journal listing all foods and liquids consumed should be maintained by the nursing staff, patient, and/or family throughout the day, and dietary adjustments can be encouraged as needed. In patients attempting to meet all needs orally (and thus avoid the need for an enteric access tube), supplemental "protein shakes" can be quite helpful in boosting total protein-caloric input.

Enteral Access for Feeding

Burn victims, particularly those suffering from larger burns, frequently prove incapable of eating sufficient quantities to meet their nutritional needs. Direct enteral feeding ("tube feeding") is the route of choice to supplement or replace oral intake.

Either gastric or small-bowel access tubes can be used for delivering EN. Gastric feeding access allows for direct (trophic) feeding of the gastric mucosa. In the immediate postburn phase of resuscitation, though, gastric dysmotility can present quite early in response to burn injury and pose significant risk for aspiration and (particularly in children) vagally mediated cardiac events. As such, we recommend placement of a venting naso- or oro-gastrostomy tube for the duration of initial resuscitation.

The same dysmotility effect does not tend to manifest in the small bowel as rapidly or as profoundly as in the stomach. Feeding using a nasojejunal tube advanced past the ligament of Treitz can be initiated within 6 hours following injury and may help in preempting the onset of

starvation-associated ileus. This approach also allows continuous feeding during surgeries and physical therapy sessions. It should be noted that some authorities recommend attempting gastric feeds before resorting to postpyloric feeding, reasoning that gastric feeds may minimize the risk of gastric ileus associated with severe injury.

Nasojejunal feeding may be preferable in some settings because it does not need to be stopped prior to surgery to prevent aspiration. Contrary to the previously postulated protective effect of the pyloric sphincter, the largest randomized controlled trial and most recent meta-analysis of earlier studies indicate that nasogastric and nasojejunal feeds are associated with comparable rates of pneumonia.[50]

In the past it was thought that monitoring residual stomach volumes via gastric tubes prevented aspiration pneumonia by (1) serving as a marker of enteric feed intolerance and (2) alerting the clinician to gastric distension so that feeds can be held to avert impending reflux and/or aspiration. Recently large, multiinstitutional clinical trials have shown that larger gastric residual volumes do not actually predict aspiration, and forgoing gastric residual monitoring altogether did not increase the incidence of pneumonia.[51–53] In both studies, increasing or eliminating the gastric residual volume threshold led to significantly improved nutritional intakes.

DIET COMPOSITION AND ENTERAL FEED FORMULAS

Numerous enteral formulations are available and can be classified according to their composition. Standard formulas are sterile, nutritionally complete, and intended for patients with a normal GI tract who cannot ingest adequate nutrients and calories by regular oral diets. Modular formulas consist of a singular macronutrient as a source of calories (e.g., fiber, protein) and are generally used by mixing with standard or specialty formulas (Table 28.1).

In a subset of distinctly hypermetabolic patients, the use of high-sugar, high-protein diets consisting of 3% fat, 82% carbohydrate, and 15% protein stimulates protein synthesis, increases endogenous insulin production, and improves lean body mass accretion.[13]

Muscle protein degradation is markedly decreased with the administration of a high-carbohydrate diet compared with fat-containing diets. Endogenous insulin concentration is increased, improving the net balance of skeletal muscle protein by decreasing protein breakdown. (See the previous discussion on "substrate-specific requirements" for further discussion of the impact of augmenting various nutritional components.)

Immunonutrition

As noted earlier, immune dysfunction represents one of the most critical complications of malnutrition in burn patients. Specific nutrients, including arginine, omega-3 polyunsaturated fatty acids, glutamine, and nucleotides, have been shown to modulate the host response in animal and clinical experiments, with potential improvements in immune function. Clinically arginine supplementation is intended to support T lymphocytes and provides a substrate for the generation of nitric oxide. Inclusion of nucleotides nonspecifically enhances immune competence. Long-chain omega-3 fatty acids decrease the production of inflammatory eicosanoids, cytokines, and adhesion molecules. This occurs directly by replacing arachidonic acid as an eicosanoid substrate, inhibiting arachidonic acid metabolism, and giving rise to antiinflammatory resolvins. The indirect effect occurs through the modulation of transcription factors that regulate the expression of inflammatory genes. Omega-3 polyunsaturated fatty acids are potentially useful antiinflammatory agents and may be beneficial for patients at risk of acute and chronic inflammatory conditions (Table 28.2).[54]

Immune-enhancing formulas consist of nutritional components enriched with arginine, glutamine, nucleotides, and omega-3 fatty acids. Although most formulations are hyperosmolar at full strength, dilution by 25% to 50% to make isotonic and hypotonic formulas, respectively, is initially preferred to minimize the possibility of diarrhea from excess osmotic load and to facilitate absorption.

A myriad of clinical trials of immunoenhancing nutritional therapies over the past 5–10 years have yielded conflicting results ranging from great promise early on to disappointing and even concerning results from more recent trials. Most troublesome, the REDOX trial, which examined the impact of glutamine supplementation in a large, heterogeneous population of critically ill patients, found that patients receiving glutamine supplementation had no benefit but, rather, an actual increase in mortality as compared to those subjects treated with standard of care. Naturally this finding has greatly dampened enthusiasm for glutamine supplementation and immunonutrition in general.

While application in broader patient populations was disappointing, studies limited to major trauma and burn patients show a more consistent benefit. It is thus quite possible that glutamine supplementation and immunonutrition can still benefit certain subsets of critically injured patients, including those with massive burns.[29,55–59] Studies of serum glutamine levels in broad populations of critically ill patients suggest that not all are deficient. Thus the advantage of immunonutrient supplements may be greater in populations with a greater risk for deficiency—i.e., premorbidly malnourished patients or acutely catabolic trauma and burn patients.[60–65] Finally post-hoc analysis of the redox data suggested that the majority of the mortality risk associated with glutamine supplementation could be attributed to those patients already in multiorgan or renal failure prior to initiation of treatment. It is therefore quite possible that glutamine supplementation could prove particularly beneficial should a different set of exclusion criteria be applied. Clearly there is significant work to be done before the precise role of immunonutrient supplementation is made clear.

PARENTERAL NUTRITION

For decades, the critical-care literature has emphasized the significant morbidity and even mortality risks associated with the use of PN. This emphasis on the risks of PN has led to the widespread dogma that the beneficial impact of PN can outweigh its risks only when applied to patients who are otherwise facing prolonged total starvation. More recent reassessments of PN suggest that the risk profile of

PN has declined significantly over the past 20 years in the setting of improving efficacy of contemporary critical care practices.[66–69]

Although PN undoubtedly involves significant risks and morbidity, there is reason to believe that recent advances in critical care (e.g., improved glycemic control practices, increased evidence of infection control techniques) have significantly mitigated these risks. Multiple large trials have evaluated the use of PN as a supplement to rather than replacement for EN, with variable results. Large multiinstitutional clinical trials in broader populations of critically ill patients have found that the use of PN as a supplement to EN or as a replacement for EN (i.e., TPN) no longer worsens outcomes even in patients able to tolerate EN. Perhaps most

convincingly, Harvey et al. randomized 2400 ICU patients to receive either EN or PN and found no indication of increased 30-day morbidity or mortality in the PN group.[70] While extremely provocative, these findings have not been tested in burn patients specifically. Such studies would be well-warranted and should be encouraged.

The utility of supplemental PN (applied liberally) remains a matter of considerable debate. It is our opinion that supplemental nutrition can be quite helpful when applied selectively, based on the clinician's assessment of the individual patient's metabolic needs and nutritional status. It is our practice to use supplemental PN in the acute phase of burn injury response in any patients unable to tolerate enteral feeds at quantities sufficient to meet (or at least approach) protein-caloric requirements. Alternatively in those patients who manifest enteral feeding intolerance in the subacute phase of their burn injury response, we typically prescribe supplemental PN only to those with evidence of preexisting malnutrition at the time of burn.[71–73]

Prior to receiving PN, patients should be hemodynamically stable and able to tolerate the fluid volume and nutrient content of parenteral formulations; PN should be used with caution in patients with congestive heart failure, pulmonary disease, diabetes mellitus, and other metabolic disorders because the significant amounts of fluid and sugar may be difficult for patients to tolerate (Table 6.9). While there has been some debate as to the optimal timing for initiating TPN in patients unable to tolerate adequate EN, results of recent large randomized controlled trials suggest that early initiation of TPN is an appropriate general strategy in such patients (Tables 28.3 and 28.4).[66,74,75]

MEETING PRESCRIBED FEEDING GOALS

Frequently failures to provide adequate nutrition result not from underprescription, but from unanticipated (and often undetected) gaps in execution. Even in the setting of a fully invested care team treating under a clearly articulated nutritional care plan, calories provided will frequently fall short of the amount prescribed because, for example, enteral feeds are held for studies or procedures or interrupted by the clamping of enteral tubes for medication administration or transport. Even PN may be interrupted for transportation or compounding delays.[76,77] The key to

Table 28.5 Complications of Enteral Feeding

Problem	Common Causes	Management
Diarrhea	Medications (e.g., antibiotics, H_2 blockers, laxatives, hyperosmotic, hypertonic solutions), feeding intolerance (osmolarity, fat), acquired lactase deficiency	Measure stool output Rule out infection (bacterial, viral, parasitic) Supply fiber Change medication or formula Check osmolarity and infusion rate Replace lost fluids as needed Administer antimotility medications (e.g., loperamide, codeine)—Note: do not administer antimotilities until *Clostridium difficile* colitis has been ruled out
Nausea and vomiting	Delayed stomach emptying, constipation, medications, odor and appearance of formulations	Administer feedings at room temperature Use isotonic formulations Use a closed system when possible Reduce doses of narcotics Use gastroprokinetic agents (metoclopramide, erythromycin) Monitor gastric residuals and stool output
Constipation, fecal impaction	Dehydration, lack or excess of fiber	Monitor fluid balance daily Rectal disimpaction Consider the use of cathartics, stool softeners, laxatives, or enemas
Aspiration pneumonitis	Long-term supine position, delayed stomach emptying, altered mental status, malpositioned feeding tube, vomiting, nonfunctional nasogastric drainage tube	Place head of bed at 45 degrees during feedings Stop EN if gastric residual volume exceeds 200 mL Use of nasoduodenal or nasojejunal tubes has not been shown to decrease aspiration risk (when compared to gastric feeding)
Hypervolemic hyponatremia (overhydration)	Excess fluid intake, refeeding syndrome, organ failure (e.g., liver, heart, kidney)	Monitor fluid balance and body weight daily Consider fluid restriction Change formula (avoid low-sodium intake) Initiate diuretic therapy
Hypernatremia	Dehydration, inadequate fluid intake	Increase free water
Dehydration	Diarrhea, inadequate fluid intake	Determine cause Increase fluid intake
Hyperglycemia	High content of carbohydrate in feedings, insulin resistance	Evaluate and adjust feeding formula Consider insulin regimen Check for dextrose-based carriers in IV medications
Hypokalemia, hypomagnesemia, hypophosphatemia	Diarrhea, refeeding syndrome	Correct electrolyte abnormalities Determine cause Reduce rate if refeeding syndrome is present and monitor patient
Hyperkalemia	Excess potassium intake, renal impairment	Change feeding formula Reduce potassium intake Consider insulin regimen

minimizing such gaps between prescribed and delivered calories is awareness, with careful monitoring of delivery. Once recognized, such gaps can be minimized by making a conscious effort to keep all feeding interruptions to a minimum and establishing some mechanism to compensate for anticipated gaps in nutrition. For example, when prescribing tube feed rates, we often increase the resting energy expenditure (REE) multiplier to 1.4 or even 1.6 to compensate for such gaps.

COMPLICATIONS OF NUTRITIONAL SUPPORT

Complications of nasogastric and enteric feeding include nausea and vomiting, epistaxis, sinusitis, nasal necrosis, aspiration leading to pneumonia, tube malpositioning, dislodgment, and feeding-associated diarrhea. Fine-bore tubes are more comfortable but can become blocked easily. Auscultation examination of gastric fluid aspirate and pH testing can be used to confirm tube position, particularly for large-bore nasal tubes, although many units prefer radiologic confirmation. Tubes can also be inserted under endoscopic or fluoroscopic guidance (Table 28.5). (See the preceding section on "delivering enteral nutrition" for a discussion of ways to minimize aspiration risk.)

Unfortunately in burn patients efforts to deliver adequate nutrition enterally are frequently complicated by the degree of feeding intolerance manifested by either diarrhea or ileus (i.e., aperistalsis). GI ileus may reflect an underlying deterioration; therefore monitoring gastric residual volumes serves as an indicator of intercurrent conditions such as sepsis. In burn patients specifically, residuals that increase above the amount of food delivered routinely every hour have been shown to correlate with the development of bacterial sepsis. A full sepsis workup should be considered in any critically ill or injured patient with a sudden increase in gastric residuals over 200 mL.[78]

Ileus is derived from mesenteric hypoperfusion prior to adequate resuscitation, and it is reversed once the patient has been resuscitated. Conversely overresuscitation leads to GI edema and should also be avoided. The initiation of

immediate enteral feeding allows the delivery of calculated caloric requirements by the third day postinjury. Early enteral feeding is associated with reduction of hypermetabolism and less intense elevations in glucagon, cortisol, and catecholamine levels.[18,20,45,60]

Diarrhea probably represents the most common complication of EN and typically presents an ongoing challenge in the management of the massively burned patient. The source of this diarrhea is multifactorial, making it fairly difficult to manage. In the setting of shock, diarrhea can represent mucosal failure from incipient intestinal ischemia. A variety of medications can contribute to this problem, most notably antacid agents and antibiotics. Infectious causes are not particularly common but nonetheless must be ruled out. *Clostridium difficile* should always be ruled out due to its potential for severe deterioration and the risk for contagion to other patients. Cytomegalovirus enterocolitis can emerge secondary to burn-associated immunosuppression. Naturally, specific pathogens endemic to the individual patient's exposure history should always be considered.

The most common source of diarrhea in burn patients treated with enteral tube feeds is likely the feeds themselves. The high osmolar concentration of these feeds, the volume of feeds required to meet the high caloric requirements of burn patients, and the gut response to stress all combine to result in a state of relative *solute overload*. Inappropriately rapid administration of hyperosmolar solutions may result in diarrhea, dehydration, electrolyte imbalance, hyperglycemia, and loss of potassium, magnesium, and other ions through diarrhea. Reducing the osmolality by decreasing formula strength while adjusting the rate is the first step in addressing this complication. If aggressive administration of hyperosmolar solute continues, pneumatosis intestinalis with bowel necrosis and perforation can result. Hyperosmolar nonketotic coma can also occur with enteral feedings. In some cases, diarrhea may persist even after converting to isoosmolar feeds, reflecting intestinal failure from shock and/or ischemic insult. In such situations, it may be necessary to convert to TPN with trophic feeds until intestinal function returns.

Support with PN offers a distinctly different profile of side effects. The potential complications associated with the attendant access requirements (i.e., central lines) must be considered, particularly given the decreasing use of central lines for nonnutritional applications in contemporary critical care. And, of course, the PN formula itself can significantly disturb metabolic and electrolyte homeostasis. Without the benefit of first-pass liver metabolism and responsive regulation of absorption by the functional intestinal mucosa, the direct infusion of nutritional elements can result in precipitous, often dangerous shifts in serum chemistry (Table 28.6).

Table 28.6 Complications of Parenteral Nutrition

Problem	Common Causes	Management
Hypoglycemia	Excess insulin administration, sudden cessation of PN infusion	Stop insulin Start 10% dextrose IV Give a 50% dextrose ampule before resuming central line feeding
Hyperglycemia	Excess dextrose concentration, stress-associated (e.g., sepsis), chromium deficiency	0.1–0.2 U insulin/g dextrose therapy, SQ or IV insulin sliding scale, limit dextrose content, consider discontinuing PN until improved blood glucose control
Hypertriglyceridemia (acceptable concentrations <400 mg/dL)	Dextrose overfeeding, rapid administration of intravenous fatty emulsion (>110 mg/kg/h)	Infusion of IVFE should be restricted to less than 30% of total calories or 1 g/kg/day, given slowly, over no less than 8 to 10 h, if administered separately
Essential fatty acid deficiency (e.g., dermatitis, alopecia, hepatomegaly, thrombocytopenia, anemia)	1- to 3-week administration of PN lacking linoleic and alpha-linolenic fatty acid emulsions	2–4% daily energy requirements should be derived from linoleic acid, 0.5% from alpha-linolenic acid[43] (500 mL of 10% IVFE over 8–10 h, twice weekly)
Electrolyte and mineral abnormalities	Inadequate monitoring Inadequate supplementation in TPN formula	Electrolytes should be checked daily and parenteral nutrition formulas should be adjusted daily until electrolytes stabilized Parenteral iron uncommonly increases risk of anaphylactic reactions
Azotemia	Dehydration, excess protein, inadequate carbohydrate calories	Free water, 5% dextrose via a peripheral vein
Metabolic bone disease (osteoporosis in 41% of those on long-term home PN)	Unclear, multifactorial (e.g., postmenopausal, long-term PN, Cushing's syndrome, Crohn's disease, malabsorption, multiple myeloma, osteogenesis imperfect, corticosteroids, heparin, immobilization)	Early screening of risk factors, DEXA, management of premorbid conditions Special PN considerations: Supplement calcium, P, Mg, Cu Minimize aluminum contamination, treat metabolic acidosis, avoid heparin
Elevated liver function parameters (increased transaminase, bilirubin, alkaline phosphatase levels)	Common following initiation; usually temporary	If persistent, usually caused by amino acid load; reduce protein delivery

DEXA, Dual-energy x-ray absorptiometry.

Refeeding syndrome is a rare but dramatic clinical entity occasionally seen when initiating nutritional support in patients with long-standing starvation. It is heralded by the development of refractory hypokalemia, hypomagnesemia, and hypophosphatemia. Electrolyte abnormalities can result in cardiac failure and dysrhythmias, respiratory failure, neurologic disturbances, and renal and hepatic dysfunction. This should not present a concern in patients treated with early initiation of nutrition postinjury and continuous nutritional support.

Nutritional Assessment and Monitoring

Goal-directed nutritional support is a cornerstone of effective burn care. Underfeeding can result in stalled wounded healing, pulmonary compromise, increased immunocompromise, and a myriad of secondary and tertiary complications. Overfeeding is detrimental as well, leading to hypercapnia and metabolic acidosis, hyperglycemia, hypertriglyceridemia, hepatic dysfunction, and azotemia. Thus an ongoing nutritional assessment is the starting point for any nutritional therapy.

TOTAL CALORIC REQUIREMENTS

Determining nutritional requirements for patients is essential to effective care because the provision of inadequate or excess calories can adversely affect outcome. Caloric requirements in patients with severe burns are particularly difficult to predict because energy expenditure varies widely both from patient to patient and over the course of any individual patient's care. Energy demand and the metabolic response shift gradually with changes in body composition and acutely with acute physiologic stresses such as operative interventions or septic episodes.

A variety of equations have been created to estimate caloric requirements in burn patients (Tables 28.7 and 28.8). Although these are useful for establishing a quick estimate of caloric needs, their accuracy is limited.[79] Because no algorithm can fully accommodate the complex interactions among surgical stress, wound burden, infectious complications, and metabolism seen in the thermally injured patient, in situ measurement of REE are particularly valuable in this population.

An evaluation of the metabolic status can be performed by indirect calorimetry using bedside metabolic carts, which measure REE using expired gas volumes; oxygen consumption (VO_2) and carbon dioxide production (VCO_2) are measured directly as follows:

$$\text{REE (kcal/day)} = 1.44\,(3.9\,VO_2\,[\text{mL/min}] + 1.1\,VCO_2\,[\text{mL/min}])$$

These steady-state measurements have been shown to predict 24-hour energy expenditure with remarkable accuracy.[79] Measurements obtained are generally reliable and reproducible over a wide range of catabolic conditions, metabolic rates, and values of Fio_2. Given the significant changes in energy expenditure occurring over the course of care, the use of bedside carts for repeated measurements is

Table 28.7 Formulas for Estimating Caloric Requirements in Adult Burn Patients

Formula	Equation	Comments
	HARRIS-BENEDICT[61]	
Men	BEE (kcal/ day) = 66.5 + (13.75 × W) + (5.00 × H) − (6.76 × A)	Multiply BEE by stress factor of 1.2–2.0 (1.2–1.5 sufficient for most burns) to estimate caloric requirement
Women	BEE (kcal/day) = 655 + (9.56 × W) + (1.85 × H) − (4.68 × A)	
	CURRERI	
Age, 16–59 years	Calories (kcal/day) = (25 × W) + (40 × % BSAB)	Specific for burns, may significantly overestimate energy requirements, maximum 50% BSAB
Age >60 years	Calories (kcal/day) = (20 ×W) + (65 × % BSAB)	

A, Age (yr); *BEE,* basal energy expenditure; *% BSAB,* percentage of total body surface area burned; *H,* height (cm); *W,* weight (kg).

Table 28.8 Formulas for Estimating Caloric Requirements in Pediatric Burn Patients

Formula	Sex/Age (Years)	Equation (Daily Requirement in kcal)
WHO	Males 0–3	(60.9 × W) − 54
	3–10	(22.7 × W) + 495
	10–18	(17.5 × W) + 651
	Females 0–3	(61.0 × W) − 51
	3–10	(22.5 × W) + 499
	10–18	(12.2 × W) + 746
RDA	0–6 months	108 × W
	6 months–1 year	98 × W
	1–3	102 × W
	4–10	90 × W
	11–14	55 × W
Curreri junior	<1	RDA + (15 × %BSAB)
	1–3	RDA + (25 × %BSAB)
	4–15	RDA + (40 × %BSAB)
Galveston infant	0–1	2,100 kcal/m^2 BSA + 1,000 kcal/m^2 BSAB
Galveston revised	1–11	1,800 kcal/m^2 BSA+ 1,300 kcal/m^2 BSAB
Galveston adolescent	12+	1,500 kcal/m^2 BSA+ 1,500 kcal/m^2 BSAB

ideal for calculating optimal nutritional requirements in these extremely metabolically labile patients.

To attain a value for REE, indirect calorimetry is performed with the patient completely at rest—ideally hours removed from any acute manipulation such as medical or surgical procedure, rehabilitation therapy, and the like. To estimate the actual daily energy expenditure, this result is increased by 10–20% to allow for variability and activity.[79,80]

Indirect calorimetry also provides insight into the substrate metabolism balance via the respiratory quotient ($RQ = VCO_2/ VO_2$). An RQ in the range of 0.7 to 1.0 is seen in the normal uptake of mixed substrates. An RQ of 0.7 or less is consistent with either an increased portion of fat calories supplied (or utilized) or underfeeding. On the other hand, an RQ higher than 1.0 suggests lipogenesis from either carbohydrate-bias skewed input or overfeeding.

Traditionally nitrogen balances have been used to assess the balance between protein anabolism and catabolism in trauma patients. A negative nitrogen balance occurs when the excretion of nitrogen exceeds the daily intake (i.e., net catabolism), whereas a positive nitrogen balance is associated with muscle gain. Unfortunately the variable and often large quantities of nitrogen lost in the wound exudate of burn patients make measurement of nitrogen balance distinctly difficult in these patients.

BODY COMPOSITION

Ultimately body composition and changes therein represent the most fundamental and meaningful reflection of a patient's nutritional status and the efficacy of his or her nutritional therapy.

Total Body Weight

Although total body weight is the simplest means of following global changes in body composition, its value as a reflection of nutritional status is extremely limited. Changes in total body weight seen over the short term (i.e., days) are far more sensitive to fluid shifts than they are reflective of meaningful changes in tissue mass. Over prolonged periods of time (e.g., weeks to months), severe decline in total body weight certainly indicates malnutrition and lean body mass attrition (presuming, of course, that one corrects for amputations or massive tissue excisions). However total body weight measures are largely influenced by significant changes in body fat seen over the course of acute illness. As such, even on this longer time-scale, the quantity of change in total body mass does not necessarily correlate to the quantity of lean body mass loss, nor does preservation of total body weight imply conservation of lean body mass.

Muscle and Lean Body Mass

"Lean body mass" refers to nonadipose tissue mass, exclusive of any added mass from acute shifts in water content. because the total mass of viscera and bone matter do not change at rates capable of causing significant change in lean body mass over the course of weeks to months, changes in lean body mass over such periods are interpreted as reflections of change in muscle mass. A patient receiving and assimilating adequate substrate and energy to support all of his or her physiologic needs will maintain or build muscle mass. Accumulation of fat, on the other hand, frequently occurs in the face of significant malnutrition and physiologic deterioration. As such, lean body mass serves as the most appropriate surrogate marker for nutritional well-being available in the context of acute burn care.

Massive thermal injury induces a profound protein wasting state. The loss of muscle seen during the acute response to a massive burn injury represents one of the most impressive and tangible nutritional phenomena one can encounter clinically—a muscular young patient presenting with massive burns can easily waste away to a bony, emaciated appearance over a 2-week period. This negative nitrogen balance is not simply a product of starvation, but also a function of an inexorable upregulation of protein catabolism. Muscle catabolism has been shown to persist in burn patients, even in the setting of aggressive feeding and protein supplementation. The net effect of this metabolic shift is manifest through a rapid and profound loss of lean body mass.[7,12,14,81–83]

Obesity

Multiple studies have identified high rates of critical malnutrition in obese patients who, despite generous fat stores, show markedly low lean body masses—a phenomenon termed *sarcopenic obesity*.[84,85] Furthermore patients will often continue to lose lean body mass despite their excessive caloric stores. In patients with sarcopenic obesity, surgical morbidity and mortality rates correlate far more closely with lean body mass than with gross mass or any calculated "ideal" weight. As such, obesity should not be interpreted as a state of overnourishment, but quite the opposite.

In the broader critical care literature, there has been a compelling discussion of the potential benefits of hypocaloric, high-protein feeding regimens in the critically ill obese.[84] Given the profoundly hypermetabolic state associated with thermal injury, use of an "underfeeding" strategy in an obese burn patient raises considerable concerns for safety and is probably best reserved for a research setting.

Even in those patients not obese at time of injury, body composition in burn patients frequently moves toward a state of sarcopenic obesity. As emphasized earlier, the metabolic shift toward proteolysis persists even in the face of aggressive nutrition. In the context of this muscle-wasting milieu, any access or "free" calories available are more likely to be stored as fat while muscle is broken down during periods of acute caloric debt. Thus Hart et al. demonstrated that "increased feeding leads to fat rather than lean mass accretion."[13]

Ideal Body Weight

The term "ideal" is not particularly apt, as there is not a particular limit to how much lean body mass a patient can healthfully maintain—with lean body masses for well-nourished nonobese patients determined by a combination of environmental and genetic factors. Nonetheless equations for "ideal body weight" (IBW) are useful in patients whose total weight is distorted by pathologic processes. While limited in their accuracy, they do provide rough estimates of baseline weight for patients whose total weight is distorted by pathologic processes such as chronic morbid obesity or, particularly in burn patients, massive fluid shifts.

Derived ideal body weights can be helpful when using weight-based formulas to determine starting points for quantitative treatment decisions such as drug doses, tidal volume settings, endpoint physiologic indices, and the like. Values for IBW can be found in standardized tables that relate height to expected weight, or IBW can be estimated by the following equations:

- Men: 48 kg for the first 152 cm and 2.7 kg for each additional 2.54 cm
- Women: 45 kg for the first 152 cm and 2.3 kg for each additional 2.54 cm

Clinical Imaging

Dual-Energy X-Ray Absorptiometry. Dual-energy x-ray absorptiometry (DEXA) is a useful technique for monitoring long-term nutritional progress by measuring changes in body tissue composition, including lean body mass, fat mass, and bone density. DEXA's precision, accuracy, and versatility make it extremely useful in a research setting. Practically speaking, though, few burn centers have the infrastructure in place to regularly perform such assessments on critically ill patients.

Computed Tomography and Ultrasound. More readily available, high-resolution computed tomography (CT) scanners have been shown to reliably predict DEXA results. However significant cost, radiation exposure, and need for patient transport all serve as barriers to widespread clinical use. More recently, multiple groups have shown that measurements from a limited bedside ultrasound (US) exam can be used as an accurate and convenient means of serial assessment. The thickness of a patient's quadriceps measured at bedside has been shown to be powerfully predictive of CT and DEXA assessments of total lean body mass.[86,87] Given its ubiquitous availability, low cost, ease of use, and minimally invasive nature, bedside ultrasound has significant potential for widespread clinical application in nutritional assessment and monitoring. For burn patients, who are at a uniquely high risk from nutritional morbidity and frequently present a myriad of unique transportation challenges, this bedside measure may prove quite valuable.

Albumin and Serum Markers for Nutrition

Serum protein markers, most notably albumin, have demonstrated significant value in assessing nutritional status and predicting outcomes in the setting of patients considered for elective surgery. Unfortunately the value of serum protein levels as indicators of nutritional status is extremely limited during the acute-phase response to injury, inflammation, infection, and surgical stress. The physiologic stress response upregulates expression of acute-phase reactive proteins, with unpredictable effects on "marker" protein levels. In the setting of acute burn care, presenting albumin levels or short-term changes therein should not be interpreted as being indicative of nutritional progress.[34,88,89]

Conclusion

Burns involving more than 20% of the total body surface area represent a massive metabolic injury. The metabolic response to massive burns creates an immediate, intense, and persistent strain on the patient's nutritional status. The systemic response to burn injury alters essentially all aspects of energy substrate metabolism. The net total energy expenditure and requirements are markedly augmented by massive burn. Alterations in glucose metabolism favor gluconeogenesis and limited oxidation capacity. Alterations in lipid metabolism favor lipogenesis and the accretion and sequestration of fat in a manner that diverts energy from critical functions. Finally a surge in proteolysis creates an immediate and prolonged protein-wasting state that results in profound lean body mass loss and, at worst, compromises in immune, respiratory, and healing processes.

Given the immense metabolic challenges created by burn injury, optimizing nutritional support is essential to improving outcomes in this patient population. Total calories provided should be based on ongoing assessment of energy expenditure, ideally using indirect calorimetry. Providing calories in excess of the patient's needs (i.e., overfeeding) is counterproductive. While carbohydrates delivered will frequently provide the majority of calories given, care should be taken not to give loads that exceed established limits of glucose oxidation. Provision of adequate protein is critical to effective nutritional support, and protein supplementation is likely the ideal means to augment caloric load when carbohydrate provision is "maxed out." The amount of exogenous fat required to avoid essential fatty-acid deficiencies is relatively modest and can be met with relatively minimal amounts of fat alimentation. Administration of excessive amounts of fat-based calories can be detrimental to care—although significant research is required to determine how the risk–benefit profile of fat alimentation may differ with use of alternate fat sources.

EN is the first line of nutritional support in the burn patient, and enteral feeding should be administered as soon as possible. While oral feeding is theoretically possible, few patients with massive thermal injuries will be capable of meeting their full nutritional needs through oral intake alone. Typically EN will be provided in part or in whole via enteric access tubes. The enteral system can be accessed via the stomach for feeding if necessary, although this may be compromised by gastroparesis. Postpyloric feeding access offers the benefit of circumventing the potentially paretic stomach, thus allowing for more dependable sustained feeding early in the course of treatment. Care should be taken to minimize the risk of aspiration by undertaking frequent assessment for nausea or distention. Routine serial evaluations of gastric residuals have not been shown to be beneficial. Care should be taken to minimize interruptions in feeding to ensure that the gap between calories prescribed and delivered is minimized as much as possible.

Accurate serial assessment of nutritional status and body composition is central to identifying patient needs, trajectory, and efficacy of care. Unfortunately serum protein markers and changes in total body weight are inaccurate reflections of nutritional status, with poor specificity and sensitivity. Changes in lean body mass and body composition represent the ultimate reflection of cumulative nutritional status, and evolving applications of imaging technology have made routine serial evaluation of lean body mass feasible.

The physiologic response to massive thermal injury represents an enormous nutritional insult. The consequences of this intense acute malnutrition include compromises in immune function, wound healing, and mobility—all major drivers of morbidity and mortality in thermal trauma. As such, thoughtful and comprehensive nutritional support based on continuous assessment of nutritional needs is essential to optimizing outcomes in acute burn care.

29 Modulation of the Hypermetabolic Response after Burn Injury

ASHLEY N. GUILLORY, CRAIG PORTER, OSCAR E. SUMAN, RAMON L. ZAPATA-SIRVENT, CELESTE C. FINNERTY, and DAVID N. HERNDON

Introduction

A severe burn elicits a stress response that initially assists the body in compensating for and adapting to a traumatic injury. There is an elevation in circulating concentrations of catecholamines such as epinephrine and norepinephrine alongside a concurrent increase in inflammatory cytokine production. This stress response is also associated with a significant increase in metabolic rate.[1–3] Altered protein and glucose metabolism are key factors contributing to burn-induced hypermetabolism.[4] This hypermetabolic, hyperinflammatory state promotes muscle protein catabolism and organ failure, among other detrimental effects.[5] If this response continues unchecked, as occurs in severely burned patients, the resultant hypermetabolic state hinders patient recovery and reintegration into society. Thus the mechanisms underlying the development and persistence of the post-burn stress response, as well as interventions to ameliorate these responses, remain areas of intense research.

Cardiovascular Dysfunction

One of the most profound and well-documented components of the burn-induced hypermetabolic response is cardiac dysfunction. Immediately following injury, patients experience shock accompanied by reduced heart rate, cardiac output, and contractility. By 2–3 days after injury, the cardiovascular system rebounds, and heart rate and cardiac work increase significantly above normal levels.[6,7] Post-burn heart rates approach 160% of those in nonburned, healthy patients.[5] Systolic dysfunction and increased myocardial energy demand also occur.[8,9] These alterations in cardiac function are associated with longer stays in the ICU in addition to increased morbidity, as quantified by number of surgical interventions.[10] Furthermore tachycardia and energy expenditure remained elevated for up to 3 years after the external wounds were healed, underscoring the longevity of the cardiovascular response to severe burns.[11,12]

Skeletal Muscle Catabolism and Regeneration

Post-burn pathophysiological skeletal muscle catabolism and loss of lean body mass (LBM) significantly prolong rehabilitation. Muscle wasting occurs due to an imbalance in the ratio of protein synthesis to protein breakdown.[13] Catabolism of LBM correlates with increased morbidity and mortality in burn victims. After an LBM loss of 10%, marked delays in wound healing and higher infection rates proportionally increase as the percentage of LBM loss increases.[14] Acutely the net LBM losses from muscle wasting lead to prolonged mechanical ventilation, inhibition of cough reflexes, and a delay in mobilization, contributing to increased mortality in these patients.[15] Chronically these losses reduce strength and the possibility for full rehabilitation. Similar to other characteristics of hypermetabolism, burn-related cachexia can continue for several years following injury.[3] Furthermore, persistent protein catabolism has been hypothesized to account for the growth delay that frequently occurs in our pediatric burn patients.[16]

LBM wasting is hypothesized to be due to a redistribution of protein as well as use of the skeletal muscle as a fuel source.[8] Nitrogen balance studies (whole-body and cross-leg) show persistent muscle breakdown for nearly a year post-burn.[17] Our patients experience an average nitrogen loss of 20–25 grams per square meter of total body surface area (TBSA) per day, a rate at which lethal muscle cachexia becomes imminent in less than 1 month if left untreated.[8] Since a significant portion of insulin-stimulated glucose uptake occurs in the skeletal muscle, significant LBM loss may contribute to post-burn insulin resistance.[18] Flakoll and coworkers showed that increased plasma glucose levels stimulated whole-body proteolysis in the absence of changes in leucine oxidation or nonoxidative disposal.[19] While LBM catabolism is elevated, a decrease in regenerative capacity occurs, further reducing LBM. Satellite cells, the muscle stem cells that regenerate skeletal muscle, are impacted by burn injury. Within the skeletal muscle tissue, although there is an increase in satellite cell proliferation, there is a concurrent increase in apoptosis, leading to a net reduction in satellite cells. The end result of the increase in net protein breakdown alongside a decrease in satellite cells appears to be a reduction in total LBM.[20]

In addition to the alterations in skeletal muscle protein synthesis, breakdown, and regeneration, oxygen consumption is also greatly increased after burn injury.[21] However the molecular mechanism underlying these alterations is not clearly defined. Recently Porter and colleagues reported burn-induced derangements of skeletal muscle mitochondrial function and posited that these changes are a key contributor to the mechanism of burn-induced

hypermetabolism.[22] Mitochondrial respiration in severely burned patients is uncoupled for more than 1 year post-burn, resulting in increased heat production. This heat production accounts for nearly a third of the total energy expenditure of the patient and provides a novel therapeutic target to alleviate hypermetabolism.[23,24]

Insulin Resistance and Hyperglycemia

Hyperglycemia is another common metabolic derangement in response to burn injury that occurs in both pediatric and adult burn patients and persists well after the initial discharge from the ICU.[7,25,26] Insulin resistance and hyperglycemia contribute to poor wound healing as well as muscle catabolism.[27–29] Elevated cortisol and catecholamine levels increase the delivery of glucose to vital organs, thus inhibiting insulin's anabolic functions.[30] Catecholamines impair glucose disposal and contribute to peripheral insulin resistance by inhibiting both insulin release and glucose uptake (Fig. 29.1).[31,32] The availability of gluconeogenic substrates such as glycerol lactate and alanine is increased by lipolysis of adipose tissue, glycogenolysis, and proteolysis of skeletal muscle post-burn, which augments hepatic glucose production (Fig. 29.1).[31,33–37] Moreover, elevated blood glucose levels fail to suppress hepatic glucose release, exacerbating hyperglycemia in burn patients.[38] This is further complicated by catecholamine-mediated glycogen breakdown.[35] Impaired mitochondrial function in the liver and the skeletal muscle has been associated with altered lipolysis and insulin signaling post-burn by dampening insulin's inhibition of glucose production in the liver and altering glucose uptake into skeletal muscle.[33,38–40] Glucagon and pro-inflammatory cytokines such as interleukin-6 (IL-6) also play a role in modulating glycogenolysis, gluconeogenesis, and insulin signal transduction, resulting in further augmentation of hyperglycemia and insulin resistance.[41–49]

Alterations in Lipid Metabolism and Fat Composition

Catecholamine-induced lipolysis increases plasma free fatty acid concentrations, which contributes to organ steatosis and insulin resistance in patients with severe burns. Kraft et al. showed that increased plasma triglyceride levels in severely burned children correlated with poorer outcomes, including impaired organ function, thus confirming an earlier report linking elevated triglycerides with morbidity.[50,51] Loss of peripheral subcutaneous fat may also play a role in the development and persistence of insulin resistance after a severe burn.[52] Recently browning of white adipose tissue (the adoption of a thermogenic brown phenotype by

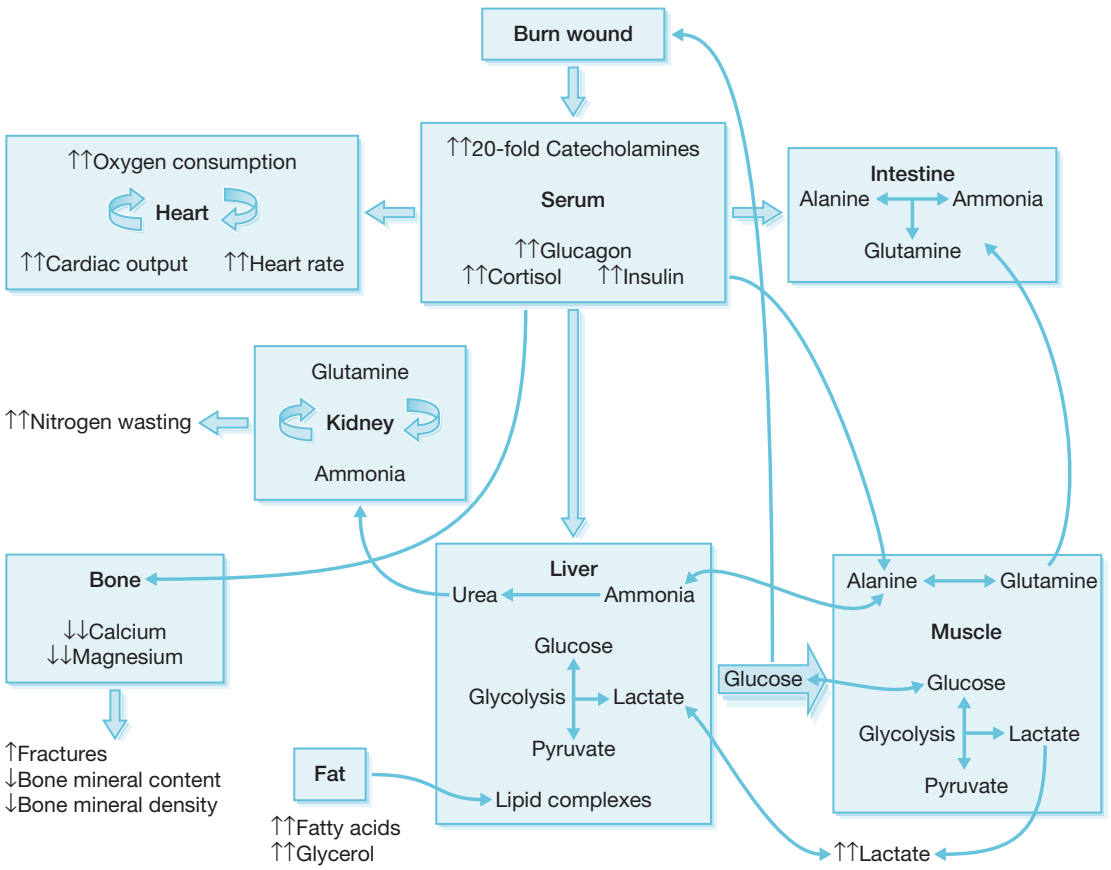

Fig. 29.1 The effects of metabolic dysfunction after severe burn injury. (From Williams FN, Jeschke MG, Chinkes DL, Suman OE, Branski LK, Herndon DN. Modulation of the hypermetabolic response to trauma: temperature, nutrition, and drugs. *J Am Coll Surg.* 2009;208(4):489–502.)

white adipocytes) and the implications this potentially has for patients with diabetes and/or metabolic syndrome has become the topic of intense research. White adipose tissue isolated from severely burned patients underwent browning, where the development of smaller adipocytes with more mitochondria in addition to elevated expression of uncoupling protein 1 were observed.[53] This response has since been confirmed by others, affirming that increased adrenergic and inflammatory stress in white adipose tissue post-burn is associated with browning.[54] Browning of white adipose tissue has been proposed to play a role in burn-induced hypermetabolism, where adipose tissue becomes a more thermogenic tissue in response to severe burn trauma. Emphasis of future research should be placed on developing both nonpharmacologic and pharmacologic therapeutic approaches to attenuate or reverse this hypermetabolic response in adipose tissue.

Nonpharmacological Modulation of the Hypermetabolic Response

ENVIRONMENTAL SUPPORT

In addition to acting as a protective barrier, the skin plays a critical role in insulation and thermoregulation. Burn patients with extensive burn wounds and skin loss also lose a significant portion of body water, which is also accompanied by heat loss.[55] Despite increased water evaporation and heat loss, core and skin temperatures are elevated in these patients.[56] Resting energy expenditure is increased more than twofold post-burn (prior to current treatments such as early wound excision) but can be reduced by approximately 30% by increasing the temperature of the room and using occlusive wound dressings.[56] Thus environmental modulation is a key primary treatment goal that is too often underutilized.

EARLY WOUND EXCISION AND CLOSURE

The practice of early excision of necrotic tissue and burn wound closure has improved mortality and morbidity rates.[57–59] Early burn wound closure is also associated with diminished incidence of excessive scars and joint contractures, which results in faster patient rehabilitation.[57] The use of various skin substitutes to cover wounds can reduce hypermetabolism by restoring the protective barrier required for thermoregulation and prevention of heat loss and water evaporation. Of note, blood loss is a critical issue during these operations, as approximately 5% of the total blood volume is lost with the excision of every 1% of the body surface.[60,61] Blood loss is a major determinant of morbidity and mortality, and a variety of techniques need to be used to control bleeding, including the local application of fibrin or thrombin sprays, epinephrine-soaked pads (1 : 40 000), topically administered epinephrine (1 : 10 000–1 : 20 000), or electrocautery of blood vessels.[62] Additional use of tourniquets for pre-excisional tumescence with epinephrine and saline may also help limit blood loss.[63] Thus novel skin substitutes and therapies to improve wound healing and prevent blood loss are the focus of ongoing research.

NUTRITIONAL SUPPORT

Adequate nutrition is a critical issue for severely burned patients because patients treated solely with oral supplementation may still lose one-quarter of their preadmission weight within the first several weeks.[64] The marked post-burn changes in lipid, carbohydrate, and protein metabolism determine the caloric needs of each respective patient. Insufficient nutrition may exacerbate muscle wasting and prolong wound healing. However high-fat nutritional intake is associated with obesity and hepatic steatosis after burn injury, negatively impacting morbidity and mortality.[65,66] Caloric enteral intake guided by energy expenditure is currently recommended to provide sufficient energy while avoiding overfeeding, which may exacerbate hypermetabolism.[8,57] Over the past 40 years, several formulas have been derived to calculate patient-specific caloric requirements including the Curreri formula (25 kcal/kg per day plus 40 kcal/% TBSA burned per day).[67–70] Recently, the European Society for Clinical Nutrition and Metabolism and the American Society for Parenteral and Enteral Nutrition released guidelines recommending that enteral feeding begin as soon as possible after admission with 1.5–2 g/kg and 3 g/kg of protein for severely burned adults and children, respectively.[71,72] Many ICUs deliver a substantial percentage of calories as fat (>25%) because essential fatty acid deficiency frequently accompanies long-term nutritional supplementation.[73] This approach reduces carbohydrate requirements and burn-induced glucose intolerance, and, therefore, dietary compositions of 30–50% fat are now the standard of care when treating critically ill patients. Unfortunately enhanced fat administration in burn patients is associated with hepatic steatosis, hypoxemia, hyperlipidemia, higher infection rates, and higher postoperative mortality rates.[51,74] Hepatic triglyceride levels are higher, thereby limiting the utility of exogenous lipids as a post-burn energy source.[33,73,76,77] The incidence of fatty liver is reduced in patients receiving Vivonex T.E.N. compared to those fed milk.[78] Additional benefits attributed to Vivonex T.E.N. included improved survival, significantly lower incidences of sepsis, and reduced length of ICU stay per %TBSA.[78] A high-carbohydrate enteral diet was associated with a reduction in muscle wasting compared to a high-fat, low-carbohydrate formula.[79] We thus advocate nutritional regimens for burn patients that reduce fat intake to no more than 3% of the total energy provided.

EXERCISE

Despite nutritional interventions, cachexia and wound contractures are common comorbidities of major burns.[17] While undergoing the hormone and inflammatory stress responses, patients with large burns are immobile for extended periods, further prolonging rehabilitation and recovery. The utilization of exercise therapy attenuates loss of muscle mass and function and improves cardiopulmonary function. A regimented exercise program improved pulmonary and skeletal muscle function in both pediatric and adult burn patients.[80–83] A 12-week exercise program beginning immediately following discharge from the ICU also significantly increased percent predicted peak heart rate and maximal oxygen consumption.[84] Progressive resistance

exercises maintain or even increase LBM, facilitate the formation of muscle proteins by incorporating amino acids, enhance muscle strength, and increase walking distances by 50%.[82,85] Celis et al. reported fewer corrective surgeries in burned children after resistance exercise training.[86] Similarly, Paratz et al. reported that severely burned adults who participated in an exercise program required fewer contracture releases.[87]

Recent studies have shown that exercise training in adults improves psychosocial outcomes, such as quality of life, in addition to the expected improvements in physical function.[87] This finding was corroborated by Rosenberg and colleagues in pediatric patients.[88] The combination of exercise training and pharmacological therapies to attenuate hypermetabolism, such as propranolol or oxandrolone, is also being investigated. Peak oxygen consumption was significantly higher in patients receiving both propranolol and exercise training.[89] The combination of oxandrolone and exercise resulted in a significant increase in lean body mass.[90] Finally Wurzer et al. reported that the benefits of a 12-week post-ICU discharge exercise program were no longer apparent at 2 years post-burn, indicating that patients should continue to exercise to maintain the aforementioned benefits.[84]

Pharmacological Modulation of the Hypermetabolic Response

RECOMBINANT HUMAN GROWTH HORMONE (rhGH)

As demonstrated by our group, during the acute hospitalization period, daily intramuscular injection of rhGH (0.2 mg/kg) reduces the hepatic acute-phase response, improves muscle protein kinetics, maintains muscular growth, blunts hypermetabolism, reduces cardiac output, and decreases donor site healing times by approximately 1.5 days.[91–96] Pediatric patients receiving rhGH for 1 year had significantly higher body weight and LBM at the end of the treatment period compared to their placebo-treated counterparts. Additionally rhGH-treated patients had improved growth as measured by bone mineral content and height percentiles at both 1 and 2 years after injury.[95] Similar improvements with rhGH treatment, such as increased LBM and muscle strength, have been reported in burned adults.[97]

RhGH mediates its effects through its secondary mediator insulin-like growth factor 1 (IGF-1).[98] In patients receiving rhGH, serum IGF-1 and IGF-binding protein (IGFBP)-3 increased 100% over the levels measured in healthy controls.[99] Nevertheless, as demonstrated in a study by Takala and colleagues, in 532 nonburned critically ill patients, increased rhGH (0.10 ± 0.02 mg/kg) correlated with increased morbidity and mortality rates and was associated with hyperglycemia and insulin resistance.[100–102] This may be reflective of an age-specific effect, however, because in severely burned children, mortality rates were not affected by either short- or long-term rhGH administration.[95,103] However rhGH-treated burn patients did display an increased incidence of hyperglycemic episodes and increased plasma levels of free fatty acids and triglycerides.[91]

INSULIN-LIKE GROWTH FACTOR-1

Since the positive effects of rhGH on the post-burn hypermetabolic response are predominantly mediated by the secondary mediator IGF-1, it is not surprising that administration of recombinant human IGF-1 would have similar results. Indeed, administration of equimolar amounts of recombinant human IGF-1 along with its binding protein, IGFBP-3, attenuated muscle catabolism, restored gut mucosal integrity, enhanced immune function, and returned serum concentrations of constitutive proteins to nonburned levels.[104–108] However the administration of IGFBP-3 was associated with increased neuropathies in this patient population and is not currently recommended for clinical use.

OXANDROLONE

The use of oxandrolone, an analog of testosterone possessing only 5% of testosterone's virilizing androgenic effects, enhances anabolism of muscle protein by improving the efficiency of protein synthesis in severely burned children.[109] Oxandrolone administration decreases loss of body weight and improves healing of the donor site wound.[110] In a large clinical trial by our group, 0.1 mg/kg oxandrolone administered twice daily reduced length of the acute hospitalization, sustained LBM, and improved liver protein synthesis.[111] Severely burned pediatric patients receiving oxandrolone for 1 year experienced improved growth, decreased cardiac work, and improved muscle strength.[112] Oxandrolone treatment also improved lung function at rest and during exercise in this patient population.[113] These improvements were maintained for up to 4 years after treatment had ended.[112] The benefits of oxandrolone administration after burn injury were further enhanced when the treatment period was increased from 1 to 2 years.[114]

PROPRANOLOL

The catecholamines norepinephrine and epinephrine activate cardiac β-adrenergic receptors to increase heart rate and cardiac work in response to severe burn trauma. Propranolol is a nonspecific β-adrenergic antagonist that prevents catecholamine activation of β-adrenergic receptor-mediated signal transduction. The administration of propranolol (titrated to decrease heart rate by 15–20%) diminishes cardiac work and reduces hepatic steatosis, as shown in several studies.[9,77,115–118] Also, administration of propranolol leads to reduced skeletal muscle catabolism and increased LBM post-burn, as demonstrated using stable isotope studies and body composition analysis.[5] In the post-burn environment of heightened protein breakdown and peripheral lipolysis, propranolol enhances protein synthesis and improves post-burn morbidity.[119,120] Similar to oxandrolone, long-term propranolol administration was associated with decreased cardiac work, resting energy expenditure, and other key markers of the hypermetabolic, hypercatabolic response to burn injury.[118] Furthermore patients treated with propranolol for 12 months showed improved LBM accretion and reduced bone mass.[118] While the majority of investigation into the use of propranolol post-burn has been in pediatric patients, we have shown that, in adult

patients, propranolol administration can reduce blood loss as well as improve wound healing.[121] Thus, β-adrenergic blockade with propranolol may represent the most efficacious anti-catabolic therapy for severe burns.

There are also several published studies that investigated the use of rhGH in severely burned patients who were also receiving propranolol. The premise of these studies was that the co-administration of rhGH and propranolol would have an additive effect to reduce post-burn hypermetabolism and catabolism. In a cross-over study of six burned children, heart rate and the rate of release of free fatty acids were significantly reduced with co-administration of propranolol and rhGH.[119] In a later study, there was no evidence of an additive effect of combining rhGH and propranolol, although propranolol did reduce heart rate and energy expenditure and improve anabolism. This study also did not find evidence of an anabolic effect of rhGH alone.[122] A prospective randomized control led trial of rhGH and propranolol co-administration showed that the addition of propranolol reduced rhGH side effects by reducing peripheral lipolysis and inflammation.[123] These data indicate that the beneficial effects of these drugs have different mechanisms and do not display characteristics of a synergistic or additive relationship.

Recently we investigated whether co-administration of oxandrolone and propranolol would further improve post-burn outcomes. Indeed, co-administration of these drugs decreased duration of growth arrest and increased growth rate following the resumption of growth in pediatric burned patients.[124] Thus oxandrolone, either alone or with propranolol co-administration, is a viable and promising therapeutic for attenuating post-burn hypermetabolism and catabolism.

INSULIN

Like other components of the stress response to burns, hyperglycemia and insulin resistance persist for up to 3 years post-injury and may have further long-term health implications for burn survivors.[7,17,27] The most common in-hospital treatment for post-burn hyperglycemia is insulin administration. In addition to its well-known effects on gluconeogenesis, proteolysis, and fatty acid synthesis, insulin also promotes antiinflammatory signaling pathways. Pediatric burn patients treated with insulin had significantly better outcomes as evidenced by faster wound healing and reduced muscle wasting.[125–127] Despite these improvements, insulin administration in this patient population must be performed cautiously. Studies in critically ill patients using either an intensive insulin dosing regimen or a continuous hyperinsulinemic, euglycemic clamp showed that high insulin doses increased episodes of severe hypoglycemia.[128–132] In addition to the risks associated with high doses of insulin, it is difficult to maintain a continuous hyperinsulinemic, euglycemic clamp in severely burned patients because of their dependence on enteral feeding in the early stages of recovery. Burned patients also undergo frequent procedures that require the cessation of enteral nutrition, such as operations and dressing changes. These periods of feeding cessation result in an increased risk of hypoglycemia.[8] In a study of 243 severely burned children, those who did not receive insulin had shorter length of stay and no mortality compared to children who received insulin. Therefore, burned patients receiving insulin had significantly higher resting energy expenditure and mortality rates than patients who did not receive insulin.[133] These results indicate that, although attenuating some aspects of the post-burn hypermetabolic response, insulin treatment may still contribute to post-burn morbidities and should be used with caution.

METFORMIN

Metformin is a biguanide drug that corrects hyperglycemia by stimulating peripheral glucose disposal and blunting hepatic glucose production. Moreover, unlike insulin, metformin is not associated with hypoglycemic events.[134–136] In severely burned patients, metformin not only improved glucose levels but also improved muscle protein synthesis.[136,137] A recent study in burned adult patients confirmed the benefits of metformin treatment on glucose levels and insulin resistance.[138] Similar to insulin, metformin reduced the post-burn inflammatory response.[138] Insulin sensitivity was also enhanced with metformin administration.[139] One contraindication of metformin administration in burned patients is the development of lactic acidosis.[140] There has been one case report of lactic acidosis in a burn patient who was receiving metformin clinically for type 2 diabetes mellitus prior to injury.[141] However, in a cohort of 18 metformin-treated severely burned adult patients, lactic acidosis was not observed.[138] Studies are ongoing to evaluate the incidence of lactic acidosis in burn patients and whether metformin will continue to be a valid hyperglycemia treatment in this patient population. Preliminary data indicate that metformin is safe and effective in severely burned patients.[138]

Alternative Therapeutic Options

There have been a variety of drugs investigated to attenuate the post-burn hypermetabolic hypercatabolic response. Many of these drugs work to resolve hyperglycemia, such as glucagon-like-peptide-1 (GLP-1) and peroxisome proliferator-activated receptor-γ (PPAR-γ) agonists. An analog of GLP-1, exenatide, decreased burn-induced hyperglycemia but required adjunctive insulin therapy to be effective.[142] Fenofibrate, a PPAR-γ agonist, not only improved plasma glucose levels but also improved insulin signaling in the muscle and liver, with the end result of increased insulin sensitivity.[38] Fenofibrate also improved skeletal muscle mitochondrial enzyme activity and respiratory function as well as whole-body and muscle fat oxidation.[38,143] Ketoconazole is an antifungal agent that has been shown to reduce cortisol production, and it was hypothesized that cortisol reduction would diminish post-burn hypermetabolism and inflammation. However, despite effectively reducing urine cortisol levels, ketoconazole did not significantly reduce any other aspect of the hypermetabolic response.[144]

Conclusion

The physiologically exhaustive metabolic derangements accompanying severe burns contribute to morbidity and mortality in this patient population. Outcomes for these

Table 29.1 Summary of the Effects of Various Pharmacologic Interventions on Key Components of the Hypermetabolic Response to Burn Injury

Drug	Cardiovascular	Skeletal Muscle	Insulin Resistance	Lipid Metabolism and Fat Composition
rhGH	↓Cardiac output	↑Protein kinetics ↑Body weight ↑Bone mineral content ↑Height percentiles	↑Hyperglycemia	Unknown
IGF-I	Unknown	↓Muscle catabolism	↑Insulin sensitivity hypoglycemia	Unknown
Oxandrolone	↓Cardiac work ↓Lung function	↑Protein synthesis ↓Loss of lean body mass ↑Growth ↑Muscle strength	No difference	↓Free fatty acids
Insulin	↑Resting energy expenditure	↓Loss of lean body mass	↓Hyperglycemia	↑Liver fat ↑Free fatty acids ↓Fat oxidation
Metformin	↑Resting energy expenditure	↑Protein synthesis	↓Hyperglycemia ↑Insulin sensitivity	Antilipolytic
Fenofibrate	Unknown	↑Mitochondrial enzyme activity	↓Hyperglycemia ↑Insulin sensitivity	↑Fat oxidation
GLP-1	No difference	Unknown	↓Hyperglycemia	Unknown
Propranolol	↓Cardiac work ↓Tachycardia ↓Resting energy expenditure	↓Skeletal muscle catabolism ↑Lean body mass	↑Insulin sensitivity	↓Hepatic steatosis ↓Free fatty acids
Ketoconazole	No difference	No difference	No difference	No difference
rhGH + propranolol	↓Resting energy expenditure ↓Cardiac work	↓Skeletal muscle catabolism ↑Lean body mass	↑Insulin sensitivity	↓Free fatty acids
Oxandrolone + propranolol	Unknown	↓Duration of growth arrest ↑Growth rate	Unknown	Unknown

patients have been significantly improved by advances in nonpharmacologic and pharmacologic therapies (Table 29.1). However therapeutic strategies to abate the persistent hypermetabolism and hyperglycemia remain challenging. Early burn wound excision and grafting represents one of the greatest improvements in the past two decades, improving both morbidity and mortality. Currently the most effective therapy to reduce the burn-induced hypermetabolic and hypercatabolic responses is β-adrenergic blockade via propranolol administration. rhGH, IGF-1, and oxandrolone (Table 29.1) have also been successfully used in the attenuation of the hypermetabolic and hypercatabolic responses. While intensive insulin therapy can improve mortality and morbidity, there is a need for additional strategies, such as metformin, that lack the increased risk of hypoglycemic events associated with insulin treatment. Nonetheless further work is needed to elucidate the ideal glucose ranges and safety of the aforementioned therapies in this unique patient population.

Introduction

Burn trauma begins via a cutaneous thermal injury with or without an inhalation injury. These local primary injuries initiate a series of pathophysiologic cascades previously discussed. Fluid shifts into thermally damaged tissue as well as global endothelial activation; glycocalyx damage and systemic inflammation cause burn edema. The resultant distributive shock combines with humorally mediated myocardial suppression to induce burn shock requiring fluid resuscitation. Immune hyperactivation, hypermetabolism, and adrenal hyperreactivity exacerbate this primary injury. Concomitantly, host defenses such as intact skin[1] and gastrointestinal mucosa[2,3] are compromised, resulting in significant microbial insult from commensal and pathologic organisms.[1] Ultimately, the common lethal end point of burn trauma and shock is multisystem organ failure (MOF). In one cohort of 821 severe pediatric burns there was a 19% incidence of MOF with a 100% mortality when involving three or more organ systems.[4]

Many scoring systems are currently used to quantify MOF. The DENVER2 system is widely used in research and clinical care by scoring pulmonary, renal, hepatic, and cardiac function from 0 to 3 with a total of 12 points available (Table 30.1). There is an inflection point after a score of 3 with significantly increased mortality. The Sequential Organ Failure Assessment score is based on scores of six systems from 0 to 4 for pulmonary, coagulation, liver, cardiovascular, central nervous, and renal (Table 30.2).[5] This definition system, popularized in sepsis and shock arenas, is at the core of the SEPSIS3 criteria to define septic shock recently published in the *Journal of the American Medical Association*.[6]

Regardless of the definition used, the more organ systems fail, the greater the mortality. Currently the best predictive model for burn mortality is proteomics combined with clinical covariates.[4] The time course of these failures and patterns of multiple failures are demonstrated in Fig. 30.1 and Table 30.3.[4] There are two well-described pathways to MOF in burn patients: early and late.[8] The early clinical sequence is characterized by resuscitation failure leading to adult respiratory distress syndrome (ARDS), hemodynamic failure, renal failure, liver failure, gut failure, and sepsis. In the late cascade seen in patients surviving resuscitation, pulmonary failure, hemodynamic instability, renal failure, gut failure, and liver failure also occur. Vasomotor and cardiac failures are terminal events in both. Survival can be seen in patients with greater than three organ system failures, but mortality increases with more failed systems.[7] Understanding the progression of the syndrome aids in prognostication and simplifies decisions regarding termination of futile efforts.[8,9] This chapter discusses the etiology and prevention of MOF; management will be covered in the critical care chapter.

Jeschke and Herndon reviewed 573 patients and determined that burn sizes associated with mortality, sepsis, infection, and MOF are 60% total body surface area (TBSA) in children and 40% in adults.[10] Kraft and Jeschke monitored MOF in 821 patients to define its course. Respiratory failure had the highest incidence in the first 5 days. Cardiac failure occurred throughout the hospital stay. Hepatic failure increased with hospitalization length and is associated with high mortality in the late cascade. Renal failure had an unexpectedly low incidence but was associated with high mortality in the first 3 weeks. Three or more organ failures was universally fatal in their cohorts. Overall mortality for patients with MOF was 41% compared to 2% without.[4] The Helsinki Burn Center reported their adult burn mortalities between 1999 and 2005 as 71 burn deaths of 1370 patients with 40% caused by MOF and 40% due to untreatable burn injury. On average, four organ failures were noted in the deaths, with acute renal failure being the most common. Sepsis was associated with MOF in all of their deaths.[11]

Etiology and Cellular Response

Attempts to define the etiology of MOF range from genomic and cellular to systemic and epidemiologic. Inadequate oxidative metabolism secondary to hypoperfusion leads to further organ failure as well as the release of humoral inflammatory mediators causing further cellular dysfunction. In ischemia–reperfusion models, oxygen radicals are generated resulting in peroxidation of cell membrane lipids and accumulation of activated neutrophils,[12] with progressive cellular and whole-organ dysfunction. Critically ill patients suffer from supply-dependent oxygen consumption because of defects in cellular oxygen extraction and utilization.[13,14] This results in inadequate aerobic metabolism unless supranormal levels of oxygen are supplied.[15] Grossly inadequate delivery of oxygen to cells dependent on aerobic metabolism can lead to cellular dysfunction, and this may be followed by organ failures.[16]

Mitochondrial-specific damage is one of the earliest responses to burn injury. There is tissue-specific damage to

Table 30.1 DENVER2 Criteria for Multisystem Organ Failure

Component	Measurement	Score			
		0	1	2	3
Pulmonary	PaO_2/FiO_2	≥250	175–249	100–174	<100
Renal	Creatinine	≤1.8	>1.8–2.5	>2.5–5.0	>5.0
Hepatic	Bilirubin	≤2.0	>2.0–4.0	>4.0–8.0	>8.0
Cardiac	Inotropes	See definitions below			

Cardiac Score: Scoring for cardiac component is a combination of number and dosage of inotropes administered.
S = small dose, M = moderate dose, L = large dose
Patient receives 0 agents: cardiac score = 0

Patient receives 1 agent:				**Patient receives 2 agents:**				
Dose size	S	M	L	Dose size	(S, S)	(S, M)	M, M)	(L, anything)
Cardiac score	1	2	3	Cardiac score	2	2	3	3

Patient receives 3 or more agents: cardiac score = 3

mitochondrial DNA, most profoundly in the lungs and hearts of burned mice associated with a time-dependent increase in oxidative stress and neutrophil infiltration.[17] Porter and Herndon investigated postburn mitochondrial dysfunction by measuring mitochondrial respiration in saponin-permeabilized myofiber bundles and noted diminished mitochondrial coupling control persisting at 2 years postburn.[18] Uncoupling protein-1 thermogenesis increases after burn trauma and is a mechanism of hypermetabolism in burn victims.[19] This response is both adrenergic-mediated and responsive to ambient temperature, linking thermal regulation to skeletal muscle metabolism.[20] Jeschke and Herndon described the pathophysiologic response to severe burn injury in 242 children with a mean burn size of 56%. All patients were hypermetabolic with significant muscle protein loss, loss of bone mineral content, and profound alterations of serum proteome. Cardiac function was compromised, insulin resistance appeared in the first week, and patients were hyperinflammatory with marked changes in interleukin (IL)-8, monocyte chemotactic protein-1 (MCP-1), and IL-6.[21] Among 821 severely burned children, 586 never developed organ failure by the DENVER2 criteria. Respiratory failure was the most common organ failure occurring in 230, then cardiac in 77, with renal only occurring in 16[4] (Fig. 30.1).

The Inflammation and Host Response to Injury Large-Scale Collaborative Research Program defined the leukocyte transcriptome after severe trauma and burn injury and found a similar "genomic storm" among different injuries, revealing a fundamental human response to severe inflammatory stress.[22] The transcriptome of leukocytes following burn was linked to their immunologic response and related to outcomes. In their study of 167 subjects over 28 days they defined greater than twofold transcriptome changes in 80% of leukocyte genes (5136) compared to healthy controls. Within the first 12 hours the gene expression favors innate immunity and inflammatory response, including NB1, MMP8 (neutrophil collagenase), lactotransferrin (LTF), and haptoglobin (HP) with a marked downregulation of T-cell function and antigen presentation (Fig. 30.2). They found the genomic response was similar between isolated endotoxin challenge, minor trauma, and severe burn, differing primarily in the magnitude and duration of the response, thus postulating that the persistence of cellular debris in the plasma as a danger-associated molecular pattern (DAMP) continues the nonresolving inflammation[23] (Fig. 30.3). These descriptions of genomic response to burn injury reflect a global response and do not account for complex interplays or subpopulations of different cell types within the total leukocyte populations, the microenvironmental effects within different compartments where the immune cells exert their effects, proteomic or metabolomic effects, nor that certain transcripts in low abundance or with a small change may have profound effects. These data do highlight the complexity and universality of the immunologic response to severe injury or minor endotoxemia.

Tompkin's data demonstrate systemic inflammatory response syndrome (SIRS) underlies cellular events leading to MOF. Although many MOF patients will have different engines,[24] such as sterile burn wounds, sepsis is the most common late initiator of SIRS.[1] One overwhelming infection is not required; small repetitive infections may trigger the cascade,[25] perhaps by priming immune cells and making them react more profoundly to each consecutive stimulus.[25] Endotoxin from Gram-negative bacteria is a major intermediary via Toll-like receptor (TLR) pathways,[26] but Gram-positive bacteria cause similar insults.[27] With the advent of early burn wound excision,[28] infected wounds and wound sepsis are decreasing in incidence; pneumonia rather than wound sepsis causes most infectious deaths in burn patients today.[29] Complete wound closure, without donor sites (e.g., with skin substitutes), decreases oxygen consumption[30] thereby ameliorating the inflammatory response to the open wound. Incomplete wound closure does not have this effect.[31] Increased levels of circulating mediators such as IL-6, IL-8, and tumor necrosis factor (TNF) have been shown to originate from the burn wound[32] and contribute to hypermetabolic and inflammatory states seen in burn patients. IL-8 has been demonstrated to be upregulated in the lung after burn injury.[32] The stimulus for this upregulation, which is associated with pulmonary dysfunction, may come from the wound.[32]

A significant source of endotoxemia and septic load leading to MOF is gut barrier failure.[33] Bacterial densities range from near 0 in the stomach, to 10^4–10^5 in the distal small bowel, to 10^{11}–10^{12}/g of stool in the normal colon.[34] Although not seen immediately after trauma,[35] serial insults result in increased translocation of bacteria and their products into the portal and lymphatic circulations. Hemorrhagic shock,[36] endotoxin administration,[37] burns,[38] and burn wound sepsis[39] have each been shown to result in increased translocation of bacteria from the gut. Using polyethylene glycol 3350 as a tracer, increasing burn wound size was demonstrated to increase gut permeability to macromolecules such as endotoxin.[40] Smaller molecules,

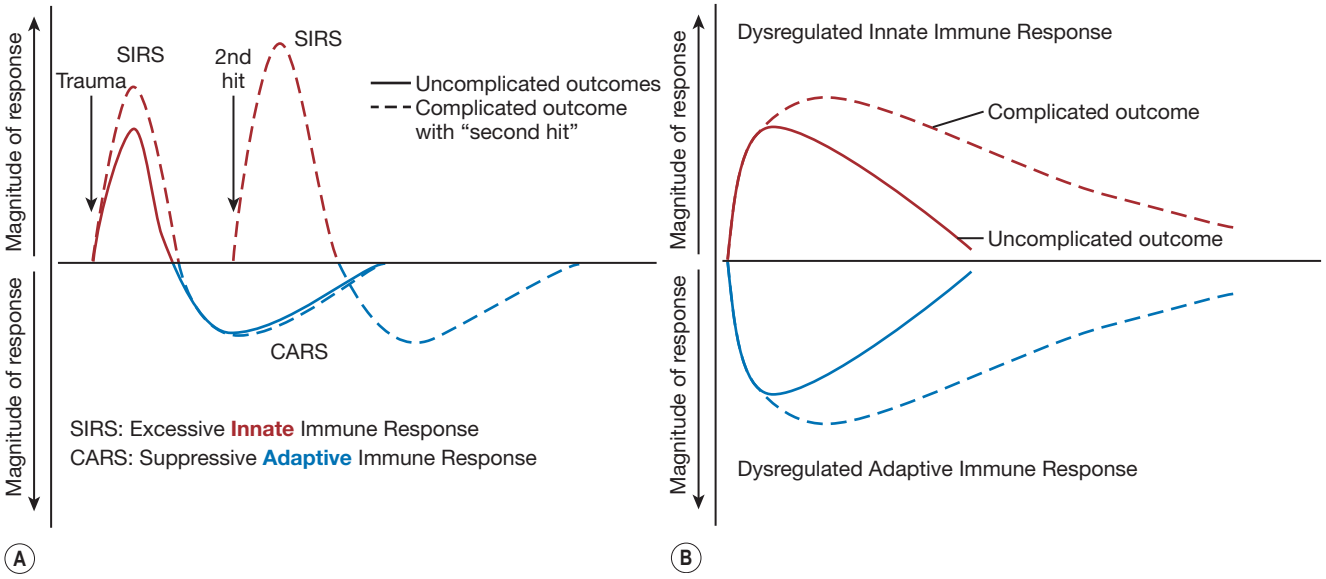

Fig. 30.3 Comparison of the genomic response of leukocytes to burn in complicated and uncomplicated outcomes. (From Xiao W, Mindrinos MN, Seok J, et al. A genomic storm in critically injured humans. *J Exp Med*. 2011;208(13):2581–2590.)

with lactulose as the tracer, passed more readily through the gastrointestinal membrane after injury.[41] Both intra- and transcellular processes allow transloaction.[42,43] Consequences of loss of the gastrointestinal barrier are profound. Translocating whole bacteria can be a direct source of sepsis or can activate Kupffer cells[2,3] and promulgate an inflammatory response in conjunction with bacterial products such as endotoxin.

COMMON GROUND: HUMORAL MEDIATORS

In patients receiving critical care (fluid resuscitation and wound care) for the acute burn injury and its attendant burn shock, the principal determinants of organ failure are humoral mediators.[44] Investigators are unraveling these humoral factors using blocking antibodies, soluble receptors, and receptor antagonists.[45]

Further studies of leukocyte transcriptome after severe trauma and burn injury demonstrated that humoral inflammatory mediators underlie cascades responsible for mortality in burn patients. Sood and Herndon used early leukocyte mRNA genomics to correlate transcriptome changes with outcomes in 324 severely burned patients. In many ways their mortality findings were as expected. Ages older than 60 carry a relative risk of death (RR) of 4.53, burns greater than 40% carry an RR of 4.24, and inhalation carries an RR of 2.08, all independently associated with mortality. They found 39 gene signatures within the leukocyte transcriptome inherent in the "genomic storm" associated with platelet activation and degranulation, cellular proliferation, and downregulation of proinflammatory cytokines (see Fig. 30.1).[46]

Jeschke and Herndon worked to differentiate burn survivors from nonsurvivors based on profoundly different trajectories in inflammatory and hypermetabolic responses. Nonsurvivors had significantly higher IL-6, IL-8, granulocyte colony-stimulating factor, monocyte chemotactic protein-1, C-reactive protein, glucose, insulin, blood urea nitrogen, creatinine and bilirubin, and hypermetabolic response.[47] IL-8 is a major mediator for inflammatory responses and tracks correspondingly with body surface area burned and incidence of MOF. High levels were associated with sepsis, MOF, and mortality suggesting that IL-8 may provide a valid biomarker for monitoring sepsis, infections, and mortality in burn paitents.[48]

The humoral inflammatory mediators believed to underlie MOF in burn injury are the same factors and cascades governing the fundamental human responses to severe injury and have been discussed for decades: endotoxin, arachidonic acid metabolites, cytokines, platelet activating factor (PAF), activated neutrophils and adherence molecules, nitric oxide, complement, and oxygen free radicals.

Endotoxin, a lipopolysaccharide component of Gram-negative bacteria outer cell walls, induces many of the symptoms associated with sepsis: fever, hypotension, the release of acute-phase proteins, and the production of multiple cytokines including TNF and IL-1 via interaction with TLRs.[49] Endotoxin injection alone causes the same changes in the leukocyte transcriptome as severe burn injury.[23] It also activates complement[50–52] and the coagulation cascade[53] and results in the release of PAF.[54] Potential sources of endotoxin include both Gram-negative bacteria in foci of infection and within the gut when the gut barrier fails.

Arachidonic acid (AA) makes up approximately 20% of cell membranes and is released from these membranes in response to a multitude of stimuli, which activate phospholipases A_2 and C, and is then metabolized by active mediators. The cyclooxygenase pathway yields prostaglandins and thromboxanes, whereas the lipoxygenase pathway results in the production of leukotrienes.[55] Prostaglandins and leukotrienes interact with other mediators in a complex fashion and are later degraded.[56] Cyclooxygenase products like prostacyclin inhibit platelet aggregation, thrombus formation, and gastric secretion,[57] whereas other products like thromboxane A_2 (TXA_2) cause platelet aggregation, have profound vasoconstricting effects on both the splanchnic and pulmonary microvasculature, and induce bronchoconstriction and increased membrane permeability.[58] Aspirin irreversibly inhibits cyclooxygenase, driving AA down the lipoxygenase pathway.[59] The lipoxygenase pathway results in the formation of leukotrienes. There are two types based on their metabolism after the action of 5-lipoxygenase, leukotrienes (LT) C_4, D_4, and E_4 (the sulfidopeptide group), and LTB_4.[51] Multiple stimuli by several cell types, including neutrophils, macrophages, and monocytes, generate leukotrienes.[52] Vessel walls are also capable of generating leukotrienes.[60] LT C_4, D_4, and E_4 have variable actions on vascular tone dependent on the presence or absence of other mediators, including cyclooxygenase products.[61] In addition to their variable effects in redirecting blood flow, LT C_4, D_4, and E_4 increase vascular permeability[62] and are elevated immediately prior to the development of pulmonary failure.[63] The principal effect of LT B_4 is enhancement of neutrophil chemotaxis.[64] Thus, leukotrienes as a group may be involved in the edema formation and pulmonary and systemic vascular changes seen in MOF.

Cytokines are regulatory proteins secreted by immune cells and have multiple paracrine and endocrine effects. There are six major classes:[65] interleukins, TNF, interferons, colony-stimulating factors, chemotactic factors, and growth factors. Those most extensively characterized in sepsis are IL-1, IL-6, and TNF.

IL-1 and IL-6 are elevated in septic states; high levels are associated with fatal outcomes[66] and predict systemic infection.[67] IL-1β causes hypotension and decreased systemic vascular resistance, which may be synergistic with the effects of TNF.[68] TNF causes hypotension, cardiac depression, and pulmonary dysfunction in animals.[69,70] When administered to humans, TNF causes fever, hypotension, decreased systemic vascular resistance, increased protein turnover, elevation of stress hormone levels,[66,71] and activation of the coagulation cascade.[68]

PAF is a nonprotein phospholipid secreted by many cells including platelets and endothelial and inflammatory cells,[72] and it is a major mediator of the pulmonary[73] and hemodynamic[74] effects of endotoxin. The major effects of PAF are vasodilation, cardiac depression, and enhancement of capillary leak. Its complex interactions with other mediators remain poorly understood.

Although tissue injury can occur in the absence of neutrophils,[75] the inflammatory process results in local accumulation of activated inflammatory cells that release various local toxins such as oxygen radicals, proteases,

eicosanoids, PAF, and others. When unregulated, such accumulations of activated cells can cause tissue injury.[76] The initial attachment of neutrophils to the vascular endothelium at an inflammatory site is facilitated by the interaction of adherence molecules on the neutrophil and endothelial cell surfaces.[77]

Induced by numerous stimuli, these neutrophil adherence receptors are, intriguingly, reduced after major thermal and nonthermal injury,[78] perhaps explaining in part the increased incidence of infection. The importance of this adherence mechanism can be seen in patients deficient in one integrin class of neutrophil adherence receptors, CD-18, who suffer from frequent bacterial infections.[79] The biology of the transmembrane polypeptides governing these complex cell-to-cell interactions is an active area of research[80] and holds promise for therapeutic interventions.

Oxygen radicals, such as hydrogen peroxide and superoxide anion, are released by activated neutrophils in response to a variety of stimuli[81] and when xanthine oxidase is activated after reperfusion in ischemia–reperfusion models. These highly reactive products cause cell membrane dysfunction, increased vascular permeability, and release eicosanoids.

Nitric oxide, released when citrulline is formed from arginine, was identified as an endothelial product in the mid-1980s.[82] Its half-life is merely a few seconds because it is quickly oxidized, but it has profound local microvascular effects. Nitric oxide synthesis is stimulated by various cytokines, endotoxin, thrombin, and injury to the vascular endothelium. It is a potent vasodilator,[83] but its actions vary depending on the vascular bed and presence of other mediators.[84] Nitric oxide is one of the major mediators of hypotensive response to sepsis.[85,86]

Antigen–antibody complexes activate the complement cascade, and complement fragments thus generated interact with other cytokines to promulgate the inflammatory response.[87] Diminished levels of the natural inhibitor of C5a have been demonstrated in patients with ARDS.[88] Administration of anti-C5a antibody diminishes hypotension in an animal model of endotoxemia.[89]

Organ-Specific Failure and Prevention

MOF reversal is challenging, making prevention paramount.[90] Genomic data have demonstrated that patients with MOF began on the same path as those who recover without complications.[23] Prevention is based on arresting the "engines" that drive and amplify the process: sepsis, gut barrier breakdown, the wound, and inadequate perfusion (Table 30.4). With current surgical and pharmacologic modalities, it is more practical to halt these engines than deal with an inadequately understood complex web of mediators. The interplay between organ systems and engines of MOF in the burned patient are complex. For expedience, we will discuss major organ systems sequentially.

Table 30.4 Multiple Organ Failure Etiology and Established Preventive Measures

Etiology	Prevention
Sepsis	Early excision and biologic closure of deep wounds Anticipation and early treatment of occult septic foci
Gut barrier failure	Optimize whole-body hemodynamics Early enteral feedings
Reduced organ perfusion	Optimize whole-body hemodynamics Enhanced oxygen delivery

HYPERMETABOLISM

Severe injury is associated with the hypermetabolic response, marked by increased oxygen consumption and carbon dioxide production, hyperdynamic circulation, increased minute ventilation, altered immune responses, and catabolism. Persistently higher metabolic rates are seen in nonsurvivors.[4] An essential component of modern burn management is attenuating the hypermetabolic response. Reducing the patient's metabolic demand via management of the external environment has been an indispensable component of burn care for decades.[20] Presently, β-adrenergic blockade with propranolol is the most efficacious anabolic pharmacologic therapy. While effects of growth hormone[91] were even more profound, it was associated with more adverse outcomes. Insulin-like growth factor, intensive insulin therapy, and oxandrolone have all been studied.[91]

Anabolic steroids such as oxandrolone have been used to reduce post burn catabolism and help shift patients to an anabolic state. Sousse and Suman demonstrated that long-term administration of oxandrolone significantly reduced hypermetabolism and increased height percentile, bone mineralization, lean body mass, and strength. They showed improved pulmonary functions with greater maximum expired ventilation and higher maximum voluntary ventilation.[92] Inhalation injury did not increase burn-induced hypermetabolic stress.[93] Promising investigations continue into the use of anabolic agents to treat severe burn injury, and they are rapidly becoming a standard of care in centers around the world.

CARDIOVASCULAR

Several hours post burn, a profound shock state develops due to loss of preload as burn edema advances. In the immediate post-burn ebb phase, cardiac function is depressed in an IL-1B- and TNFα-dependent manner that can be blocked with a CD14 knockout or halted with nuclear factor (NF-κB) blockers. By 48 h post burn the myocardium becomes tachycardic with increased cardiac output and hyperinflammatory in a β-adrenergic-mediated manner.[94] The decrease in right ventricular ejection fraction seen after endotoxemia can be alleviated by blockade of thromboxane.[95] Initially, systemic vascular resistance is increased; however, as systemic inflammation and sepsis emerge during the flow phase, vasoplegia ensues and exacerbates the cardiogenic and distributive shock states that promote MOF.[96]

Twenty-four to 48 hours after injury the ebb phase ends, the cardiac pathology enters the flow phase, marked by

elevated cardiac outputs. The pathophysiology of this phase of cardiac dysfunction has been thoroughly described.[94] Two primary drivers are prolonged elevated levels of catecholamines and sepsis. Sepsis can continue to produce myocardial dysfunction in a cytokine-mediated process. Persistent β-adrenergic receptor activation causes uncoupling from G-proteins, decreases cyclic adenosine monophosphate (cAMP) production and altered phosphorylation down the mitogen-activated protein kinase (MAPK) and Akt (protein kinase B) pathways away from the target of rapamycin (mTOR), and reduces sarcoplasmic reticulum calcium ATPase 2 (SERCA2) and ryanodine receptor (RyR). Collectively these make the myocardium less responsive to catecholamines and perturb calcium homeostasis. Further nitric oxide secretion from inflamed and burned tissue alters mitochondrial respiration and competes with calcium for binding sites on myosin, thus furthering the calcium dysregulation. The prolonged leakage of calcium from the sarcoplasmic reticulum depletes calcium stores and depresses contractility. These changes conjointly drive the myocardium toward apoptosis, which is detected within 3 hours postburn in the ebb phase but can continue into the flow phase.[94]

Additionally, pulmonary hypertension and right ventricular failure have a high mortality. In burn patients this can result from sepsis-related myocardial effects or acute fluid overload with resuscitation and/or edema mobilization. Left heart failure, acute pulmonary embolism, sepsis, acute lung injury, and perioperative state are other common causes.[97] Jeschke reported nonsurvivors having a 30% higher cardiac index at 29–34 days and 91–180 postburn than survivors, thus demonstrating the increased cardiac demand required in the persistent hyperdynamic state typifying MOF. The data suggest that these patients may need a supraphysiologic cardiac index to meet their hypermetabolic needs, although no definitive studies currently exist. Effective and expeditious management of cardiovascular failure is important to preventing or ameliorating MOF and is a critical component of burn center care.

There is mounting evidence that propranolol improves cardiac outcomes after burn injury by reducing heart rate and cardiac work, thus dampening hypermetabolism and hypercatabolism. Carvedilol may hold additional promise with its added α-blocking and free radical scavenging activities.

LUNGS

Pulmonary failure is caused by direct injury from inhalation of toxins, fluid overload, heart failure, and pulmonary edema resulting from resuscitation, injury from inflammatory and septic mediators draining from the burn wounds to the pulmonary capillary beds, pneumonia, and iatrogenic ventilator injury.[11] Prevention of the pulmonary component of MOF is based on infectious prophylaxis (early ventilator weaning/daily spontaneous breathing trials, suctioning, oral hygiene, chest physiotherapy, elevating head-of-bed) and limiting factors that exacerbate pulmonary injury. Current treatments such as administration of nebulized heparin, albuterol, cortisol, and epinephrine and chest physiotherapy as well as mucolysis improve pulmonary ventilation, function, and outcomes.[4] Cox and Hawkins investigated the integrity of airway epithelium in autopsy specimens of 72 severely burned children, finding airway epithelial loss corresponded to inhalation injury and age.[98] Mortality of inhalation injury was 16.4% and was associated with increased length of mechanical ventilation and length of stay.[99]

Lopez and Enkhbaatar demonstrated that nebulized epinephrine limited pulmonary vascular hyperpermeability to water and protein flux in an ovine burn model with smoke inhalation. This preserved dynamic compliance, mean airway pressure, and P/F ratio.[100] In their ovine burn with inhalation injury model, Traber et al. administered γ-tocopherol, a reactive oxygen species scavenger. They found decreases in arginase and collagen, significantly improved diffusion capacity, decreased lung water, reduced pulmonary shunt fraction, and reduced peak pressures and bronchiolar obstruction, indicating that free radical scavengers may reduce smoke-induced chronic pulmonary dysfunction.[101,102]

In an ovine model of inhalation injury with *Pseudomonas* infection there was severe deterioration in pulmonary gas exchange and increased lung lymph flow and protein content, lung water, nitrite/nitrate concentrations, tracheal blood flow, and vascular endothelial growth factor (VEGF) expression.[103] In a different study with this model evaluating microcirculatory changes in response to activated protein C, significant reductions in heart rate and cardiac output were observed. The changes in microvascular blood flow to the trachea, kidney, and brain were normalized.[104]

For nearly 20 years the ARDSnet doctrine of limited tidal volumes, pressure-limited ventilation, positive end-expiratory pressure (PEEP), and permissive hypercapnea have dominated the field of pulmonary critical care.[105] Application of these principles to burn care has been limited due to increased CO_2 production resulting from the hyperdynamic state requiring higher minute ventilation, pulmonary edema from resuscitation increasing the A-a gradient, and decreasing compliance and airway injury from inhaled toxins causing increased resistance and mucosal sloughing and plugging. For more than 28 years, Sousse and Mlcak analyzed pulmonary outcomes in 932 burned pediatric patients with inhalation injury, stratifying for tidal volume. Their findings are staggeringly divergent from ADRSnet data; they determined high tidal volume (15 ± 3 mL/kg) corresponded to significantly decreased ventilator days and maximum PEEP and significantly increased maximum peak inspiratory pressure. ARDS was significantly decreased, but the pneumothorax rate was increased. They concluded that high tidal volumes might interrupt the events leading to lung injury following inhalation injury.[106] Of note, this study was performed in the setting of early spontaneous breathing trials and aggressive discontinuation of mechanical ventilation. It remains unclear whether these data are an aberration or, as we suspect, there is a fundamental difference in the physiology of burned lungs. In the setting of severe inhalation injury with hypoxia and hypercapnia, we have seen the remarkable ability of pediatric lungs to heal with eventual normalization of gas exchange several months post injury; this phenomenon may be attributable to a still-active stem cell population.[107]

Systemic factors beyond sepsis also affect pulmonary failure. For example, inflammation associated with burns leads to hyperglycemia. A threshold of greater than 150 mg/dL leads to overwhelming growth of bacteria in the bronchopulmonary system. Pneumonia on mechanical ventilation and ARDS were higher in patients with average daily glucose greater than 150; they had significantly longer ventilation and more infection and sepsis.[108]

GASTROINTESTINAL DYSFUNCTION

DENVER2 and SOFA scores only address the gut failure pertaining to the liver. However, other aspects of gastrointestinal dysfunction also cause significant morbidity and contribute to mortality. Intestinal circulatory disturbances, atony, ileus, edema, swelling, and loss of mucosal barrier function gut dysfunction are an engine of MOF that Lautenschlager et al. studied with isolated rat small intestine perfused with PAF. They induced mesenteric vasoconstriction, translocation of fluid and macromolecules from the vasculature to the lumen, edema, and the loss of motility seen in intestinal failure. In this model quinidine, a sodium channel blocker, inhibited this pathology whereas dexamethasone did not.[109] Oliveira and Herndon studied the role of cyclooxygenase-2 inhibitors on gastric and small bowel ileus in prostaglandin-mediated etiology for postburn ileus.[110] Gut mucosal integrity suffers when mesenteric flow is inadequate, and gut blood flow is decreased after burn injury, exacerbated by TXA_2 release.[111] Support of splanchnic blood flow is an important aspect of MOF prevention[112] accomplished as part of whole-body hemodynamic support.

In a chronic porcine model of burn injury, burned pigs were given endotoxin bolus, causing a marked decrease in systemic vascular resistance, blood pressure, cardiac index, and mesenteric blood flow. This state increased gut bacterial translocation into mesenteric lymph nodes, spleen, and burn wounds, possibly due to mesenteric ischemia and reperfusion injury.[113]

Enteral feedings have beneficial effects on outcomes compared with parenteral feedings, possibly via an enhancement of gastrointestinal barrier integrity.[114] Enterocytes are principally supported by intraluminal feedings. Guts deprived of intraluminal feedings develop mucosal atrophy.[115] Early enteral feedings are tolerated in burn patients[116] and attenuate their hypermetabolic response.[117] The value of specific nutrients to support the enterocyte is murkier than that of providing adequate mesenteric blood flow and intraluminal nutrition. Glutamine is the preferred fuel of the small bowel enterocyte.[118] Sepsis has been shown to decrease glutamine uptake by the small bowel enterocyte, which may result in barrier failure,[119] and the addition of glutamine to the nutritional regimen is theorized to improve barrier function. Glutamine is not a component of commercial parenteral nutritional formulas because of its short shelf life, although the dipeptide is well tolerated and has a longer shelf life.[120] While supplemental glutamine may improve protein balance in surgical patients[115] and partially reverse gut atrophy,[121] it has not been shown to improve gut barrier function when given parenterally.[122] The large intestinal mucosa are trophic to butyrate, a fatty acid liberated by fiber fermentation.[123] Enteral pectin may help support the colonic mucosa, but the value of such support in the hypermetabolic burn patient remains unclear.

Limited research suggests possible benefits of probiotics for gut barrier support.[124] Probiotics may improve gastrointestinal barrier function, avoiding colonization with pathogenic microorganisms and immunomodulation. They reduce bacterial translocation in the gut of burned rats.[125] Interestingly, they seem to increase diarrhea rates. Accumulating data suggest probiotics may reduce ventilator-associated pneumonia rates. There are some concerns in the current datasets that the control groups have too high an incidence of ventilator-acquired pneumonia (VAP), and there have been case reports of sepsis from probiotic organisms in high-risk patients.[126] In a series of 20 severely burned children, probiotics were found to be safe and tended toward fewer surgeries and less time to achieve complete wound closure.[127]

Decontamination of the gut lumen might diminish the impact of gastrointestinal barrier failure. Attempts have been made to assess the impact of selective decontamination of the gut[128] by coating enteric bacteria to inhibit their ability to attach to the intestinal mucosa and translocate.[129] While the rate of pneumonia may decrease by such mechanisms, there is no apparent impact on mortality.

Acute pancreatitis is also notable after severe burn injury as defined as a threefold increase in amylase or lipase with abdominal pain or feeding intolerance. In a pediatric cohort, Rivero and Jeschke reported an incidence of 13/2699 or 0.05% and found pathological evidence in 11/78 autopsies. This is in contrast to 40% of patients developing a hyperamylasemia or hyperlipidemia without symptoms. They postulated that the etiology of these pancreatitis cases was from ischemic injuries due to shock. They also noted increased mortality in the pancreatitis cohort.[130]

In a severe burn the liver plays a pivotal role in modulating inflammatory processes, immune functions, metabolic pathways, and the acute-phase response. Thermal injury causes hepatic damage by inducing hepatic edema, fatty infiltration, apoptosis, and the metabolic derangements associated with insulin resistance. Insulin administration decreases the rate of infections and the synthesis of proinflammatory cytokines and improves hepatic structure and function in severely burned and critically ill patients.[131]

Burn injury promotes catabolism and lipolysis in burned children.[132] The resulting free fatty acids are re-esterified in the liver to triglycerides where they are not secreted as very-low-density lipoprotein (VLDL) due to downregulation of transport proteins, thus leading to progressive fatty liver metamorphosis. Carbohydrates are utilized as a major energy source for critically burned patients. Lee and Herndon demonstrated that low-fat, high-carbohydrate feeds promote shorter ICU stay per %TBSA, a lower incidence of sepsis, and decreased hepatic steotosis.[133]

Acute liver failure (ALF) is uncommon after burn but carries a high mortality. It presents with hepatic encephalopathy, jaundice, and coagulopathy in the absence of chronic liver disease and carries a mortality rate of 40–50%. The cause of death is cerebral herniation in 34%, refractory hypotension, and MOF. Herndon et al. studied 142 consecutive cases of ALF in the ICU and found that 70% were due to heart failure, 13% from respiratory failure, and 13%

from toxins or sepsis.[134] Most commonly, low flow states cause ALF. The liver receives most of its blood flow via the portal system, and the dependence on portal supply is increased in critical illness because the arterial supply is reduced while the central lobular oxygen requirements increase due to metabolic and synthetic demands. In the setting of heart failure, high central venous pressures, associated with fluid overload or the need for high preload, decrease the pressure gradient across the liver and compromise portal flow (and oxygenation), leading to centrilobular necrosis. Thus, most post-burn acute liver failure is hypoxemic liver failure, with high hepatic (central) venous pressures a major (unrecognized) cause of reduced hepatic oxygen delivery.[134] Less common causes are toxins and viruses. Many drugs used in the burn ICU can cause acute liver failure: acetaminophen, amoxicillin, moxifloxacin, trimethoprim-sulfamethoxazole, fluconazole, voriconazole, amiodarone, metformin, isoflurane, opiates, phenytoin, ibuprofen, iron, and anabolic steroids make up a short list. Immunosuppression associated with burn injury predisposes activation of latent hepatitis and herpes viruses (especially cytomegalovirus), which can cause ALF. Loss of clotting factors causes coagulopathy, whereas loss of anticoagulants can causes thrombosis, collectively promoting disseminated intravascular coagulation (DIC). Burn patients with liver dysfunction become prone to hypoglycemia due to loss of glucose homeostasis.[135] ALF feeds back into MOF causing vasoplegia with diminished hepatic clearance of circulating vasoactive compounds, increased nitric oxide (NO) production, acute renal failure due to ischemia, and acute tubular necrosis (ATN), and it may progress to hepatorenal and/or compartment syndromes.

RENAL

To survive a burn injury adequate renal clearance is essential. Twenty-four h following resuscitation it is necessary to clear the excess volume administered. Renal function is critical to clear extensive metabolic wastes associated with injury and the hyperdynamic state.[136] Concurrently the kidney is subjected to prerenal insults, such as hypovolemia and shock, and to direct renal toxins, such as myoglobin and medications.[137] Aggressive treatment of compartment syndromes to prevent myoglobinemia, monitoring of abdominal compartment pressures to prevent compromise of renal blood flow, and avoidance of nephrotoxic medications are critical to maintaining renal function. Mason and Jeschke et al. prospectively analyzed 330 resuscitations dividing the patients relative to the Parkland formula resuscitation. The groups receiving greater than Parkland resuscitation had a higher APACHE score. Patients resuscitated with less than Parkland resuscitation demonstrated greater probability of acute kidney injury (AKI) (odds ratio [OR] 3.25; 95% confidence interval [CI] 1.18–8.94) without difference in infectious complications.[138] Maintenance of sufficient renal blood flow with appropriate volume resuscitation is vital to maintaining renal function. In a retrospective review of 41,179 burned Finnish patients, 86 had AKI related to the burn and 43 developed end-stage renal disease (ESRD) and required renal replacement therapy (RRT).[139] In the absence of diuretics, urine output of 0.5–1 mL/kg per hour generally indicates sufficient renal perfusion. In patients with increasing creatinine or decreased urine output, the finding of granular casts on centrifuged microscopic urinalysis is helpful in promptly differentiating organ damage (tubular necrosis) from appropriate renal response to decreased blood flow (prerenal state) and can promptly guide therapy.

Prevention of Sepsis

Sepsis is a major engine of MOF, and MOF predisposes patient to sepsis; a lethal feed-forward loop. The post-burn surge of proinflammatory mediators and resultant hypermetabolic response and protein wasting contribute to infection and sepsis.[4] In multiple series all mortalities with MOF were septic. MOF patients may have more major infections (non-MOF 2.1 versus MOF 3.3), and they do experience more sepsis (non-MOF 5%, MOF 31%).[4] Early burn excision, wound closure, regular wound surveillance and culture, and strict infection control remain the principal adjuncts to control invasive infections in burn patients.[140] Sepsis accounts for at least half of MOF cases. Overt wound sepsis and smaller septic insults are prevented by early removal of devitalized tissue because manipulation of heavily colonized burn wounds is a frequent source of transient bacteremia.[141,142] Multiple episodes of occult bacteremia occurring during frequent manipulation of heavily colonized wounds contribute to the development of MOF by priming immune cells, making them react more intensively to each subsequent insult.[25]

The role of perioperative and prophylactic antibiotics in minimizing bacteremia in the perioperative period remains controversial. There is a clear benefit to patients with injuries greater than 60% TBSA and for any patient in whom the probability of bacteremia with wound manipulation is considered to be high.[143] Culture-directed antibiotics are an important consideration because burn patients are prone to a large number of unusual and often occult infections.[144] Rapid diagnosis and treatment are assisted by a high index of suspicion.

Intravascular infections such as suppurative thrombophlebitis and endocarditis typically present in burn patients with fever and bacteremia without localizing signs. Burn patients with endocarditis rarely develop a murmur (just 9% of cases)[145] with only 10% reported antemortem.[146] Septic thrombophlebitis often presents without localizing signs, with 68% of cases having only fever and positive blood cultures.[147] Diagnosis is made by thorough examination of all sites of prior cannulation, surgical exposure of suspicious sites, and complete excision of involved veins.[148] Vigilant care, scheduled replacement, and early removal of intravascular devices will minimize the occurrence of catheter-related sepsis. Occult intracompartmental sepsis can also present with fever and bacteremia without localizing signs and is diagnosed only by careful examination and exploration of suspicious compartments.[149]

Pneumonia, seen in approximately 35% of patients with inhalation injury, adds 20–60% to the expected mortality.[150] Pneumonia should be vigilantly anticipated and aggressively treated with pulmonary care and specific antibiotics. The incidence of nosocomial pneumonia increases with longer durations of intubation,[151] emphasizing the importance of judicious use of mechanical ventilation and

early extubation protocols such as daily spontaneous breathing trials.

Suppurative sinusitis is a rare cause of sepsis in the ICU traditionally described as resulting from transnasal tube placement in a case series published in 1986.[152] Many burn centers routinely use prolonged nasotracheal tubes due to their dramatically lower rates of dislodgement and lower sedation requirements and do not report high rates of sinusitis. Subsequent studies have brought this etiology into question, and, in our experience, we have had zero episodes in the past 20 years.[153] Furthermore this is not a typical cause of septic shock even when it occurs. If suppurative sinusitis does occur, it is treated with tube removal, topical decongestants, and appropriate antibiotics, rarely requiring surgical drainage.

Acalculous cholecystitis presents with generalized sepsis without localizing signs, making diagnosis difficult.[154] Percutaneous cholecystectomy tube drainage has become the management of choice in suspected cholecystitis in critically ill patients.[155] This allows diagnosis and decompression in patients too unstable for immediate operation.

Ensuring Adequate Oxygen Delivery

Oxygen is one of the most sensitive substrates in cells. The normal intracellular partial pressure of oxygen is 0.5 mm Hg for all mitochondrial function. Failure to deliver adequate oxygen resulting in organ dysfunction is a definition of shock and a common cause of MOF. Inadequate oxygen delivery shifts cells to anaerobic metabolism and increases in the liberation of intracellular oxygen free radicals with the activation of xanthine oxidase.[156]

Sufficient oxygen delivery requires adequate resuscitation and re-establishment of cardiovascular and pulmonary homeostasis. The practical details of resuscitation, particularly resuscitation endpoints, remain controversial. The Rivers et al.[157] study highlighted the utility of aggressive pursuit of predetermined resuscitation endpoints in septic shock. Large trials failed to replicate their results, which may be the result of the early goal-directed therapy protocols becoming the standard of care with resultant improvements in control group mortality. Regardless, optimizing preload, assuring appropriate afterload, optimizing inotropy, and tracking end organ perfusion remain the hallmarks of critical care support in algorithms from the Advanced Burn Life Support to the Surviving Sepsis Campaign.[158] Additional resuscitation endpoints beyond urine output, such as lactic acid and base deficit,[159] and advanced hemodynamic monitoring tools are improving resuscitation accuracy and minimizing the morbidity of under- and overresuscitation. Computerized resuscitation algorithms help achieve sufficient fluid resuscitation while minimizing overresuscitation. Resuscitation strategies and their effects are discussed at length in other chapters of this text. Complications of anasarca caused by massive crystalloid resuscitation can be reduced with the addition of colloid to resuscitation.[160]

Inadequate oxygen delivery leads to organ dysfunction. Clinicians should ensure that injured patients are resuscitated to conventional clinical endpoints of appropriate urine output, skin perfusion, blood pressure, and sensorium. In selected critically ill patients, invasive and noninvasive monitoring is justified to optimize preload, afterload, inotropy, and oxygen delivery and consumption particularly in patients where urine output becomes an unreliable endpoint.

The Potential Role of Nutritional and Specific Immunomodulators

Prevention of MOF by modulating the common pathway that leads to organ dysfunction is the holy grail of critical care. The three general approaches to this goal are nutritional, nonspecific, and specific immunomodulation.

NUTRITIONAL IMMUNOMODULATION

Three categories of substances show promise as potential nutritional immunomodulators: long-chain fatty acids; arginine, glutamine, and branched-chain amino acids; and nucleotides. Long-chain fatty acids are important constituents of cell membranes and can profoundly influence cell function.[161] Omega-3 long-chain fatty acids play a particularly important role in the membranes of immunocompetent cells.[162] Animal data suggest that supplementation of a diet with omega-3 fatty acids may improve immune function after burn injury;[163] however, there are no clear clinical data.

The potential immunostimulating effects of specific amino acids, particularly arginine, glutamine, and the branched-chain amino acids leucine, isoleucine, and valine, remain an area of research. Arginine has important functions in the urea cycle and in generating nitric oxide and may have important effects on immunity.[164–166] Animal data suggest improved immunocompetence and outcome after burn with arginine supplementation,[167–169] but human data are not adequate to support its routine administration. Glutamine may be essential in hypermetabolic patients,[118,119] and its administration may support the gut barrier, thereby abrogating the consequences of barrier failure.

NONSPECIFIC AND SPECIFIC IMMUNOMODULATION

It seems unlikely that a magic immunomodulating bullet will prevent the development of MOF in critically ill patients, particularly with uncontrolled sepsis, compromised gut barrier, unaddressed burn wounds, or inadequate hemodynamic support. Efforts at nonspecific immunomodulation include the use of steroids,[170] immunoglobulin G,[171] and naloxone[172] with no significant impact on patient outcomes. With the exception of steroids for adrenal insufficiency[173] and naloxone for those with opiate intoxication, there is currently no role for these substances in critically ill burn patients.

Addressing toxicity of lipopolysaccharide has been attempted by absorption,[174] prevention with polymyxin B,[175] and antiendotoxin antibodies. Although multiple trials have been attempted with multiple antibodies no compelling data have yet brought one into broad clinical practice.[176–179]

Immunomodulation has also targeted arachidonic acid metabolites or eicosanoids, both cyclooxygenase and lipoxygenase products. Animal models of sepsis demonstrate that cyclooxygenase pathway blockade has demonstrated improved survival,[180] improved pulmonary hemodynamics,[181] and improved mesenteric blood flow.[182] Human data are currently lacking, but it has been suggested that nonsteroidal antiinflammatory agents improve symptoms associated with endotoxin infusion in normal volunteers[183] and septic patients[184] and may improve immune function after surgical trauma.[181] In an animal model, infusion of the vasodilating AA metabolite prostacyclin ameliorates the pulmonary dysfunction associated with endotoxin infusion.[38] Lipoxygenase pathway blockade reduces pulmonary dysfunction in mice,[185] sheep,[186] and pigs.[187] The ultimate role of lipoxygenase blockade in human remains to be investigated.

Cytokines have also been targeted. IL-1 receptor antagonist enhances survival in an animal model.[188] Infusion of IL-1 may improve immune function in humans.[189] Current understanding of the complex functions of this cytokine is inadequate to allow intelligent intervention. TNF blockade attenuated the physiological effects of both endotoxin infusion and Gram-negative sepsis in animal models.[190,191] Anti-TNF administration prior to experimental sepsis[192] and endotoxemia[193] has variable effects on survival.

Interference with the effects of PAF has been shown to decrease neutrophil priming by human burn serum,[194] improve endotoxin-induced pulmonary dysfunction,[195] decrease eicosanoid release,[196] attenuate thromboxane release, and improve survival[197] in various animal models of endotoxemia. These exciting initial results, and the availability of several blockers and receptor antagonists portend a future use for PAF modification.

Efforts to modulate both the adherence and function of inflammatory cells are an exciting area of research because activated neutrophils play an important role in the development of MOF. Blockade of neutrophil adhesion receptors with monoclonal antibodies enhances survival in animal models of endotoxic and hemorrhagic shock.[198]

Oxygen free radicals generated by activated neutrophils or xanthine oxidase may oxidize membrane lipids, forming lipid peroxides and resulting in membrane dysfunction.[199] Native antioxidant systems do exist but can be overwhelmed. Circulating levels of vitamin E, a natural antioxidant, are low in patients with ARDS.[200] Efforts to modify oxidant activity include blockade of free radical generation, addition of free radical scavengers, augmentation of host antioxidant defenses, and prevention of amplification of tissue damage by neutrophils.[199] Particularly intriguing are free radical scavengers such as superoxide dismutase[201] and spin-trapping nitrones,[202] which improve survival in animal models of endotoxic and hemorrhagic shock. Despite encouraging initial animal studies, such therapy is not yet appropriate in human patients.

The continuous synthesis of NO plays an important role in the regulation of pulmonary and systemic vascular tone in sepsis,[203] and this presents potential opportunities for intervention.[204] Aerosolized NO has been shown to be useful in reversing the pulmonary hypertension associated with ARDS as well as in improving V:Q mismatch,[205] and NO synthesis blockade may improve the hypotension and renal dysfunction associated with sepsis. Its complex interactions with other cytokines and variable effects on different vascular beds currently render any NO-based interventions investigational or for selected critical care indications.

Most patients who die in the burn unit after surviving the initial injury and resuscitation succumb to MOF.[206] Modifying the cascade leading to MOF at the cellular and subcellular levels is enticing, but our fragmented understanding of these processes mitigates against such therapy in human patients at present.

31 Acute Renal Failure in Association with Thermal Injury

JOSHUA S. CARSON, JEREMY GOVERMAN, and SHAWN P. FAGAN

Introduction

Acute renal dysfunction represents a critical complication of an acute thermal injury and is associated with a significant increase in morbidity and mortality. Currently, the incidence of acute renal failure (ARF) in burn patients varies between 0.5% and 30%, and the risk of mortality associated with renal failure in burn patients has been reported to be as high as 54–100%.[1–11]

Prior to 1965, there were no reported survivors from ARF following a thermal injury.[12] Clearly the care of patients with renal injuries has improved during the past 50 years. However, while advances have been made in the understanding of burn-associated ARF, very few specific interventions have been clearly shown to change outcomes in these patients. Even renal replacement therapy (RRT), one of the core milestones of modern medical progress, has yet to show a significant improvement in the mortality rate of burn patients suffering from ARF.[13] As such, the optimal treatment for acute renal failure remains prevention.

This chapter will review the definition, etiology, pathophysiology, diagnosis, and treatment of acute renal failure in association with thermal injury (Fig. 31.1).

Definition

Intuitively ARF is easily understood as an abrupt decline in renal function. Precisely how to quantify renal function and where to place the threshold for "failure" has long been open to interpretation. Until 2004, with no consensus regarding a definition for ARF, more than 30 different definitions were used within the literature at the time. The need for a common working definition of renal failure prompted an effort to standardize the definition of renal insufficiency, with the International Acute Dialysis Quality Initiative (ADQI) group developing the RIFLE criteria for kidney injuries in 2004. The RIFLE criteria divided renal compromise into five discrete categories: Risk, Injury, Failure, Loss, and End-stage renal disease (Fig. 31.2). In addition to establishing a common definition, the RIFLE criteria provided a means to quantify degrees of acute kidney insufficiency or injury (AKI).[14] In 2007, the Acute Kidney Injury Network (AKIN) introduced an updated definition of acute kidney injury; see Tables 31.1 and 31.2.[15] The AKIN definition simplified the stratification of renal injury into three stages (I, II, and III), with the RIFLE Failure, Loss, and End-stage renal disease categories folded into grade III. There was also an increased sensitivity (relative to the RIFLE criteria) by virtue of use of an absolute increase in serum creatinine of 0.3 mg/dL or more as sufficient to define a stage I injury. In 2012, the Kidney Disease Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group published a consensus definition of renal injury that essentially merged the two previous frameworks, with slight adjustments.[16]

While the proliferation of consensus definitions may seem to undermine the basic goal of establishing a universal metric for research and clinical applications, the three systems have proved fairly interchangeable. Multiple studies applying the different scoring systems to the same patient populations have found that they ultimately yield similar results.[17,18] Specifically in burn populations, Chung et al. found that RIFLE and AKIN identified similar subpopulations when applied to a large cohort of patients.[19]

Etiology

Burn-associated acute kidney injuries can generally be divided into two categories, early and late. AKI presenting within the first 48 hours of the burn injury (i.e., early AKI) typically results from either uncontrolled burn shock, underresuscitation, or protein degradation products. Renal injury manifesting later in the course of acute burn care (i.e., late-onset AKI) typically represents either a medication toxicity or a complication of sepsis.

EARLY

Within the first 24–28 hours of a massive burn injury, AKI results from the pathologic response to thermal injury. Early burn-associated AKI is multifactorial, with hypovolemia, inflammatory mediators, cytokines, extensive tissue destruction and release of denatured proteins, iatrogenic causes (nephrotoxic agents), and cardiac dysfunction all contributing to the renal insult. In the setting of delayed resuscitation, hypovolemia is the most immediate threat to renal function. And yet AKI can still develop in the thermally-injured patient despite aggressive fluid resuscitation and a normal urine output. In such cases, renal injury might reflect a fluid-refractory, inflammatory shock in response to the burned tissue, cardiac dysfunction, or injury from nephrotoxins, which can be either endogenous (denatured proteins) or exogenous (medications) in nature.[20,21]

Hypovolemia

In large surface area burns, decreased renal blood flow results from massive fluid shifts and losses. Local and systemic cytokine release leads to "capillary leak," shifting

fluids from the intravascular to interstitial space. Burn-induced compromise of the water-tight dermal barriers results in rapid evaporative losses from the extravascular compartment, which facilitates further extravasation of the intravascular compartment in a vicious cycle.[22] Given the sheer speed and volume fluid shift seen in burn shock, profound intravascular hypovolemia can result. Renal blood flow is restricted in a compensatory response to hypovolemia resulting in renal ischemia. The ischemic insult is known to produce oxygen free radicals that cause direct tubular damage as well as disruption of tight junctions, resulting in obstructing casts that further reduce effective glomerular filtration rate (GFR).

Hypovolemia can develop within the course of minutes in the absence of appropriate fluid replacement. As such, hypovolemia represents by far the most likely source of AKI

Fig. 31.1 Autopsy specimen from a patient with acute tubular necrosis and renal failure. Note the edema and the alteration of medullar pyramids. Acute renal failure in burn patients carries a high mortality.

Table 31.1 Comparison of Serum Creatinine Criteria in RIFLE, AKIN, and KDIGO Systems

SERUM CREATININE CRITERIA FOR THE DEFINITION AND CLASSIFICATION OF ACUTE KIDNEY INJURY				
RIFLE Criteria—The Acute Dialysis Quality Initiative (ADQI)		**AKIN Criteria—Acute Kidney Injury Network**	**KDIGO Criteria—Kidney Disease Improving Global Outcomes**	
Risk	Increase in serum creatinine ≥1.5 times baseline OR Decrease in GFR ≥25%	Increase to 1.5–1.9 times baseline OR Increase in serum creatinine of ≥3 mg/dL (26.2 µmol/L) from baseline	Increase to 1.5–1.9 times baseline OR Increase in serum creatinine of ≥0.3 mg/dL (26.2 µmol/L) from baseline	Stage I
Injury	Increase in serum creatinine ≥2.0 times baseline or decrease in GFR ≥50%	Increase in serum creatinine to 2–2.9 times baseline	Increase in serum creatinine to 2–2.9 times baseline	Stage II
Failure	Increase in serum creatinine ≥3.0 times baseline OR Decrease in GFR ≥75% OR An absolute serum creatinine ≥354 µmol/L with an acute rise of at least 44 µmol/L	Increase in serum creatinine to ≥3 times baseline OR Serum creatinine ≥4.0 mg/dL (354 µmol/L) with an acute rise of ≥05 mg/dL (44 µmol/L) OR Initiation of renal replacement therapy	Increase in serum creatinine to a level ≥4.0 mg/dL (353.6) OR Initiation of renal replacement therapy	Stage III

Note—Urine output-based criteria are the same in all three systems.

Table 31.2 Comparison of Serum Creatinine Criteria in RIFLE, AKIN, and KDIGO Systems

KDIGO CRITERIA FOR RENAL INJURY		
Stage	**Serum Creatinine Criteria**	**UO Criteria**
I	Increase to 1.5–1.9 times baseline OR Increase in serum creatinine of ≥0.3 mg/dL (26.2 μmol/L) from baseline	<0.5 mL/kg/h for ≥6 h
II	Increase in serum creatinine to 2–2.9 times baseline	<0.5 mL/kg/h for >12 h
III	Increase in serum creatinine to a level ≥4.0 mg/dL (353.6) OR Initiation of renal replacement therapy	<0.3 mL/kg/h ≥24 h or anuria ≥12 h

From Khwaja A. KDIGO clinical practice guidelines for acute kidney injury. *Nephron Clin Pract*. 2012;120(4):c179–184.

in any burn patient showing signs of renal insult within 24 hours of their burn.

Overresuscitation and Abdominal Compartment Syndrome

Unfortunately, overadministration of fluids can be just as harmful as underresuscitation. Studies have shown that AKI can develop in burn patients despite fluid resuscitation volumes in excess of that recommended by the Parkland formula and despite normal average urine output (0.5–1.0 mL/kg per hour).[5,23] Furthermore the risks of overresuscitation have been well-documented and include pneumonia, acute respiratory distress syndrome (ARDS), compartment syndromes, and an overall increase in mortality.[23,24]

Despite the physician's greatest effort to monitor endpoints of resuscitation, obligatory intercompartmental fluid shifts will occur during resuscitation.[25] These intercompartmental fluid shifts can be particularly hazardous if they occur into fascial bound compartments, such as the peritoneal cavity. Numerous studies from trauma literature have described the adverse physiologic effects of increasing intraabdominal pressure on visceral perfusion.[6,26,27] Intraabdominal hypertension (IAH) is a known pathological process that may occur during initial burn resuscitation as defined by intraabdominal pressures (IAPs) of greater than 12 mm Hg. Abdominal compartment syndrome (ACS) is defined as an IAP of greater than 20 mm Hg with at least one concomitant organ failure. The exact level of abdominal hypertension required to compromise visceral perfusion varies depending on a variety of patient factors and is difficult to predict.[28–30] O'Mara et al. demonstrated that the volume and type of fluid resuscitation affects the development of ACS in the burn patient and suggested that fluid resuscitation with crystalloid of greater than 0.475 L/kg should alert the clinician to possible IAH/ACS and to monitor for decreased cardiac output, decreased lung compliance, or decreased renal perfusion. In a mixed population of critically ill patients, a multicenter prospective trial has demonstrated that the occurrence of IAH during the ICU stay was an independent outcome predictor.[28]

Rhabdomyolysis

Rhabdomyolysis frequently presents within 24 hours of thermal injury and represents a well-documented risk for AKI and subsequent renal failure.[31] Rhabdomyolysis can arise secondary to direct thermal damage or compartment syndrome and is commonly seen following a severe electrical injury. The release of myoglobin into the systemic circulation results in blockage of renal tubules, constriction of afferent arterioles, and the generation of oxygen free radicals. Myoglobinuria occurs when serum myoglobin exceeds 1500–3000 ng/mL. Myoglobinuria does not always result in renal injury, but certain risk factors have been identified. The risk of renal injury is directly related to the amount of iron-containing molecules released, the state of hydration, and the degree of associated acidosis.[32] Elevated creatinine at baseline and creatinine kinase levels greater than 5000 U/L have been associated with the development of AKI and the need for RRT, both in general trauma populations and in studies of burn patients.[32,33]

Cardiac Dysfunction

Patients suffering burns greater than 50% total body surface area (TBSA) are subject to decreased cardiac output, increased myocardial workload, and myocardial ischemia. Several authors have suggested theories to explain the decreased cardiac output associated with thermal injury: (1) increased sympathetic activity with impaired adrenal response, (2) hypovolemia resulting in myocardial ischemia, and (3) direct myocardial suppression.[34–40] Of the potential theories, direct myocardial suppression by tumor necrosis factor (TNF; i.e., myocardial depressant factor) has gained substantial interest. TNF is known to be released by myocytes stimulated by endotoxin or direct thermal injury.[41–47] The effects of TNF on cardiac function include reversible biventricular dilatation, decreased ejection fraction, and decreased stimulation to catecholamines (Fig. 31.2).[41,48,49] This is typically a transient phenomenon, and, with adequate support, it usually resolves within 24–72 hours. Without appropriate support, though, frank heart failure can develop, bringing a myriad of complications with long-lasting or even permanent sequelae. Although most early cardiac dysfunction caused by TNF can be reversed by inotropic support, the key is early diagnosis to prevent ineffective renal perfusion and thus prevent the morbidity and mortality associated with renal insufficiency.

Cardiac dysfunction is known to result in reduced renal blood flow and hence to contribute to AKI. Although diminished cardiac output following thermal injury has been attributed to decreased preload or hypovolemia, there is also evidence of direct myocardial suppression, The impact of this suppression can range from clinically undetectable to frank cardiac shock. Often, this presents as a lack of appropriate cardiac compensation for distributive burn shock. Myocardial dysfunction after thermal injury is commonly overlooked by physicians due to the concentrated effort to correct the overwhelming state of hypovolemic shock and electrolyte abnormalities. In a patient presenting with burn shock (i.e., hypoperfusion) and found to have a cardiac index in "normal" range (rather than the expected supranormal values), serious consideration should be given to

inotropic support, particularly when accompanied by the finding of a low systemic vascular resistance index.

In any case of suspected cardiac dysfunction, a typical workup should be performed to rule out any coronary or mechanical etiology. Absent any such finding, an effective burn surgeon must rapidly reestablish adequate renal blood flow by correcting the diminished preload state while keeping in mind the impact of burn injury on the entire cardiovascular system.

LATE

AKI presenting later in the course of treatment for a massive burn typically occurs as a component of multiorgan failure, most commonly from sepsis. Given the high risk for infection and the difficulty of diagnosing such infections in this patient population, underlying infection and sepsis must be seriously considered in any patient found to have new or worsening renal failure more than 48 hours out from their initial injury.

Iatrogenic renal injury is also an important consideration in late burn-associated AKI, particularly given these patients' frequent exposure to multiple antibiotics and diuretics.

Sepsis

Early aggressive resuscitation and excision have significantly influenced the course of ARF immediately associated with thermal injury. Acute renal dysfunction associated with the septic syndrome nonetheless continues to cause significant mortality.[50,51]

Sepsis and septic shock are the most common cause of death in the ICU and are seen in up to 87% of cases of acute renal dysfunction in the burn ICU.[9,10] Several authors have found the degree of sepsis to be directly related to the incidence of acute renal dysfunction (Table 31.3).[52,53] The pathophysiology of AKI associated with sepsis is multifactorial in nature but begins clinically with a generalized arterial vasodilatation secondary to a decreased systemic vascular resistance (Fig. 31.2). Initially bacteria or their products activate sepsis-associated mediators (cytokines) locally at the site of direct invasion. The homeostatic balance between production and inactivation of these mediators is altered, allowing for systemic release and causing direct damage to the endothelium and vasoparesis, as well as a procoagulant state. It has been theorized that acute renal insufficiency associated with sepsis is the result of each of these pathological processes.

The vasoparesis seen in sepsis results in a profound state of hypotension, which activates the neurohumoral axis. In an effort to maintain systemic arterial circulation, the sympathetic nervous system and the renin–angiotensin–aldosterone axis respond by increasing cardiac output and by direct renal arteriolar vasoconstriction. Furthermore, the systemic inflammatory response results in the release of additional vasoconstricting cytokines (i.e., TNF, endothelin), locally secreted vasodilators (endothelial and inducible nitric oxide) to counterbalance these sepsis-associated vasoconstrictors.[50,54] Ultimately, this compensatory response comes at the cost of renal perfusion by further exaggerating the prerenal state.

Finally, as mentioned previously, sepsis induces a procoagulant state by affecting the expression of complement and the fibrinolytic cascade.[55–57] This alteration in the homeostasis of coagulation may result in a state of disseminated intravascular coagulation (DIC) with direct injury to the kidney by glomeruli microthrombi.[58] The net result is a lack of perfusion to the kidneys during sepsis that will ultimately culminate in ischemic acute tubular necrosis.

Table 31.3 Renal Failure Dysfunction and Sepsis

	Sepsis	Severe Sepsis[a]	Septic Shock[b]
Acute renal dysfunction	19%	23%	51%

[a]Sepsis associated with lactic acidosis or altered mental status.
[b]Sepsis associated with hypotension.

TOXINS

Antibiotics

Given the immunocompromise associated with massive burn injuries, burn patients tend to accrue significant exposure to systemic antibiotics over the course of their care. Unfortunately, many of the systemic antimicrobial agents most commonly used in burn patients carry significant risk of nephrotoxicity.

With meticillin-resistant *Staphylococcus aureus* (MRSA) now endemic in most hospital systems, vancomycin has become a standard first-line agent for empiric coverage of nosocomial infections in ICUs, including burn units. Given the well-documented nephrotoxic potential of vancomycin, alternative options should always be considered in patients already showing signs of early AKI, especially when cultures or Gram stains indicate a source of infection other than MRSA.

When vancomycin is clearly indicated, there are measures one can take to minimize the risk of nephrotoxity. Multiple studies have indicated that longer duration of therapy and higher serum concentration troughs are associated with increased risks of vancomycin-associated renal injury.[59,60] As concomitant aminoglycoside therapy has also been shown to significantly increase the chance of renal insult, these agents are best avoided when using vancomycin as a component of combination antimicrobial therapy. Some have advocated treatment with continuous infusion of vancomycin rather than intermittent boluses to avoid renal injury. In aggregate, though, the literature supporting this approach is fairly underwhelming. Meta-analysis by Hanrahan et al. identified a trend toward decreased rates of AKI in patients treated with vancomycin via continuous infusion versus intermittent bolus administration, but this did not reach statistical significance.

The incidence of multiresistant organisms is and will continue to be an ongoing challenge. This had led to the use of antimicrobial agents that carry a significant risk of nephrotoxicity. The use of these potentially nephrotoxic antimicrobial agents must be weighed on a risk–benefit scale due to the potential morbidity associated with inducing AKI. Antimicrobial therapy should be based on culture data, with the goal of down escalating therapy to the fewest

necessary antimicrobials and safest complication profile (i.e., the least nephrotoxic).

Diagnosis

Technically, using the consensus definitions discussed earlier, diagnosing AKI requires no more than measuring serum creatinine, eGFR, and/or urine output and identifying injury when any of these measures meet criteria set by the chosen definition (i.e., AKIN, RIFLE, or KDIGO). However, additional investigation is often warranted in order to delineate the nature and etiology of each individual case of AKI to allow for more informed treatment. Furthermore, a vigorous research effort is ongoing to identify novel biomarkers which might serve as a means to identify impending AKI earlier in the process.

URINE VOLUME

Urine represents by far the simplest and most intuitive monitor of renal function. Urine volume is a specific but, unfortunately, not very sensitive test for renal failure.[61] Most clinicians regard the presence of "adequate" urine output of little diagnostic value in the evaluation of renal dysfunction since severe renal injury may exist with any volume of urinary output. Urine output is not determined by the GFR alone but by the difference between GFR and tubular reabsorption. As such, AKI-associated tubular dysfunction can offset the decline in GFR, resulting in preserved urine output volume.

However anuria—a urine output of less than 50 mL/day or complete cessation of GFR—is a clinically significant finding.[9] By far, the most common cause is a severe prerenal condition. Although it is true that other conditions (acute cortical necrosis, bilateral arterial occlusion, and rapidly progressive acute glomerulonephritis) may cause anuria, their incidence is exceedingly low in the acute burn care setting, and the diagnosis is usually readily apparent due to additional clinical signs.

While a return of urine output in the oliguric or anuric patient may offer encouragement, it does not necessarily indicate reversal of the inciting renal injury. Of particular concern, one must be careful to watch for a conversion of anuric or oliguric renal failure to polyuric renal failure. Failure to appreciate a polyuric renal failure and replace inappropriate fluid losses could result in a second prerenal insult, increasing the risk of permanent damage.

URINALYSIS

Creatinine Clearance

Creatinine clearance is an inexpensive, consistent, time-tested technique for providing a rough estimate of GFR and renal function. Creatinine clearance measurement does involve the inconvenience of sustained urine collection, traditionally over a 24-hour period. However, this can be markedly simplified by forgoing the 24-hour convention for a more practical short-term (e.g., 6 hours or even 2 hours) collection, which has been shown to be just as accurate as the 24-hour assay and provides a more responsive measure of real-time function.

A significant disadvantage of creatinine clearance is that it becomes less accurate as GFR drops. This is due to the fact that renal tubules secrete a small amount of creatinine into the urine (in addition to that which is filtered). Normally, renal tubular secretion is so minor that it does not significantly impact the creatinine clearance calculations at normal GFRs, but can create significant distortion as the real GFR drops. The impact of these variations in tubular creatinine secretion can be largely overcome by administering cimetidine, which inhibits tubular creatinine secretion, an hour before urine collection.[62,63]

FeNa

The primary goal of evaluating urinary electrolytes in a thermally injured individual is to differentiate between the prerenal and renal forms of AKI. It has been well established that a prerenal state in the presence of a functional nephron is associated with enhanced absorption of sodium or a low fractional excretion of sodium. The fractional excretion of sodium (FeNa) is defined as:

$$\text{FeNa} = [(\text{urine sodium} \times \text{plasma creatinine}) / (\text{plasma sodium} \times \text{urinary creatinine})]$$

with a value less than 1% associated with a prerenal condition and a value greater than 1% associated with organ dysfunction (i.e., "renal" renal failure).[62] There are several conditions which affect renal absorption of sodium and thus have been shown to affect the calculated value (Table 31.4).

Fractional excretion of urea (<0.35) has shown marginally improved sensitivity and specificity over sodium in distinguishing between prerenal and renal forms of ARF.[64] Several additional indexes can be used to differentiate between the two forms of ARF (Table 31.5).

Microscopy

Microscopic examination of urinary sediment is an easy and inexpensive initial evaluation of AKI that often lends insight into the underlying renal pathology.[20,65] The combination of normal urinary sediment, hyaline casts, and oliguric/anuric urinary output would suggest a prerenal condition. The presence of epithelial casts and abundant tubular epithelial cells is pathognomonic for acute tubular necrosis. Similarly the identification of pigmented casts on

Table 31.4 Factors That Affect Fractional Secretion of Sodium

Condition	Effect on Fractional Sodium Excretion
Glycosuria	Increase
Diuretics	Increase
Mannitol	Increase
Dopamine	Increase
Myoglobinuria	Decrease
Radiocontrast media	Decrease

Table 31.5 Differential Diagnosis of Acute Renal Failure

Urinary Index	Pre-Renal	Renal
U_{osm} (mOsmol/L)	>500	<350
U_{Na} (mEq/L)	<20	>40
Specific gravity	1.020	1.010
U_{creat}/P_{creat}	>40	<20
Fractional excretion of sodium	<1	>2
Fractional excretion of urea	<35	>50

Table 31.6 Factors Affecting Serum Creatinine

Factors	Effect on Serum Creatinine
Liver insufficiency	Decreased production
Decreased muscle mass:	
deconditioning	Decreased production
aging	Decreased production
Trauma	Increased production
Fever	Increased production
Immobilization	Increased production

microscopic evaluation signifies the diagnosis of myoglobinuria, likely secondary to rhabdomyolysis.

SERUM BIOMARKERS

Creatinine

For generations, creatinine has served as the most widely used marker of renal function. There is no question that creatinine levels correlate to renal function, and acute elevations of creatinine are clearly associated with an increased risk of renal failure and additional mortality. Indeed, serum creatinine levels (and changes therein) are central components to all of the three consensus AKI definition and staging systems proposed in the past 15 years.

Despite these advantages, serum creatinine levels cannot be counted on for accurate real-time assessment of renal function. Creatinine rises slowly in response to an acute drop in GFR, with a lag time of hours to days seen between the actual drop in GFR and the increase in serum creatinine levels. As serum creatinine levels reflect a balance between the rate of production and excretion of this endogenous protein, it takes time for serum creatinine levels to reach a new equilibrium when one side of this equation (excretion) changes (see Table 31.6). Therefore, even once the serum creatinine has begun to rise, it is typically hours to days before it reaches a new steady state. This makes it difficult to identify real-time changes in renal function and impossible to recognize the real-time stabilization or resolution of renal injuries.

NGAL

Neutrophil gelatinase-associated lipocalin (NGAL) is a polypeptide released by damaged nephron tubular cells in the setting of local inflammation.[64] In multiple settings, NGAL has been shown to be identifiable in the serum and urine within 1–4 hours of ischemic renal insult and highly predictive of AKI. Multiple groups have found NGAL elevations earlier in a patient's course to be predictive of subsequent AKI. Sen et al. and Yang et al. demonstrated that elevations in whole-blood levels of NGAL occurred as early as 4 hours postburn. Furthermore, on multivariate analysis, NGAL levels identified a risk for subsequent AKI well before urine output rates or changes in serum creatinine.[66]

Others

Various investigators have identified additional novel early markers in burn patients. Serum uric acid levels, interleukin-18, and a novel protein named "kidney injury molecule-1" have all been found to predict AKI shortly after injury in isolated single-institution studies.[67,68]

Treatment

The key to the treatment of AKI is prompt diagnosis coupled with a rapid reversal of the underlying pathophysiology while avoiding iatrogenic injury. Early in the course of acute burn care, the emphasis is on treating the underlying burn shock and minimizing the exposure to secondary injury from nephrotoxic injury products. Later in the course of acute care, the focus is on monitoring for the emergence of new signs of renal injury and eliminating or treating the underlying cause—typically infection or chemotherapeutic nephrotoxicity. In either context, the most effective approach is one that detects the presence (or imminence) of renal injury as early as possible such that the underlying insult can be minimized or reversed as soon as possible.

Any injury that progresses to fulminant renal failure despite initial therapeutic maneuvers requires RRT. This section will address treatment and prevention of burn-associated renal injuries.

RENAL PROTECTION IN THE EARLY PHASE OF ACUTE BURN CARE

Resuscitation

As stated previously, the vast majority of cases of AKI presenting within 24 hours of injury results from inadequate renal perfusion.[7,69] Several authors have demonstrated that the timing of initiation of resuscitative fluids is directly related to the incidence of renal dysfunction. Resuscitative efforts should therefore begin immediately to reestablish effective renal perfusion. Several resuscitative formulas have been established based on multivariate logistic regression analysis (Table 31.7). Which formula to use is far less important than the flexibility and care with which they are applied. The clinician must recognize that these formulas are estimates to be used as starting points. The true amount is directly dependent on the patient's own physiologic status

Table 31.7 Burn Formulas for Estimating Initial Resuscitation

	Crystalloid	Colloid
Colloid:		
Evans	NS 1 mL/kg/%burn	1 mL/kg/%burn
Crystalloid:		
Parkland	4 mL/kg/%burn	
Modified Brooke	2 mL/kg/%burn	
Pediatric formulas:

Children	TBSA	
Galveston Shriners Institute for Burn	5000 mL/m^2 BSA + 2000 mL/m^2	
Children	TBSA	

TBSA, Total body surface area; *BSA*, burn surface area.

and degree of injury, neither of which can be fully captured by a single formula.

Burns of greater than 20% TBSA generally require intravenous resuscitative efforts, and the initial volume of fluids should be proportional to the area of burn injury. Kim et al. showed that burn size is an independent predictor of ARF in the burn population.[70] The timeliness of resuscitation is particularly critical because the duration of ischemic time is critically important to the development of AKI. Nguyen et al. found initial management of the thermally injured individual to be critically important to overall survival.[71] Early aggressive hydration had a protective effect against ARF. Similarly, the Shriners Burn Institute for Children, Galveston, observed that the time to initiation of resuscitative fluids was directly related to the incidence of renal dysfunction and overall mortality. They concluded that early, aggressive fluid resuscitation lessens kidney damage and thus prevents renal dysfunction, which improves overall outcome.[72]

The clinician must continuously monitor parameters of regional and global perfusion in order to guide fluid therapy and prevent overresuscitation. If the ability to assess true volume status (preload) or effective renal perfusion is difficult, one should initiate monitoring of central pressures or global volume-related variables (i.e., global end diastolic volume, extravascular lung water volume, intrathoracic blood volume).[73] The best means to measure the degree of resuscitation is unknown; however, if adequate volume loading does not produce sufficient mean arterial pressure (60–65 mm Hg), the use of vasopressors is indicated. While there has been some recent interest in the strategy of titrating to a higher mean arterial pressure as a possible means of protecting renal function in shock, a multiinstitutional randomized clinical trial comparing resuscitation strategies using high (80–85 mm Hg) versus standard (65–70 mm Hg) goals for mean arterial pressure found no improvement in renal outcomes in those patients in the high-target group.[74] The one exception to this finding was the subgroup of patients with premorbid hypertension who did indeed benefit from the use of higher mean arterial pressure (MAP) endpoints.

As critical as volume repletion is to effective resuscitation, it does not follow that more is always better. Rather, what is required is the continuous application of enough fluid to maintain perfusion and avoid ischemic insult. Administering fluids in excess of those immediately required at any point in time provides no additional benefit and certainly does not help in reversing any prior renal insult.

It must be emphasized that the exact amount of fluid required for any particular burn is not a constant, predetermined value but an ongoing function of the injured patient's dynamic physiology. Several studies of AKI incidence in large burn series found that patients with and without AKI showed no significant difference in the total fluid volumes received in the first 24–48 hours. In contrast, multiple studies have identified longer time to resuscitation as a clear risk factor for early AKI in burn patients. Likewise markers of hypoperfusion (e.g., serum lactate levels, base deficits, and SOFA scores) consistently have been shown as significant associations with renal injury and failure.[7,21,69,75–77] The key to renal protective resuscitation is not so much in providing adequate fluid over the period of resuscitation as it is a matter of minimizing the amount of time the patient spends in a state of hypoperfusion and, thus, minimizing the cumulative ischemic injury.

The primary goal is to reestablish effective renal perfusion through a well thought out resuscitation plan based on demonstrated resuscitation formulas and modified by variables correlated with the degree of resuscitation.

Other Acute Issues

Heart. Although establishing an effective circulating volume is of prime importance, an astute clinician should also carefully assess myocardial contractility to exclude myocardial dysfunction as a contributing factor to ineffective renal perfusion (see preceding discussion).

Remove Nephrotoxins. In addition to the effects of shock and dehydration, a burn injury can result in a renal injury indirectly via secondary rhabdomyolysis. Burn patients can develop rhabdomyolysis via a variety of mechanisms. Most commonly, restrictive eschars from circumferential burns can combine with the burn-associated edema to create a tourniquet effect on the extremities, resulting in ischemic muscle injury. Muscle can also be injured by direct thermal injury in fourth-degree burns or via mechanical trauma in the setting of coincident nonthermal trauma. Unfortunately any significant burden of muscle necrosis results in marked swelling and (if untreated) a spiral of compartment syndrome and additional rhabdomyolysis.

Rhabdomyolysis clearly increases the risk for AKI in burn patients because free myoglobin is quite nephrotoxic in sustained exposures. Fortunately, this is reversible if the pathological source is identified early and appropriate treatment is initiated.[76,78] In the setting of rhabdomyolysis, intensive hydration with isotonic crystalloids is recommended. While alkaline-diuresis with sodium bicarbonate solution and mannitol was long held as the standard therapy for this condition, the theoretic advantages of this therapy failed to translate into any improved outcomes when studied in a clinical setting.[33] Of first priority, though, is arresting the

underlying process by halting progressive ischemia with aggressive escharotomy and fasciotomy and resecting any necrotic muscle to remove the source of myoglobin poisoning.

Late

Workup. An AKI presenting late in the burn patient's course can owe to any combination of a myriad of pathologies. Any indication of new-onset renal injury late in the burn victim's course should prompt a rapid and comprehensive screen for typical sources of renal injury—hypovolemia, cardiac dysfunction, nephrotoxins, obstruction, and the like. Naturally, any such pathology should be addressed immediately if encountered. However, because infection and sepsis are by far the most common etiology of renal failure in a burn patient's course, an intensive search for occult infection should be undertaken immediately upon recognizing a new renal insult regardless of any other identified contributors.

Sepsis Treatment. The most effective therapy is prevention or early recognition of the septic state (Box 31.1). Every thermally injured patient should be continuously monitored for early markers of sepsis (feeding intolerance, increasing insulin resistance, elevation of acute-phase reactants) so that early therapy may be initiated.

Box 31.1 Definition of Sepsis in Burns

At least three of the following:

I. Temperature >39°C or <36.5°C
II. Progressive tachycardia
  A. Adults >110 bpm
  B. Children >2 SD above age-specific norms (85% age-adjusted max heart rate)
III. Progressive tachypnea
  A. Adults >25 bpm not ventilated
    i. Minute ventilation >12 L/min ventilated
  B. Children >2 SD above age-specific norms (85% age-adjusted max resp. rate)
IV. Thrombocytopenia (will not apply until 3 days after initial resuscitation)
  A. Adults <100 000/μL
  B. Children <2 SD below age-specific norms
V. Hyperglycemia (in the absence of pre-existing diabetes mellitus)
  A. Untreated plasma glucose >200 mg/dL or equivalent mM/L
  B. Insulin resistance—examples include
    i. >7 units of insulin per hour intravenous drip (adults)
    ii. Significant resistance to insulin (>25% increase in insulin requirements over 24 h)
VI. Inability to continue enteral feedings >24 h
  A. Abdominal distension
  B. Enteral feeding intolerance (residual >150 mL/h in children or two times feeding rate in adults)
  C. Uncontrollable diarrhea (>2500 mL/d for adults or > mL/d in children)

In addition, it is *required* that a documented infection is identified via:

A. Culture-positive infection, or
B. Pathologic tissue source identified, or
C. Clinical response to antimicrobials

Once a clinically significant infectious organism is identified, early goal-directed therapy should be initiated. Rivers et al. demonstrated a significant reduction in mortality if an early goal-directed algorithm is applied to the septic patient.[79] The principle is simple: establish early source control while providing effective antibiotic therapy and maximizing global, and therefore renal, perfusion. While larger, more recent studies have raised questions about the specific monitoring techniques and intervention thresholds used in the Rivers trial, the basic principle of early diagnosis and treatment remains invaluable.[80]

Rapid identification and correction of underlying sepsis are critical to the preservation of renal function because no renal protective pharmacological agent has been demonstrated to prevent or limit renal dysfunction. The importance of infectious surveillance in the thermally injured patient cannot be overstated. The goal is to effectively treat local infections and prevent systemic dissemination to avoid the morbidity and mortality of septic shock.

Medical Therapy: Fenoldopam. Naturally, there has long been much interest in identifying a pharmacologic agent capable of protecting the kidney from injury in high-risk settings. For many years, intensivists regularly employed low-dose (aka "renal-dose") dopamine infusions with hopes of preserving renal function. In theory, the receptor activation profile of dopamine in these dose ranges should result in selective augmentation of renal perfusion pressure. Unfortunately multiple clinical trials consistently failed to identify any improvement in renal outcomes associated with renal-dose dopamine treatment.

More recently, interest has emerged in the possibility that fenoldopam, another selective adrenergic agonist, might provide more consistent, targeted support of renal perfusion. Fenoldopam is a pure $\alpha 1$ agonist that decreases renal vascular resistance in an NO_2-independent manner. This offers a distinct advantage in the setting of postischemic AKI, where nitric synthase activity is typically saturated early in the course of injury. As of yet, the role of fenoldopam remains unclear. The largest randomized controlled trial of fenoldopam infusion for renal protection (to date) was performed in the context of cardiac surgery and failed to show any reduction in renal outcomes. However the current literature documenting the use of fenoldopam in burn patients is limited to a single retrospective study that did indicate a renal-protective effect in burn patients at high risk for AKI. [81,82]

Renal Replacement Therapy

Fortunately, due to major advances in burn care resuscitation and the treatment of sepsis, renal failure requiring RRT is unusual in the burn setting.[83] The reported incidence is approximately 1–3%. Unfortunately, though, the overall mortality associated with renal failure requiring RRT approaches 80%.[8,10]

Burn patients with preexisting renal insufficiency are at particular risk for RRT due to the large positive fluid balances associated with the initial resuscitation therapy, enhanced catabolism leading to elevated urea levels, and the need for substantial nutritional support to maintain a positive nitrogen balance.[83]

Modalities. Peritoneal dialysis has a long history of successful use in both acute and chronic settings.[84] However, in burn patients, this form of therapy is limited by clearance rates and the need for catheter insertion through the abdominal wall: a common donor site or burned area.

Over the past two decades a number of RRT modes have been studied in general ICU patients: intermittent hemodialysis (IHD), continuous renal replacement therapy (CRRT), and sustained low-efficiency dialysis (SLED). No consensus exists as to which mode is superior because each has advantages and disadvantages depending on the clinical scenario (Table 31.8).[83,85] It has been suggested that CRRT is best suited for those patients demonstrating severe hemodynamic instability, persistent ongoing metabolic acidosis, and large fluid removal requirements. Preliminary reports using CRRT in the thermally injured population have demonstrated improved survival.[86,87] These studies are limited to single-institutional data.

The optimal time to initiate RRT in the thermally-injured patient with AKI has not been determined. Traditional thresholds (i.e., absolute indications used to initiate dialysis in the setting of chronic renal failure) are less relevant in the thermally injured patient. Burn injury predisposes to organ failure, catabolism causes increased urea generation, large open wounds result in electrolyte shifts, and nephrotoxic agents are often required as treatment. For intensive care populations at large, the standard of care is to initiate CRRT only upon evidence of extreme metabolic derangements or other life-threatening events.[88] However, there continues to be interest in the potential benefit of initiating RRT earlier in the course of AKI, with ongoing clinical studies indicating potential advantages of early RRT.[89,90] A recent randomized multicenter trial by Gaudry et al. challenged this hypothesis by suggesting early RRT has no survival advantages over delayed RRT.[91] In addition, they found potential benefits to delayed RRT if close monitoring of the patient is performed in the ICU setting. Emerging trials continue to offer evidence on both sides of the argument—a controversy which will likely be with us for years to come.[92,93]

Although very early initiation of RRT in ICU patients has not clearly been demonstrated to improve outcome, preliminary evidence exists to suggest a more aggressive approach to RRT initiation in the thermally injured patient.[86,87] As

Table 31.8 Advantages and Disadvantages of Intermittent Hemodialysis (IHD) and Continuous Renal Replacement Therapy (CRRT)

Intermittent Hemodialysis	**Continuous Renal Replacement Therapy**
I. Advantages	**Disadvantages**
Rapid clearance of acidosis, uremia, potassium, and certain toxins	Slow
Patient mobility	Immobility
Can perform without anticoagulation	More frequent need for anticoagulation
Reduced exposure to artificial membrane	Continuous exposure to artificial membrane
Reduced incidence of hypothermia	Hypothermia
Masks fever temporarily	Masks fever continuously
Less blood loss from monitoring and/or filter clotting	Greater potential blood loss from monitoring and/or filter clotting
Lower costs in most centers	Higher costs in most centers
Less risk of dialysate compounding errors	Greater risks of replacement fluid and/or dialysate compounding errors
[a]Less removal of amino acids, endogenous hormones, and cofactors	[b]Increased removal of amino acids, endogenous hormones, and cofactors
II. Disadvantages	**Advantages**
Rapid solute and fluid shifts	Gradual solute and fluid shifts
–hemodynamic instability	–greater hemodynamic stability
–disequilibrium syndrome	–no or little risk of disequilibrium syndrome
–worsens brain edema	–no worsening of brain edema
Frequent need for fluid or nutritional restrictions	Less need tor fluid or nutritional restrictions
Only allows for intermittent adjustment of prescription; less control of uremia, acidosis, phosphate, and fluid balance	Allows for continuous titration and integration of renal support with other ICU care and treatment goals
In many centers, requires a dialysis nurse and other resources that may limit ability to provide extended run-times and/or daily therapy in selected patients	Procedure performed by ICU nursing staff, overall better clearance of uremia, correction of acidosis, and removal of excess fluid

[a]Even with high flux membranes, removes fewer 'middle' molecules.
[b]When configured to use convection as its primary mechanism of solute clearance, removes more "middle molecules."
From Brochard L, Abroug F, Brenner M, et al. on behalf of the ATS/ERS/ESICM/SCCM/SRLF Ad Hoc Committee on Acute Renal Failure. An official ATS/ERS/ESICM/SCCM/SRLF statement: prevention and management of ARF in the ICU patient: an international consensus conference in intensive care medicine. *Am J Respir Crit Care Med*. 2010;181(10):1128–1155.

such, we favor early initiation of RRT in severe burn-associated AKI. However larger studies are clearly needed to clarify the value of this approach in the burn population.

A theoretical benefit of continuous hemofiltration is the removal of proinflammatory mediators, which may be associated with the development of multiple organ failure. The experimental and clinical data suggest that the rate of hemofiltration and the biologic nature of the filters affect the overall results.[20] Currently there are insufficient data to recommend continuous hemofiltration solely on the basis of removal of inflammatory mediators. Future randomized prospective studies may resolve this theoretical benefit.

Conclusion

Acute renal dysfunction is a critical complication of an acute thermal injury and is associated with significant morbidity and mortality. Prior to 1965, there were no reported survivors following a major thermal injury who unfortunately developed ARF. While significant advances have been made in both the treatment of major thermal injures and renal failure over the past 50 years, the combined clinical scenario still represents a significant therapeutic challenge in modern burn therapy. Collectively we have made advances in establishing a common definition of renal failure and its stages, but work must continue to identify early biomarkers of renal injury so that therapeutic interventions can be made in a more timely manner.

An astute burn surgeon or intensivist must understand that the normal renal physiology is under constant threat following a thermal injury. To avoid renal dysfunction, a physician must maintain adequate effective renal perfusion while minimizing nephrotoxic agents.

32 Critical Care in the Severely Burned: Organ Support and Management of Complications

DEREK M. CULNAN, WILLIAM C SHERMAN, KEVIN K. CHUNG, and STEVEN E. WOLF

Videos available at www.expertconsult.inkling.com

Introduction

Approximately 4000 burn victims die each year from complications related to thermal injury.[1,2] Burn deaths generally occur in a bimodal distribution, either immediately after the injury or weeks later due to multisystem organ failure (MOF), a pattern covered in Chapter 30. Recent reports reveal a 50% decline in burn-related deaths and hospital admissions in the United States over the previous 20 years.[2] In 1949, Bull and Fisher reported 50% mortality rates for children aged 0–14 years with burns of 49% of total body surface area (TBSA), 46% TBSA for patients aged 15–44, 27% TBSA for those aged between 45 and 64, and 10% TBSA for those 65 and older.[3] These dismal statistics have improved, with the latest studies reporting a 50% mortality for greater than 95% TBSA burns in children 14 years and under, 75% TBSA burns in adults, and around 30% TBSA in the elderly.[4] Therefore, a healthy young patient with almost any size burn should be expected to live, and the prospects for the older demographic are improving with modern wound treatment and critical care techniques.

Burned patients generally die from one of two causes: early deaths resulting from "burn shock" and immolation, or MOF leading to late deaths. With the advent of vigorous fluid resuscitation protocols in the severely burned, irreversible burn shock has been replaced by sepsis and the ensuing MOF as the leading cause of death associated with burns in those who do not die at the scene by a margin of 2 to 1.[4] Those with a risk of mortality who do not die precipitously will be treated by what is termed *critical care*, a service performed in specialized units containing the equipment, supplies, and personnel to institute intensive monitoring and life-sustaining organ support to promote recovery.

Critical illness in burned patients is most commonly beset by sepsis. In a pediatric burn population with massive burns of greater than 80% TBSA, 17.5% of the children developed sepsis, defined as bacteremia with clinical signs of infection.[5] Mortality in the whole group was 33%, most of whom succumbed to MOF. Some were bacteremic and "septic," but the majority were not. These findings highlight the observation that the development of severe critical illness and MOF often associate with infection, but they are by no means required to develop this syndrome. What is requisite is an inflammatory focus, which is the massive skin injury in severe burns requiring inflammation to heal.

It is postulated that the progression of patients to MOF exists in a continuum with the systemic inflammatory response syndrome (SIRS).[6] Nearly all burn patients meet the criteria for SIRS as defined by the consensus conference of the American College of Chest Physicians and the Society of Critical Care Medicine.[7] It is therefore not surprising that severe critical illness and MOF are common in burned patients.

Patients who develop dysfunction of various organs, such as the cardiopulmonary system, renal system, and gastrointestinal system, can be supported to maintain homeostasis until the organs repair themselves or a chronic support system can be established. Critical care may be loosely defined as the process of high-frequency physiologic monitoring coupled with short response times for pharmacologic and procedural interventions. Entire textbooks and many of the preceding chapters in this book are dedicated to critical care. This chapter will focus on synthesizing a critical care system for burn injury, including the organization of specialized burn intensive care units (BICUs) and organ-specific management.

Burn Intensive Care Unit Organization

PHYSICAL PLANT

Optimally, a BICU should exist within a designated burn center, ideally verified by the American Burn Association (ABA), and in conjunction with a recognized trauma center, thus providing the capability to treat both thermal and nonthermal injuries. This unit, however, need not be physically located in the same space as that designated for nonburned trauma patients. In fact, the requirement for the care of wounds in burned patients necessitates additional equipment, such as shower tables and overhead warmers, so a separate space dedicated to the severely burned should be standard. This space may be located in a separate hospital with established guidelines for transfer or a specialized unit.[8]

The optimal number of beds in the unit should be calculated by the incidence of moderate to severe burns in the referral area, which in the United States is approximately 20 per 100,000 people per year. The Committee on Trauma of the American College of Surgeons and the ABA recommend that 100 or more patients should be admitted to this facility yearly, with an average daily census of three or more patients to maintain sufficient experience and acceptable access to specialized care.[8]

Box 32.1 Assigned Burn Unit Personnel

- Experienced burn surgeons (burn unit director and qualified surgeons)
- Dedicated nursing personnel
- Physical and occupational therapists
- Social workers
- Dietitians
- Pharmacists
- Respiratory therapists
- Phychiatrists and clinical psychologists
- Prosthetists

Box 32.2 Consultants for the Burn ICU

- General surgery
- Plastic surgery
- Anesthesiology
- Cardiothoracic surgery
- Neurosurgery
- Obstetrics/gynecology
- Ophthalmology
- Orthopedic surgery
- Otolaryngology
- Urology
- Radiology
- Pediatrics
- Psychiatry
- Cardiology
- Gastroenterology
- Hematology
- Pulmonology
- Nephrology
- Neurology
- Pathology
- Infectious disease

Box 32.3 Equipment for a Fully Equipped Burn ICU

Standard

- Monitors (heart rate, electrocardiography, blood pressure, cardiac output, oxygen saturation, temperature)
- Scales
- Ventilators
- Advanced cardiac life support (ACLS) cardiac cart
- Laboratory support (blood gas analysis, hematology, chemistry, microbiology)

Specialty

- Fiberoptic bronchoscopes
- Fiberoptic gastroscopes/colonoscopes
- Dialysis equipment (peritoneal dialysis and hemodialysis)
- Portable plain radiography
- Computed tomography/fluoroscopy/angiography
- Indirect calorimeters

Most moderate to severe burns with hospital admission will require intensive monitoring for at least the day of admission during the resuscitative phase. Thereafter approximately 20% will undergo prolonged cardiopulmonary monitoring for inhalation injury, burn shock, cardiopulmonary compromise, renal dysfunction, and the development of SIRS and MOF. In these severely burned patients, the average length of stay in the BICU is approximately 1 day per % TBSA burned. Using an average of 25 days admission for a severely burned patient (20% of the burns, 4/100,000 per capita) and 2 days for those not so severely injured (80%, 16/100,000 per capita), this suggests 132 BICU inpatient days per 100,000 persons in the catchment area. Thus a 10-bed BICU should serve a population of 3,000,000 sufficiently when considered independently. Space provided should be at least 3,000 sq ft, including patient beds and support space for nursing/charting areas, office space, wound care areas, and storage.[8]

Multiply-resistant bacteria and fungi are commonly encountered in the BICU owing to the presence of open wounds. To prevent transmission of these organisms to other patients, isolation of burned patients from all other patients is recommended and should be considered when designing units for this purpose. Single rooms with negative-pressure ventilation are advisable. In addition, strict guidelines for contact precautions in wound care and interventions, and hand-washing are standard.

PERSONNEL

A BICU functions best by using a team approach among surgeons/intensivists, nurses, laboratory support staff, respiratory therapists, occupational and physical therapists, mental health professionals, prosthetists, dietitians, and pharmacists (Box 32.1). The unit should have a designated medical director, ideally a burn surgeon, to coordinate and supervise personnel, quality management, and resource utilization. The medical director will usually work with other qualified surgical staff to provide sufficient care for the patients. It is recommended that medical directors and each of their associates be well versed in critical care techniques and that each physician care for at least 50 patients per year to maintain skills.[8] In teaching hospitals, three to four residents or other qualified medical providers should be assigned to the 10-bed unit described. A coverage schedule should be devised to provide 24-hour prompt responses to problems.

Nursing personnel should consist of a nurse manager with at least 2 years of intensive care and acute burn care experience and 6 months of management responsibilities. The rest of the nursing staff in the BICU should have documented competencies specific to the care of burned patients, including critical care and wound care.[8] Owing to the high intensity of burn intensive care, at least five full-time equivalent nursing providers are required per BICU bed to provide sufficient 24-hour care. Additional personnel are required for respiratory care, occupational and physical therapy, and other support. A dedicated respiratory therapist for the burn unit at all times is optimal.

Owing to the nature of critical illness in burned patients, complications may arise that are best treated by specialists not generally in the field of burn care (Box 32.2). As such, these specialists should be available for consultation when the need arises. Given the regularity with which burn surgeons encounter subspecialty problems, such as corneal injuries, routine injuries are often managed directly by the burn surgeon without additional consultation.

EQUIPMENT

The equipment needs of the BICU include those items common to all ICUs, but some of which are specialized (Box 32.3). Each BICU bed must be equipped with monitors to

measure heart rate, continuous electrocardiography, noninvasive blood pressure, invasive arterial and venous blood pressures, end tidal carbon dioxide monitoring, and right heart cardiac output using dilution techniques or data derived from arterial pressure tracings. Arterial blood oxygen saturation measurement is also required, but continuous mixed venous saturation monitoring or the technical equivalent is optional. Equipment to measure weight and body temperature should be standard. Oxygen availability with at least two vacuum pumps must be present for each bed.

Ventilator equipment must also be available for all beds. The availability of a number of types of ventilator is optimal, including conventional ventilators with the capability to deliver both volume-targeted and pressure-targeted modes, as well as high-frequency ventilators that are oscillatory and/or percussive in design. An emergency cardiac cart containing advanced cardiac life support (ACLS) medications and a battery-powered electrocardiograph/defibrillator must be present in the unit. Infusion pumps to deliver continuous medications and intravenous/intraarterial fluids must also be readily available. A laboratory providing blood gas analysis, hematology, and blood chemistry should be located on site. Point-of-care blood analysis for glucose, arterial blood gas, and basic chemistries is strongly advised.[9,10] Microbiologic support to complete frequent, routine bacterial and fungal cultures and sensitivities must also be present, as well as virology.

Available specialty equipment should include various sizes of fiberoptic bronchoscopes for the diagnosis and treatment of pulmonary disorders, as well as personnel competent with these techniques. Fiberoptic gastroscopes and colonoscopes for gastrointestinal complications are also necessary for diagnosis, bleeding control, decompression, and difficult feeding access. For renal support, equipment to provide intermittent and/or continuous renal replacement should be present. Portable radiographic equipment for standard chest/abdominal/extremity radiographs must be immediately available. Equipment for computed tomography (CT), fluoroscopy, and angiography should be available. Indirect calorimeters to measure metabolic rate are strongly advised. Overhead warmers and central heating with individualized ambient temperature controls must be available for each room as a specialized requirement.[8]

Hemodynamic Monitoring in the Burn Intensive Care Unit

Most burned patients follow an anticipated course of recovery, which is monitored in the BICU by measuring physiologic parameters. Experienced clinicians assess these physiologic measures in a repeated and sequential fashion to discern when potential interventions may be initiated to improve outcomes. Often no intervention will be necessary from the unit's standard care protocol as the patient is following the anticipated course. At other times this is not the case, and procedural or pharmacologic intervention is beneficial. Physiologic monitoring is then used further to determine the adequacy of the interventions. The following is a survey of monitoring techniques used in the BICU.

CARDIOVASCULAR MONITORING

Arterial Lines

Hemodynamic monitoring is directed at assessing the results of resuscitation and maintaining organ and tissue perfusion. Currently used measures are only estimates of tissue perfusion because the measurement of oxygen and nutrient transfer to cells cannot be made directly at the bedside. Instead global physiologic measures of central pressures still serve as the principal guides.

Measurement of arterial blood pressure is the mainstay for the assessment of tissue perfusion. In critical illness, this measurement can be made using cuff sphygmomanometers; however in practice this technique is not useful because the measurement is episodic and placement of these cuffs on burned extremities is problematic. Diastolic pressures can also be artificially elevated in the elderly and obese. Instead continuous monitoring for hemodynamic instability through the use of intraarterial catheters is generally preferable when the patient is in the BICU for a prolonged period. Lines are typically placed in either the radial or the femoral artery. The radial artery is the preferred site for critically ill patients because of safety, with the dual arterial supply to the hand as backup should a complication arise. However it has been shown that radial artery catheters are inaccurate in the measurement of central blood pressure when vasopressors are used[11] and are notoriously inaccurate in children because of greater vascular reactivity.[12] Furthermore femoral cannulation sites are often unburned due to the insulation provided by undergarments, and they do not preclude mobilization with physical therapy or rehabilitation goals.[13] For these reasons, we recommend femoral arterial blood pressure measurement in most burned patients.

For arterial catheters, systolic, diastolic, and mean arterial pressures (MAPs) should be displayed continuously on the monitor screen. Either systolic or MAP can be used to determine adequacy of pressure, although a MAP of greater than 70 mm Hg is considered a more accurate descriptor of normal tissue perfusion on the whole. Reasons for this include the finding that, as the arterial pressure wave traverses proximally to distal, the systolic pressure gradually increases and the diastolic pressure decreases; the MAP determined by integrating areas under the curve, however, remains constant. The adequacy of the waveform must also be determined, with a diminished waveform indicative of catheter damping, requiring catheter replacement. Care must be taken to ensure that the diminished waveform is not true hypotension, which can be determined using a manual or cycling sphygmomanometer. Exaggerated waveforms with elevated systolic pressure and additional peaks in the waveform (generally only two are found) may be a phenomenon known as "catheter whip," which is the result of excessive movement of the catheter within the artery. Typically this problem is self-limited, but care must be taken not to interpret normal systolic blood pressure values with evidence of catheter whipping as unexceptional because the effect generally overestimates pressures. Again, use of MAP as the principal guideline for the assessment of blood pressure is optimal, as effects of catheter whip or other problems with intraarterial monitoring are then diminished.

Complications associated with arterial catheters include distal ischemia associated with vasospasm and thromboembolism, catheter infection, and arterial damage/pseudoaneurysm during insertion and removal. Although these complications are uncommon, the results can be devastating. Physical evidence of ischemia in the distal hand or foot should prompt immediate removal of the catheter and elevation of the extremity. If improvement in ischemic symptoms is not seen promptly (within an hour), angiography and intervention must be considered. Should thromboembolism be found, the clot can be removed with operative embolectomy or clot lysis at the discretion of the treating physician. If, during angiography, extensive arterial damage is found with ischemia, operative repair may be indicated. Consideration for anticoagulation must be made while balancing the risk of hemorrhage from open wounds versus the benefit of tissue salvage.

Evidence of catheter infection hallmarked by purulence and surrounding erythema should instigate removal of the catheter, which often will suffice. With continued evidence of infection, antibiotics and incision and drainage of the site should be entertained. Great caution must be exercised to avoid arterial bleeding if an incision is made over the catheter site. If a pseudo-aneurysm is encountered after arterial catheterization and removal without signs of distal ischemia, injection of thrombin[14] or compression with a vascular ultrasound device until no further flow is seen in the pseudo-aneurysm will often alleviate the problem without operative intervention.[15]

Cardiac Output Measurement

Pulmonary artery catheters placed percutaneously through a central vein (internal jugular, subclavian, or femoral) and "floated" into the pulmonary artery through the right heart have been used extensively in hemodynamic monitoring in BICUs. By measuring the back pressure through the distal catheter tip "wedged" into an end-pulmonary branch, an estimate of left atrial pressure can be measured. In addition, dyes or isotonic solutions injected into a proximal port can be used to determine cardiac output from the right heart. These data are used to estimate preload delivery to the heart, cardiac contractility, and afterload against which the heart must pump, which then directs therapy at restoration of hemodynamics. These catheters are used in BICUs under conditions of unexplained shock, hypoxemia, renal failure, and monitoring of high-risk patients.

The use of pulmonary artery catheters, however, has come under scrutiny from reports indicating no benefit from their use. A study of 5735 critically ill adults in medical and surgical ICUs showed an increase in mortality and use of resources when pulmonary artery catheters were used. Most of these patients had medical conditions. The authors of this report suggested that their results should prompt a critical evaluation of the use of pulmonary artery catheters under all conditions.[16] This was followed by a clinical trial in the United Kingdom demonstrating no benefit from the use of pulmonary artery catheters in a general ICU setting.[17] A more recent evaluation of the usefulness of these devices has demonstrated that, with proper training and in the appropriate setting, they can provide data not available through other modalities.[18] Over the past years, the use of pulmonary artery catheters has significantly diminished except in special circumstances, such as unexpected response to treatment, as in volume replacement for oliguria. Even in this condition, new technology based on arterial waveform analysis gives an estimate of cardiac output and end-diastolic volume, which generally gives enough information to guide appropriate therapy.[19] However, in the appropriate patients, pulmonary artery catheters may still play a valuable role.

Arterial Waveform Analysis

Multiple devices have been developed over the past decade using arterial waveform analysis to continuously measure cardiac output as well as to estimate preload. Stroke volume variation provides a good estimate of the fluid responsiveness of shock with only arterial access.[20] The transpulmonary thermodilution technique provides an even more complete hemodynamic dataset without the use of a pulmonary artery catheter. Using only a central line and central arterial line, thermodilution allows monitoring of preload with global end-diastolic volume index, intrathoracic blood volume, continuous cardiac output, and extravascular lung water index. Numerous studies have shown that these volumetric indices represent preload more precisely than urine output or cardiac filling pressures.[21] In a study involving 54 burned children, Herndon et al. determined pulse index continuous cardiac output (PiCCO) to be the superior measurement for cardiac parameters to transthoracic echocardiography and an objective cardiovascular monitor to guide goal-directed fluid resuscitation.[22]

Echocardiography

Transesophageal echocardiography has been used for a number of years as an intraoperative monitor in high-risk cardiovascular patients. It has not been used extensively in other critically ill patients because of the lack of available expertise and paucity of equipment. Since this device can be used as a diagnostic tool for the evaluation of hemodynamic function, it stands to reason that it could be used to monitor critically ill, severely burned patients. A report documented the use of transesophageal Doppler measurements of cardiac output in a series of severely burned patients and showed that intravascular volume and cardiac contractility are significantly diminished the first day after burn in spite of high-volume resuscitation.[23]

Echocardiography has also been studied as a means to supplement urine output monitoring. Investigators in China examined whether esophageal Doppler monitoring of heart function might be an improvement by studying 21 patients with massive burns (79 ± 8% TBSA burned) who were resuscitated with a goal of 1.0 mL/kg per hour. They found that cardiac output was predictably low after injury and increased linearly with time by increases in preload and contractility and decreased afterload. However changes in cardiac output were most closely associated with increased cardiac contractility and decreased afterload rather than increases in preload. Additionally urine output was not closely associated with cardiac output.[24] Held et al. evaluated 11 adult burn patients with a mean TBSA of 37% and found that changes in volume status on echocardiography preceded changes in urine output and vital signs, and they were able to titrate inotropes and vasopressors in elderly patients.[25]

These results call into question the validity of urine output as the primary measure of the adequacy of resuscitation. A similar study by investigators in Sweden probing the role of cardiac function, as measured by echocardiography, and myocyte damage, as measured by troponin abundance in the serum, showed that half of their patients had myocardial damage during resuscitation universally associated with some temporary cardiac wall motion abnormality. However systolic function was not adversely affected.[26] Bedside echocardiographic equipment and skills are increasingly common in BICUs and are an increasingly common means of hemodynamic monitoring in critical care.[27] However the intermittent nature of this procedural assessment allows it to only serve as a useful adjunct to add clarity to a difficult clinical scenario and prevents echocardiography from supplanting continuous monitoring modalities, such as thermodilution or waveform analysis. We look forward to further work regarding the optimal method of assessment of resuscitation; for the present, however, urine output remains the standard, and other measures are useful adjuncts.

Laboratory Estimates of Perfusion

Mixed venous saturation is the gold standard for the measurement of total tissue perfusion but has fallen out of favor because it requires a pulmonary artery catheter.[28] As such, peripheral surrogates, such as base deficit and serum lactate, have become the standard values followed to monitor shock. These can be measured in minutes using point-of-care techniques and rapid guide interventions.

The base deficit is a value calculated using the Henderson-Hasselbalch equation based on the relationship between pH, pCO_2, and serum bicarbonate:

$$pH = 6.1 + \log(HCO_3^-)/(pCO_2)(0.03)$$

It is the stoichiometric equivalent of base required to return the pH to 7.40. Base deficit is routinely calculated on blood gas analysis and provides a reasonable estimate of the degree of tissue anoxia and shock at the whole-body level, particularly in hemorrhagic shock. A rising base deficit indicates increasing metabolic acidosis and may stratify risk of mortality in patients after major trauma.[29] The same can be said for the use of base deficit in resuscitation of burned patients.[30,31] These studies showed a correlation between higher base deficit and increased mortality, and some have suggested that this value is a better monitor of resuscitation than the time-honored monitors of urine output and arterial blood pressure.[32] Recent studies of burned patients showed the base deficit was higher in nonsurvivors during resuscitation, although the authors could not identify a specific boundary for the effect.[33,34] Despite its utility as an indicator of shock, base deficit remains a nonspecific indicator of metabolic acidosis and may be elevated with many confounding conditions other than shock, including hyperchloremia, uremia, and alcohol, cocaine, and methamphetamine use. Interpretation can be difficult under these circumstances.

Lactate is another common measure used to determine the adequacy of tissue perfusion. Under acute low-flow conditions, cells transition from primarily aerobic metabolism to anaerobic metabolism for energy production (i.e., adenosine triphosphate [ATP]). A by-product of anaerobic metabolism is lactic acid. Under ischemic conditions, plasma lactate concentration will increase, leading to a decrease in pH. Measurement of lactate is commonly performed to determine the adequacy of generalized perfusion; increases suggest ischemia. Investigators showed that lactate does increase, along with base deficit, in burned patients during resuscitation, and higher levels are associated with poorer outcomes.[34] Later in the course, however, lactate concentrations must be used with some caution because elevated levels do not necessarily indicate ischemia. Under hypermetabolic conditions common in the severely burned, pyruvate dehydrogenase activity is sufficiently inefficient that lactate levels might be elevated without ischemia. Isolated elevations of lactate should then be interpreted with caution and confirmation of ischemia or shock by physical or other laboratory findings sought.

Multisystem Organ Failure

MOF is largely a creation of our success in critical care enabling previously moribund patients to survive long enough for organ failure to develop. Often particular organ systems are allowed to fail to maintain overall patient survival (e.g., performing an excision and grafting procedure that leads to renal failure to remove a septic burn which would otherwise be lethal). The topic of MOF is more thoroughly covered in Chapter 30, but we will briefly summarize it here.

HUMORAL MEDIATORS

Humoral inflammatory factors elaborated from the burn wound and the resultant immune, adrenal, and sympathetic activation mediate the development of SIRS.

A number of theories have been developed to explain the progression to MOF (Box 32.4). In the infection theory, as organisms proliferate out of control, endotoxins and exotoxins are released that cause the initiation of a cascade of inflammatory mediators through activation of pathogen-activated molecular pathway (PAMP) receptors, such as Toll-like receptors 2, 4, and 9,[35] as well as the recruitment of inflammatory cells. These pathways can result in organ damage and progression toward MOF if unchecked.

MOF can also be initiated by inflammation from the presence of necrotic tissue, and open wounds can incite a similar inflammatory mediator response to that seen with endotoxins. Evidence suggests that this response is due to activation of the cytokine cascade through damage-associated molecular pathways (DAMPs), which might be

Box 32.4 Theories for the Development of Multiple Organ Failure

- Microcirculatory hypothesis
- Endothelial–leukocyte interactions
- Gut hypothesis
- Two-hit theory

antigens associated with liberated mitochondria from our own cells.[37] Four of these cytokines, tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), IL-6, and IL-8, are most strongly associated with sepsis and MOF in burns.[36] The primary support of this theory is that many patients, including those burned, can develop MOF without identified infection. Regardless, it is known that a cascade of systemic events is set in motion, either by invasive organisms or from open wounds, that initiates SIRS and may progress to MOF, thus supporting early burn excision and grafting.

Another theory implicates prolonged tissue hypoxia and the subsequent generation of toxic free radicals during reperfusion as the primary mediator of end-organ damage. As discussed in Chapter 8 on burn edema, this free radical damage can be ameliorated with high-dose intravenous vitamin C during resuscitation.[38] From in vitro models and in vivo animal models, we know tissues that were in shock initially and subsequently reperfused produce oxygen free radicals known to damage a number of cellular metabolism processes. It was found that free radical scavengers, such as superoxide dismutase, improve survival in animal models, but these results have not yet been established in humans.[42] Endogenous natural antioxidants, such as vitamins C and E, are low in burned patients, suggesting that therapeutic interventions may be beneficial.[43]

The final two theories revolve around the role of the gut in the generation of organ failure and the "two-hit" theory of MOF. For years, investigators have implicated the gut as the "engine" of organ failure, which is associated with loss of gut barrier function and translocation of enteric bacteria and/or their toxic metabolites. Bacterial translocation has been shown to occur after burn in patients.[45] No studies have clearly shown whether bacterial translocation is the cause of SIRS/MOF, probably because investigators have as yet been unable to control bacterial translocation effectively during shock in humans; thus, a cause-and-effect relationship cannot be established. The "two-hit" theory ascribes a summation of insults to the development of MOF. Each of the insults alone is inadequate to cause the response, but one or more can "prime" the inflammatory response system just described, such that another normally insignificant injury causes the release of toxic mediators ending in MOF.

It is likely that some part of all of these theories is a cause for MOF in burned patients; probably the relative contribution is unique in each patient. Therefore a single solution is unlikely, and this should be kept in mind when devising strategies to improve care and outcomes.

COURSE OF ORGAN FAILURE

Generally, MOF will begin in the renal and/or pulmonary systems and progress in a systematic fashion through the liver, gut, hematologic system, and central nervous system. The development of MOF does not inevitably lead to mortality, however. Efforts to support failed organs until they recover are justified.

Critical Care Interventions

Critical care of a burn patient in the modern era is predicated upon seven key factors:

- Sufficient goal-directed fluid resuscitation
- Early burn excision and grafting
- Aggressive antimicrobial and source control of sepsis
- Aggressive and sufficient nutritional support
- Active warming
- Aggressive physical, occupational, and respiratory therapy
- Aggressive and continuous support of organ failures

Sufficient fluid resuscitation of an acute burn wound is thoroughly covered in Chapter 9 on fluid resuscitation. Various formulas to predict fluid requirement, balances between crystalloid versus colloid, and resuscitation endpoints have been advocated. Early in resuscitation it is critical to provide sufficient volume to maintain preload and perfusion in the setting of fluid losses into burn edema and distributive shock while avoiding over-resuscitation, with the resultant costs such as heart failure, liver failure, and compartment syndromes.[46]

Early burn excision and grafting has been discussed thoroughly in Chapter 12 on operative management. The overriding principle is to remove inflammatory and diseased burned tissue to break the hyperinflammatory state underlying burn shock. Early grafting reduces the inflammatory load on the patient, fluid loss, heat loss, the area susceptible to infection, and the total length of critical care. Collectively it reduces the exposure time available for MOF to occur.

Furthermore, the blood loss associated with large-scale early excision often results in a functional plasma exchange.[47] Plasma exchange has been shown to be effective in reducing burn resuscitation, ostensibly by removing the inflammatory and oxidative humoral mediators underlying burn shock. Klein et al. reviewed 44 plasma exchanges in patients reaching twice Parkland with albumin or fresh frozen plasma and found a 40% reduction in fluid resuscitation.[48] In a plasma exchange protocol triggered at 1.2 times Parkland, Neff et al. found a 24% increase in MAP, 400% increase in urine output, and 25% reduction in resuscitation rate, with a reduction in lactic acid as well.[49] In 37 patients undergoing plasma exchange with a mean TBSA of 48.6%, hourly fluid, base deficit, lactate, and hematocrit all improved and were associated with decreased resuscitation volume and increased urine output.[48] Collectively these data support the notion that plasma exchange improves burn shock; however there are thus far no studies directly linking plasma exchange resulting from intraoperative blood loss with improvements in burn outcome demonstrated in early burn excision.

Chapter 11 on infection control well defines the critical nature of early surgical source control and appropriate antimicrobials, but generally emphasizes that meticulous aseptic technique, excision of infected or devitalized tissue, coverage with viable grafts, topical antimicrobials, culture surveillance, and systemic antimicrobials when appropriate are critical components.[50] Similarly, Chapters 28 and 29 on nutrition support and hypermetabolism, respectively, effectively discuss the critical need for enteral feeding and nutritional support, physical therapy, and the requirement to keep patients warm. The remainder of this chapter is directed toward organ-specific critical care support.

TOXICOLOGICAL BURN CRITICAL CARE

Many toxins can affect the burn-injured patient, particularly with occupational injuries. Specific therapies for all toxins are beyond the scope of this chapter and require appropriate decontamination, antidotes, and consultation with material data safety sheets and poison control centers for known exposures if beyond the burn physician's comfort. However the most common toxins are cyanide and carbon monoxide.[51] Cyanide can be elaborated from the combustion of various plastics, and significant exposure can result from smoke inhalation. Mounting evidence indicates that cyanide toxicity is clinically significant in inhalation injuries, being found at clinically significant levels in up to 76% of inhalation injury patients. Few clinical labs return blood cyanide labs in a clinically useful time scale, so surrogate markers of less than 15% TBSA with smoke inhalation, Glasgow Coma Scale (GCS) under 14, abnormal hemodynamics, and/or a lactate level of greater than 10 are known sensitive indicators of cyanide toxicity of greater than 1.0 mg/L. In these cases, empiric therapy is recommended with hydroxycobalamin.[52] It is the first-line antidote for cyanide toxicity and has a very mild side effect profile of transient hypertension, bradycardia, and urine discoloration. Hydroxycobalamin is also a nitric oxide scavenger and effectively reduces the hypotension often seen in burn shock.[52]

As a common product of combustion, carbon monoxide (CO) should be considered in any inhalation injury, enclosed fire, or patient with altered mental status. Patients with carboxyhemoglobin (COHb) levels above 25% should be mechanically ventilated on 100% FIO_2, which reduces the half-life from 4 hours to 1 hour. There are rare indications for hyperbaric oxygen (HBO) because it can reduce the CO half-life to 15 minutes, particularly in the setting of pregnancy or seizures. HBO is only indicated in the burn setting if it can be immediately employed in conjunction with definitive burn care in specialized centers. For cases where instituting HBO unnecessarily delays burn care, mechanical ventilation can bring COHb to safe levels prior to HBO's institution, and appropriate burn care should take precedence.[53]

NEUROLOGICAL BURN CRITICAL CARE

The main aspects of neurologic management of burn patients are pain control, sedation, delirium management, and management of acute stress disorder or posttraumatic stress disorder (PTSD). Furthermore there can be a need for seizure treatment or prophylaxis, management of the traumatic brain injury, or drug and alcohol withdraw protocols, which can occur concomitantly with the burn injury and are beyond the purview of this chapter. An important component of neurological care is early mobilization; physical/occupational therapy should be performed unless firmly contraindicated.[13]

Pain control is the most common neurologic intervention in the burn patient. Basal pain management with narcotics such as morphine is administered as needed to maintain comfort, while taking care to avoid oversedation that can prevent achieving physical therapeutic goals. Methadone can help by providing basal pain coverage and weaning of narcotics.[51] Interventions required for the patient to heal, such as physical therapy or wound care, will create a certain amount of pain that cannot be fully alleviated without preventing the patient's progress.[54] The burn team must assess the patient's pain management and use their experience to carefully balance short-term analgesia with long-term recovery and function.

Additional analgesics of short duration should be used for painful procedures, such as extensive wound care or staple removal. Often additional narcotics, such as fentanyl or additional morphine, are sufficient. For more extensive procedures ketamine is a safe, effective, and recommended agent. Several large series support ketamine use in nurse-driven protocols. In a series of 522 painful procedures in pediatric burn patients, only 2.9% required intervention such as airway repositioning, zero intubations in lengths from 1 to 105 minutes and weights from 2 to 111 kilograms.[55] A meta-analysis of 8282 ketamine sedations from 32 ED studies demonstrated no intubations. There was a 0.8% rate of transient apnea and 0.3% rate of laryngospasm; however all were resolved with positioning and/or bag valve masking.[56] In these studies, trained nurses typically performed the sedation. Ketamine has a favorable safety profile relative to benzodiazepine and narcotics due to its lack of respiratory depression and its cardiovascular stimulating effects.[54] Care should be taken to prevent emergence delirium in adult patients.

Sedation in the BICU is more complicated, requiring the balance of short-term sedative goals and apparent patient comfort with the intermediate costs of delirium and decreased therapy participation, as well as with long-term neuropsychiatric costs. The first goal is to minimize sedation administered, which is accomplished best with the use of a sedation scale and avoiding continuous benzodiazepine infusions. The use of the Richmond Agitation Sedation Scale has been shown to decrease mean duration of ventilator and sedation consumption.[57]

Benzodiazepines have reduced utility due to increased delirium and length of mechanical ventilation. Propofol, ketamine, and remifentanil have been increasingly used as alternatives to the formerly standard benzodiazepine-based therapies.[58] When compared directly to midazolam, patients sedated with the α-adrenergic agonist dexmedetomidine have required less sedation and have less hypotension. This sedative can be considered more effective, as well as being less of a risk in terms of hypotension.[59] Benzodiazepines are associated with an increased risk of agitation and delirium, and benzodiazepine and propofol are associated with more ventilator-associated events than dexmedetomidine. Dexmedetomidine is associated with less time to extubation and higher rates of bradycardia, but this is generally well tolerated in burn patients due to their hyperdynamic state and tachycardia.[60] The less expensive oral equivalent, clonidine, is a common adjuvant to sedation working on a similar α-adrenergic mechanism as dexmedetomidine; it is currently under meta-analysis for that role.[61] Ketamine infusion has been shown to be safe and effective in continuous BICU sedation as well.[62]

Psychiatric and psychological care is a critical component of BICU care. Standard psychological therapies and interventions are important factors of burn care.[63] The critical care team can help prevent delirium and PTSD by

avoiding benzodiazepine, minimizing sedation, treating pain first, limiting sleep disturbances, encouraging mobility, reorientation, and avoiding prolonged infusion of sedatives.[64] Despite our best efforts, many patients in the BICU experience delirium and agitation. Haloperidol remains in use in critical agitation and delirium settings and has documented safety in pediatric and adult burn populations.[65] Atypical antipsychotics have gained a substantial role in basal coverage of delirium and agitation and are safe and effective. The BICU team must remember to discontinue these medications when patient are no longer delirious; 84.2% of patients started in the BICU continued use after discharge from BICU, and 28.6% continued following discharge from the hospital.[66]

CARDIOVASCULAR BURN CRITICAL CARE

Treatment of cardiovascular responses after burn requires an understanding of cardiovascular physiology and the effects of treatment. One of the hallmarks of serious illness is the direct link between cardiac performance and patient performance. Cardiac compensation to burn injury is hyperdynamic to meet hypermetabolic needs, maintain perfusion of injured vascular beds, and compensate for the vasoplegia associated with burn shock. As such, patients often require supraphysiologic cardiac output to compensate for their systemic pathology.[67] The four determinants of cardiac function and hence tissue perfusion are:

- Ventricular preload or end-diastolic muscle fiber length
- Myocardial contractility or strength of the heart muscle
- Ventricular afterload, or the degree of resistance against which the heart must pump
- Heart rate and rhythm

A thorough comprehension of the effects of each of these components on heart function is necessary to initiate effective treatments for burned patients with cardiovascular abnormalities.

Preload

Preload is the force that stretches the cardiac muscle prior to contraction. This force is composed of the volume that fills the heart from venous return. Due to the molecular arrangement of actin and myosin in muscle, the more the incoming venous volume stretches the muscle, the further it will contract. This is best demonstrated on a Frank–Starling curve (Fig. 32.1), first described by Otto Frank in a frog heart preparation in 1884; Ernest Starling extended this observation to the mammalian heart in 1914. The relationship demonstrated in the Frank–Starling curve justifies the use of preload augmentation by volume resuscitation to increase cardiac performance. However when the end-diastolic volume becomes excessive, cardiac function can decrease; probably the muscle fibers overstretch and pull the contractile fibers past each other, thereby reducing the contact required for contractile force. The preload necessary to reduce cardiac function in experimental settings is in excess of 60 mm Hg, which is rarely encountered in patients.

Preload is estimated clinically by central venous pressure, pulmonary artery wedge pressure, echocardiography, or transpulmonary thermodilution. These measures can be used to optimize preload, balancing vascular volume loading and cardiac performance against interstitial and pulmonary edema.

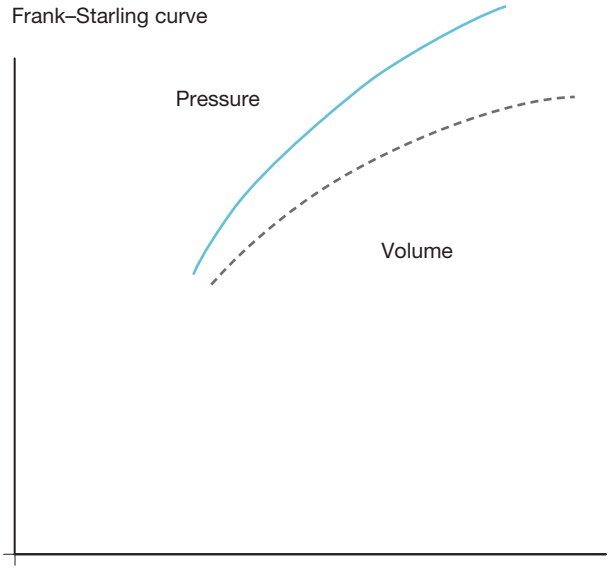

Fig. 32.1 Frank–Starling curve. The solid line depicts the pressure–volume relationship of the heart, showing that as pressure to the heart (preload) increases, the volume pumped by the heart increases. Immediately after burn, contractility diminishes, shifting the curve downward (*dashed line*). It still must be noted that, with this change, the volume pumped by the heart still increases with increased pressure (preload), validating the use of increased atrial pressure as a means of increasing cardiac output after severe burn.

Cardiac Contractility

The force with which the heart contracts is referred to as cardiac contractility. It is directly related to the number of fibers contracting, their preload and afterload. Contractility is diminished in patients with low preload or high afterload, in coronary artery disease with loss of myocardium from infarction and ischemia, in burned patients during the acute resuscitation due to myocardial depressant factor, in septic shock with Takotsobu cardiomyopathy, or in severely malnourished patients. Calculating the left ventricular stroke work from pulmonary artery catheter-derived values provides the best estimate of cardiac contractility and can be determined with the following formula:

$$\mathrm{LVSW} = \mathrm{SV}(\mathrm{MAP} - \mathrm{PCWP}) \times 0.0136$$

where LVSW is left ventricular stroke work, SV is the stroke volume (cardiac index ÷ heart rate), and PCWP is pulmonary capillary wedge pressure. In current practice, the contractility is usually tracked with arterial waveform continuous cardiac output monitoring or echocardiography.

Afterload

Afterload is the force impeding or opposing ventricular contraction and, in conjunction with cardiac output, creates blood pressure. This force is equivalent to the tension developed across the wall of the ventricle during systole. Clinically afterload is measured by arterial resistance as an estimate of arterial compliance. Arterial resistance is

measured as the difference between inflow pressure (mean arterial) and outflow pressure (venous) divided by the flow rate (cardiac output):

$$SVR = (MAP - CVP)/CO$$

where SVR is systemic vascular resistance, CVP is central venous pressure, and CO is cardiac output. Pulmonary artery catheters, arterial waveform analysis, or echocardiography calculates this value.

Heart Rate and Rhythm

For the heart to function properly, the electrical conduction system must be intact to provide rhythmic efficient contractions to develop sufficient force to propel blood through the circulatory system. For example, if the heart rate approaches 200 beats/min, the heart will have insufficient time to fill completely, thereby reducing myocardial fiber stretch and heart function. Also, if frequent premature ventricular contractions are present, the heart will not perform optimally, for similar reasons. Heart rate and rhythm are monitored continuously as routine in every critically ill patient using electrocardiography. A combination of sympathetic and adrenergic tone, combined with high atrial stretch, can predispose burn patients to atrial arrhythmias, such as atrial fibrillation (AF). Judicious fluid and electrolyte management, β-blockade, rate control, and the appropriate use of antiarrhythmics are cornerstones of treatment. An important note: mortality is higher in BICU patients after developing AF.[68]

Effects of Burn on Cardiac Performance

Severe burns affect cardiac performance in a plethora of ways. The first is to reduce preload to the heart through volume loss into burned and nonburned tissues. It is for this reason that volumes predicted by resuscitation formulas must be used to maintain blood pressure and hemodynamics. In addition, severe burn induces myocardial depression characterized by a decrease in tension development, and velocities of contraction and relaxation. CO is then reduced. These effects are most evident early in the course of injury during resuscitation; however they are followed shortly thereafter by a hyperdynamic phase of increased CO, primarily caused by a decrease in afterload through vasodilation and an increase in heart rate.

Hemodynamic Therapy: Preload Augmentation. When hypotension or other signs of inadequate cardiac function (i.e., decreased urine output) are encountered, the usual response is to augment preload by increasing intravascular volume. This is a sound physiologic approach based on the Frank–Starling principle and should be the first therapy for any patient in shock. Intravascular volume can be increased using either crystalloids or colloids to increase the CVP and PCWP to a value between 10 and 20 mm Hg. Preload goals can also be stroke volume variation below 12% or global end-diastolic volume index between 680 and 800 mL/m^2.[69] The adequacy of this therapy can be monitored by the restoration of arterial blood pressure, a decrease in tachycardia, and a urine output of greater than 0.5 mL/kg per hour.

Some caution must be exercised when augmenting preload for hemodynamic benefit in burned patients. Excessive volume administration may lead to significant interstitial edema and volume overload, with the development of peripheral and pulmonary edema. These changes can lead to conversion of partial-thickness burns to full-thickness injuries in the periphery and cause significant respiratory problems, liver failure, and compartment syndrome. Once hemodynamics are restored, fluid overload can be treated with spontaneous diuresis, pharmacologic diuresis, dialysis, or even therapeutic phlebotomy if required.

Hemodynamic Therapy: Inotropes and Vasopressors. If preload optimization is insufficient to improve hemodynamics, patients may require inotropes to increase cardiac output and/or vasopressors to increase afterload. Inotrope classes include phosphodiesterase inhibitors, digoxin, and adrenergic agonists. Phosphodiesterase inhibitors like milrinone increase contractility and decrease afterload without increasing myocardial oxygen demand by raising intracellular cyclic adenosine monophosphate (cAMP) levels to increase myocyte calcium (Ca^{2+}) levels. Digoxin increases contractility and decreases heart rate without increasing myocardial oxygen demand by inhibiting the sodium/potassium (Na^+/K^+) pump and increasing intracellular Ca^{2+}. Dobutamine is a commonly used inotrope with effects limited to β-adrenergic stimulation, thereby increasing CO and causing vasodilation. Dobutamine can be associated with increased heart rate and does increase myocardial oxygen demand. The associated vasodilation may be useful in perfusing peripheral vascular beds, as in threatened skin. The data support dobutamine reducing extravascular lung water and decreasing SVR index with increasing cardiac index and urine output, despite the global end-diastolic volume index (GEDI) being unchanged.[70]

Catecholamines, the most commonly used medication to augment blood pressure, are considered "inoconstrictors" because they have both inotropic and vasoconstrictive properties. One caveat regarding the use of these inoconstrictors is that myocardial oxygen consumption increases, which may affect the ischemic areas of the heart. However the hypotension being treated by the catecholamines will also compromise myocardial oxygen delivery substantially, so this consideration should not preclude their use by an experienced critical care burn physician. Epinephrine is the catecholamine of choice because it provides a greater proportion of its increase in blood pressure from inotropy rather than vasoconstriction. However norepinephrine is the preferred pressor in septic shock; its greater reliance on vasoconstriction versus inotropy can compromise dermal vascular beds critical to wound healing and survival in a burn patient, particularly in the setting of inadequate preload. Dopamine has generally fallen out of favor due to tachyphylaxis and tachycardias.[71] Therefore we consider epinephrine the preferred catecholamine.

Pure vasoconstrictors have a very limited role in burn care because concomitant inotropic support is advisable due to the patient's hyperdynamic state. Agents with primary effects on the α-adrenergic receptor can be used to induce vasoconstriction and increase blood pressure. Norepinephrine is often considered in this group, although 40% of its increase in blood pressure is due to α-mediated vasoconstriction, whereas 60% is from increased CO.[72,73]

Phenylephrine is a pure α-agonist, and can decrease CO and perfusion.[72,73] These agents are effective in septic shock or neurogenic shock to increase vascular tone.[74] However, in burned patients, it is believed that these agents will cause vasoconstriction of the skin and splanchnic circulation, thereby redistributing blood flow. This can cause grafts to fail and conversion of partial-thickness skin injuries to full-thickness, as well as resulting in ischemic injury to the gut. Additionally norepinephrine in both physiologic and pharmacologic doses suppressed wound macrophage efficiency in a cAMP-mediated manner via the adrenergic receptor. This may be part of the benefit provided by β-blockers.[75] The physiology of catecholamines was discussed in Chapter 23 on hormonal, adrenal, and sympathetic responses to burn injury.

Another pure vasoconstrictive agent used with great popularity is vasopressin. A very potent vasoconstrictor, it is mediated through its own receptor independent of the adrenergic receptors. Levels of vasopressin have been shown to be low in septic shock, and physiologic replacement at 0.02–0.044 U/kg per minute without titration is used in some burn units to increase MAP to good effect. Some investigators found that the use of vasopressin in this setting increased blood pressure, decreased heart rate, and spared norepinephrine dosing when used concomitantly.[76] In these physiologic replacement doses, there is believed to be minimal effect on splanchnic or dermal flow. Although there was a trend toward reduced renal failure with the administration of vasopressin, the VANISH trial failed to conclusively demonstrate reduced renal failure rates in septic patients treated with vasopressin compared to norepinephrine.[74] In an animal model, Li et al. found that adding a small physiologic dose of vasopressin to norepinephrine improved mitochondrial function and all measures of hemodynamics, as well as tissue and splanchnic perfusion.[77] In a series studying 30 septic burn patients treated with vasopressin plus norepinephrine, reduction of total norepinephrine dosing was shown. However one patient died from upper gastrointestinal necrosis; this patient presented with increased peripheral ischemia and donor site conversion, as well as skin graft failure. These data again support concerns regarding the use of pure vasoconstrictive agents when treating burn patients.[76]

Very rarely methylene blue, as a pure vasoconstrictor, may prove beneficial in treating refractory vasoplegia. It is a potent nitric oxide synthase inhibitor and, in case reports, has been shown to successfully reverse refractory vasoplegia following severe burn and thus should be in the armamentarium.[78,79]

Use of vasopressors and ionotropes in burn patients is an indispensible component of burn care. Balancing risks and benefit profiles of various medications in an individual patient's physiology is the purview of an experienced, trained burn critical care surgeon.

Effects of β-Blockade on Cardiac Performance After Severe Burn

One response to severe burn is a dramatic increase in catecholamine production; this has been linked to a number of metabolic abnormalities including increased resting energy expenditure, muscle catabolism, and altered thermoregulation. A nonspecific β-blocker, propranolol, has been used to reduce heart rate and myocardial work in severe burns.[80] Propranolol administration also reduces peripheral lipolysis[81] and muscle catabolism,[82] which are additional benefits. Wurzer et al. demonstrated that propranolol reduced cardiogenic stress by reducing cardiac index and MAP in severely burned, injured children without reducing peripheral oxygen delivery or increasing lactic acidosis events or organ dysfunction.[83] Further trials are in progress to define the benefits of β-blockade as well as its interaction with other anabolic medications such as oxandrolone. Regardless β-blockade is becoming an increasingly standard component of burn care.

PULMONARY BURN CRITICAL CARE

Lungs can be injured from inhalation injury, infection, inflammatory mediators, heart failure, or a sequela of critical care interventions, such as fluid overload or ventilator injury. Minor pathology can be treated with supplemental oxygen, diuresis, bronchodilators, or mucolytics. However mechanical ventilation is an essential treatment to manage pulmonary failure.

Mechanical ventilation in the severely burned generally occurs for three reasons: airway control during the resuscitative phase, airway management for smoke inhalation, and support during acute respiratory distress syndrome (ARDS). The first indication is for airway control early in the course, with the development of massive whole-body edema associated with the great resuscitative volumes required to maintain euvolemia. In this situation, the need for mechanical ventilation is not due to lung failure per se, but rather to maintain the airway until the whole-body edema is resolved. Once this occurs, usually 2–3 days into the course, extubation can be accomplished with minimal sequela. Ventilator management during this phase is routine. The second indication is airway management early in the course of smoke inhalation, which is a direct toxic injury to the airways and alveoli resulting in mucosal sloughing, loss of mucociliary escalator function, airway narrowing and edema, loss of surfactant, weakening of cartilaginous support of the airways, and fibrinous exudation into the airways.[53] Chapter 16 on inhalation injury comprehensively covers this issue. The third indication is the development of hypoxemia or hypercarbia due to a high alveolar-arterial (A-a) gradient, shunting, ventilation/perfusion (VQ) mismatching, poor compliance, or high resistance. Severe burns are known to be associated with hypoxemia and the development of ARDS. The clinical manifestations are dyspnea, severe hypoxemia, and decreased lung compliance, with radiographic evidence of diffuse bilateral pulmonary infiltrates.

Indications for Intubation

Intubation entails passing an endotracheal tube from either the nose or the mouth through the pharynx and into the trachea. This tube is subsequently connected to a mechanical ventilator to induce inspiration and passive exhalation. In burned patients indications for intubation are, in general, to improve oxygenation and ventilation or to maintain a compromised airway, such as in a severe inhalation injury or obtunded patient (Table 32.1).

Table 32.1 Clinical Indications for Intubation

Criteria	Value
PaO_2 (mmHg)	<60
$PaCO_2$ (mmHg)	>50 (acutely)
P/F ratio	<200
Respiratory rate	>40
Respiratory/ventilatory failure	Impending
Upper airway edema	Severe

It is important to intubate appropriate patients prior to respiratory arrest. It should be considered, however, that in a large study series more than 33% of burn patients were extubated within 1 day of intubation for transfer to a burn center without reintubation. These patients were subjected to risk without reward, and loss of an endotracheal tube in a heavily sedated or paralyzed patient is potentially fatal.[84]

Securing an endotracheal tube (ETT) to a burned and/or edematous face can be challenging. In a large survey of burn centers, ETTs were reported secured with linen nonadhesive tape in 59% of cases, manufactured devices in 48%, and orthodontically in 24%.[85] Our center has used nasal intubation with a septal tie for 20 years without accidental extubation or septic sinusitis.

Tracheotomy can provide a long-term durable airway with less patient discomfort. In a survey of American burn centers, the average tracheostomy was performed at 2 weeks; however there is a consensus that there are indications for earlier tracheostomy.[85] Interestingly, however, in a study of 600 adult medical ICU patients, Terragni et al. found that early tracheotomy did not result in significant improvement in ventilator-associated pneumonia, although the duration of ventilator-assisted respiration was reduced, as was ICU time.[86]

Pulmonary Physiology

There has been a proliferation of management strategies for pulmonary failure with an alphabet soup of ventilator modes. However the physiology of human lungs remains constant regardless of the proliferation of devices. Maintaining a broad physiologic view allows optimal matching of the ventilator's actions to the patient's needs. Lungs have three main functions:

- Ventilation
- Oxygenation
- Expectoration

Ventilation. Ventilation allows the elimination of carbon dioxide (CO_2), as measured on arterial blood gas by the $PaCO_2$. The ventilator accomplishes this with minute ventilation (V_{min}) minus dead space ventilation (V_d). In general, $PaCO_2$ varies inversely with V_{min}, so this value must be considered when making ventilator adjustments to alter $PaCO_2$. V_{min} is equal to tidal volume multiplied by respiratory rate. Therefore, $PaCO_2$ can be adjusted downward by increasing either tidal volume or respiratory rate. In general, the respiratory rate should be set between 10 and 20 breaths/min and tidal volume at 6 mL/kg ideal body weight initially. In a normal patient, V_{min} is 100 cc/kg per minute, but with the high CO_2 production seen in burn patients the needed minute ventilation can increase two- to fourfold. Adjustments can then be made in minute ventilation to optimize $PaCO_2$, which is usually 40 mm Hg but can be higher in patients with pre-existing chronic obstructive pulmonary disease (COPD) or smoking habits.[87] When making these adjustments, it should be noted that the respiratory rate cannot be increased above 40 breaths/min in those who are not neonates, and tidal volume should be minimized to avert ventilator-induced lung injury (VILI).

As respiratory rates increase in an attempt to increase minute ventilation while complying with low tidal volumes, the fraction of dead space can also increase, further impeding ventilator function. In these cases, decreasing the minute ventilation will increase CO_2 elimination. Dead space ventilation–perfusion abnormalities can be monitored with volumetric capnography performed bedside to measure physiological and alveolar dead space.[88] This can be a useful adjunct for ventilator management. Volumetric capnography accounts for total CO_2 exhaled, unlike late expiratory end-tidal CO_2 ($EtCO_2$) monitoring, which assumes an A-a gradient of only 2–3 mm Hg, inappropriate in many critical care patients. $EtCO_2$ monitoring has utility in monitoring trends or in the setting of a low gradient, as seen in traumatic head injuries. However in critically ill burn patients, the A-a gradient can be in a state of flux, calling into question values received from the $EtCO_2$ monitor and making volumetric capnography more appealing. Factors affecting the A-a gradient include CO, airway dead space, airway resistance, and metabolic rate; each of these may change in a severely burned patient, particularly those with inhalation injury. For these reasons, $EtCO_2$ monitoring is ill-advised in burned patients for the estimation of $PaCO_2$. Serial blood gas examination is a more reliable monitor.

The ARDSnet studies have well documented that ventilatory injuries to the lung can induce ARDS and have an appreciable effect on morbidity and mortality. Volutrauma occurs when an excess of volume over-distends the lungs, injuring compliant alveoli. Volumes are preferentially directed to compliant and uninjured alveoli because noncompliant alveoli have too long a time-constant to accept the volume. As healthy alveoli are sequentially injured, a positive feedback is established, and the injury continues to worsen. This is the principle underlying low tidal volume (LTV) ventilation. Use of positive end expiratory pressure (PEEP) can facilitate maintaining more compliant alveoli and reduce atelectotrauma by reducing alveolar collapse as well as preserving the lung in a more compliant portion of the pressure volume loop.[89] Furthermore having more nitrogen in the ventilated gas maintains a stenting function because it is not absorbed out of the airways as is oxygen.[90] When plateau airway pressures are greater than 30 mm Hg the ventilated lung is relatively noncompliant, indicative of ARDS or pulmonary edema, which subject the lung to barotrauma similarly. In this situation, "permissive hypercapnia" is a strategy that can be used to reduce barotrauma. This strategy seeks to limit peak and plateau airway pressures by reducing tidal volumes to allow for respiratory acidosis ($PaCO_2$ >45 mm Hg, arterial pH <7.30). This strategy was used to some extent in the trial investigating the

efficacy of pressure-limited ventilation on improving outcomes in critically ill ventilated patients.[91]

LTV ventilation has been shown in the ARDSnet trials to be protective against ARDS, but it can also compromise ventilatory function and CO_2 elimination. Burn patients represent unique challenges in mechanical ventilation and ARDS given the reduced compliance due to eschar, chest wall and pulmonary edema due to resuscitation, the unique physiology from inhalation injury, and the increased CO_2 production due to hypermetabolic response. Furthermore the work of breathing progressively increases at lower tidal volumes.[92] LTV protocols have been proved ineffective in the burn population: 33% of burn patients failed to meet oxygenation and ventilation requirements, increasing to approximately 67% in inhalation patients.[85]

Sousse et al. analyzed pulmonary outcomes in 932 burned pediatric patients with inhalation injury over 28 years, stratifying for tidal volume. Their findings, starkly divergent from ADRSnet predictions, demonstrated high tidal volume (15 +/− 3 mL/kg) was associated with significantly decreased ventilator days, maximum PEEP, and significantly increased maximum peak inspiratory pressure; ARDS was significantly decreased, but pneumothorax increased. They concluded that high tidal volumes might interrupt the sequences of events leading to lung injury following inhalation injury.[93]

Another school of thought holds that surrogate markers, such as airway pressures, should be used to avoid ARDS. By this logic, when tidal volumes were lowered, patients with more compliant lungs did poorly, whereas patients with less compliant lungs did well.[94] Regardless, lung-protective strategies are notoriously difficult to institute in the burn population, and some lung injury often must be accepted to assure overall patient survival.

Oxygenation. Like the adequacy of ventilation, oxygenation has been classically determined using the Pa_{O_2} in arterial blood. Arterial oxygenation is calculated using three factors: mean alveolar pressure of oxygen (MAP-O_2), the A-a gradient, and VQ mismatching. MAP-O_2, as determined by the ventilator, is the area beneath the pressure/time curve multiplied by the fraction of inspired oxygen (F_{IO_2}). Increasing the FiO_2 has limited ability to improve oxygenation because F_{IO_2} in excess of 60 is considered pulmonary toxic for prolonged time courses.[95] However increasing MAP-O_2 profoundly improves oxygenation, often quite safely. This can be accomplished by increasing the PEEP or the inspiratory time during which the airways are maintained at inspiratory pressure for longer, thereby enlarging the area under the curve. However as more time is maintained in inspiration, less is available for exhalation and ventilation. Thus hypercarbia and acidosis can limit the maintenance of high MAP-O_2.[96] These implications will be discussed in further detail in the ventilator mode section.

The A-a gradient is a function of the diffusion membrane separating air from blood. This is affected by pulmonary edema. A-a gradient issues are best managed by reducing pulmonary edema with diuresis, improving cardiac performance using inotropes, and allowing time for the lungs to heal their diffusion membrane by repopulating the type-1 pneumocytes.

VQ mismatching occurs as deoxygenated blood is shunted through poorly ventilated lungs and hypoxic vasoconstriction becomes dysregulated in the pulmonary vasculature. This is treated first by improving the aeration of the lung using pulmonary toileting, recruitment maneuvers, and open lung techniques to aerate long time constant aveoli.[97] Furthermore inhaled pulmonary vasodilators, such as nitric oxide or prostaglandins, can vasodilate aerated beds and improve VQ matching.[98] Finally prone positioning can also improve VQ matching, as well as posterior aeration.[99] In a survey of American burn centers, ARDS was managed through fluid restriction/diureses and enteral nutrition, as well as by neuromuscular blockade. In severe ARDS, prone positioning was used in 33% of centers and extracorporeal membrane oxygenation (ECMO) in 18%.[85]

Oxygen is principally delivered to tissues on hemoglobin, so, in general, a Pa_{O_2} value of 60 mm Hg is considered sufficient because it equates to a saturation of approximately 92%. Pulse oximetry effectively measures oxygenation and can be used to guide ventilator management. Falsely measuring methemoglobin and carboxyhemoglobin as oxygen-saturated hemoglobin, which is common initially in patients with smoke inhalation injury, highlights the shortcoming of this technique. Otherwise this is a very accurate method to determine the oxygen content in arterial blood because 97% of oxygen is carried to the tissues via hemoglobin. This assertion has been corroborated by in vitro studies showing the accuracy of pulse oximetry to within 2–3% of oxyhemoglobin levels.[100] The major limitations of this technique lie in its insensitivity to changes in pulmonary gas exchange. Because of the shape of the oxyhemoglobin dissociation curve, when the Sa_{O_2} exceeds 90% and the Pa_{O_2} is greater than 60 mm Hg, the curve is flat, and changes in Pa_{O_2} can move considerably with little variation in Sa_{O_2}. Regardless it is presumed that an Sa_{O_2} value of greater than 92% is indicative of adequate oxygenation. That the oxygenation saturation measurement is a continuous direct measure immediately available whereas blood gas measurement of Pa_{O_2} is intermittent is an advantage that should not be overlooked.

A commonly used parameter to assess the adequacy of oxygenation is the ratio of Pa_{O_2} to F_{IO_2} (P/F ratio). It is an easily calculated surrogate for the A-a gradient.[101] As such, the P/F ratio is one of the criteria utilized to diagnose ARDS in the Berlin definition (Table 32.2). ARDS is defined as bilateral opacities not explained by effusion, collapse of nodules occurring within 1 week of a clinical insult not fully explained by cardiac failure, or fluid overload associated with a P/F ratio of less than 300. ARDS is stratified to mild, with a P/F between 200 and 300; moderate, between 100 and 200; and severe, below 100.[101]

However, not incorporating MAP, a key determinant in oxygenation, is a major flaw when utilizing the P/F ratio. Thus two patients on two different levels of ventilator support (one on minimal PEEP, the other on maximal) are indistinguishable based on this parameter, although they are clearly disparate when using the A-a gradient. To account for this variable, the oxygenation index (OI) may be used:[102]

$$\text{Oxygenation index (OI)} = (\text{Mean airway pressure } (mmH_2O) \times FiO_2)/PaO_2$$

Table 32.2 Berlin Definition—ARDS

Onset within one week of onset of injury or illness	
Bilateral lung opacities not explained by effusion, atelectasis, or nodules	
Respiratory failure without cardiac failure or fluid overload	
Diminished oxygenation	
Mild	200 < P/F < 300
Moderate	100 < P/F < 200
Severe	P/F < 100

P/F = partial pressure arterial oxygen/fraction of inspired oxygen

This parameter is particularly helpful in determining a patient's oxygenation status in relation to the level of ventilator support: the higher the number, the worse the level of oxygenation. Generally, an OI of greater than 20 should be a cause for concern.

Expectoration. The final aspect of pulmonary physiology necessary for consideration in pulmonary critical care is expectoration. The injured lung must clear its secretions, damaged mucosa, pathogens, and aspirated material. In the case of an inhalation injury, there is the transudate of fibrinous material and sloughing of injured mucosa that must be cleared in the setting of a compromised mucociliary escalator. Chest physiotherapy, mucolytics, suctioning, and particular ventilator modes aid in the expectoration of the lungs.[103]

A commonly used technique to treat inhalation injury is the combination of nebulized heparin and N-acetylcysteine with albuterol and pulmonary toileting.[104] The goal is that the heparin will prevent coagulation of the transudated plasma, which comes through the injured pulmonary capillaries. The N-acetylcysteine serves as a mucolytic agent and allows expectoration, along with the sloughed mucosa, during physiotherapy and suctioning.

In a meta-analysis of five studies comprising 286 patients, inhaled heparin was found to reduce ventilator days and resulted in more patients alive at day 28 with lower lung injury scores, although methodological issues were noted.[105] However, in a follow-up analysis of those studies, individual patient data provided no convincing evidence regarding any benefit of heparin nebulization in intubated and ventilated ICU patients, although none of these patients had inhalation burn injuries.[105] In a review of inhalation-injured patients, Kashefi found a nebulized heparin and N-acetylcysteine/albuterol protocol did not reduce mortality or duration of mechanical ventilation, but did increase pneumonia rates.[106] Conversely Sood and Waldroth more recently published a case-control study of 72 inhalation-injured patients and found that a 7-day course of nebulized heparin with N-acetylcysteine and albuterol decreased mean ventilator days from 14 to 7 and increased ventilator-free days. There was no change in mortality, pneumonia rates, or bleeding in their study. In this series of inhalation-injured patients, nebulized heparin was found to be safe and effective.[104] This efficacy is consistent with our own clinical experience.

Mechanical Ventilation

Mechanical ventilation is an essential component of burn pulmonary critical care. Mechanical ventilatory support allows life to be sustained with lungs that would otherwise inexorably lead to death. It is important that the use of mechanical ventilation provide the minimal interruption to burn care, including both wound care and physical therapy. The safety of mobilization of mechanically ventilated patients is well documented, including out-of-bed mobilization of intubated patients (Fig. 32.2).[13]

The principal clinical difference between mechanical ventilation and spontaneous ventilation is the effect of positive pressure, as opposed to normal physiologic negative pressure. The use of positive pressure improves ventilation by recruiting alveoli and increasing functional residual capacity (i.e., the number and volume of open alveoli at the end of expiration), thus improving VQ mismatch and reducing shunting of blood past nonventilated lung areas (Fig. 32.3). Positive pressure ventilation also allows maintenance of higher MAP-O_2 to overcome high A-a gradients. Adverse effects of positive-pressure ventilation lie in its propensity to produce trauma to the airways (barotrauma) and its effects on intrathoracic pressure, which can impede venous return to the heart, thus reducing cardiac output.

In a survey of American burn centers, pressure support ventilation and volume assist control were the most common *starting* ventilator modes for all burn patients; however 53% of centers report using an open lung technique such as high-frequency percussive ventilation (HFPV), high-frequency oscillation ventilation (HFOV), or airway pressure release ventilation (APRV) in the setting of inhalation injury.[85]

When oxygenation begins to decline, initial maneuvers are to increase the F_{IO_2} to greater than 40%, possibly to 100%. Concentrations of oxygen greater than 60% are considered toxic to airway epithelium over the course of hours; other means to increase oxygenation should be employed.[95] As discussed earlier, treating hypoxia is first accomplished by increasing the MAP-O_2 by raising the level of PEEP incrementally until the desired level of oxygenation is reached while keeping the F_{IO_2} to less than 60%. Once a level of 15–20 mm Hg of PEEP is reached, other means of increasing MAP-O_2 will need to be employed. These consist of ventilator modes, including inverse ratio ventilation, HFOV, HFPV, and APRV.

After MAP-O_2 is maximized, therapies are directed at improving VQ mismatching with inhaled nitric oxide or prone positioning. ECMO has been used with success in burn patients when the lungs are too injured to perform life-sustaining gas exchange. This must be done with caution given the need for anticoagulation and the limitation imposed in the ability to mobilize the patient, both of which can compromise other critical aspects of burn care.[107]

Ventilator Modes. Regardless of the mode (Fig. 32.4), the basic pulmonary physiology principles balancing ventilation, oxygenation, and expectoration against VILI lung injury are the purview of a skilled burn surgeon and respiratory therapist.

Expert consensus and recommendations on safety criteria for active mobilization of mechanically ventilated critically ill adults. *Crit Care.* 2014;18[6]:658.)

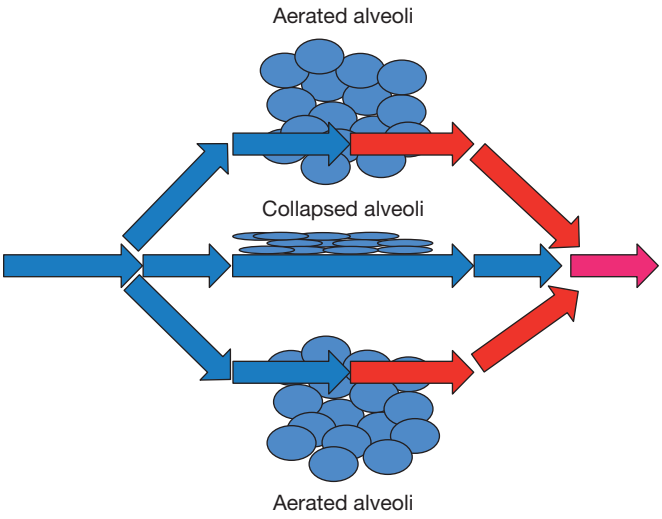

Fig. 32.3 A schematic of intrapulmonary shunting. Blood comes into the lung and then divides into capillaries and passes close to alveoli, where gas exchange occurs. In the case of alveolar collapse, the passing blood does not undergo gas exchange and thus returns to the pulmonary vein unchanged (low oxygen concentration, blue color). This then mixes with oxygenated blood from the aerated alveoli (high oxygen concentration, red color) to return to the heart and the periphery. In effect, more collapsed lung equates to less oxygenation through this process.

Volume-control mode delivers a preset tidal volume regardless of patient effort and is typically used only under general anesthesia due to ventilator–patient *dyssynchrony*; it takes all respiratory control away from the patient (Fig. 32.5). Assist-control mode differs by allowing the patient to demand additional breaths with a ventilator-preset minimum rate. All breaths are delivered at a prescribed volume, irrespective of any patient attempts for a larger or smaller breath. Some patients find this mode uncomfortable due to the inability to control their volume and require greater sedation than they would under other modes.

Volume-cycled ventilation delivers a set volume of air regardless of pressure required. In the case of poor lung compliance, such as ARDS, this mode could lead to excessive ventilator pressures and significant airway injury. For this reason, *time-cycled pressure control ventilation* was developed; this delivers inspiration at a given flow rate to a preset pressure. The breath is terminated at a set cycle time, not on the basis of volume of flow, as with volume-controlled ventilation. Therefore pressure control has the advantage of limiting inspiratory pressure despite changes in compliance. It has the disadvantage of a variable tidal volume during dynamic changes in lung compliance, which can lead to inadequate or excessive minute ventilation if compliance respectively worsens or improves.

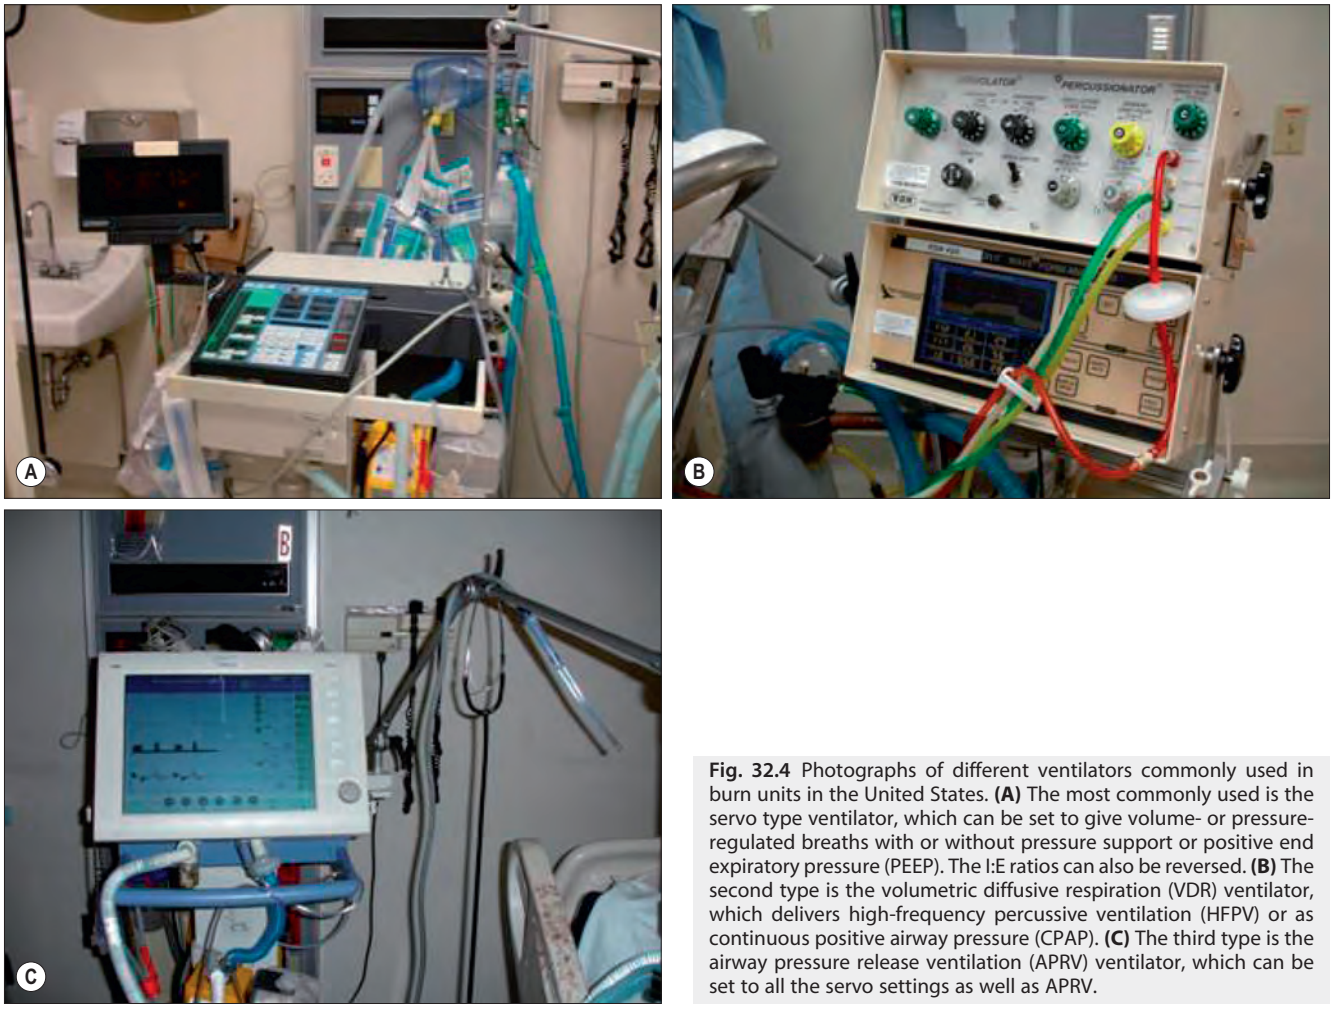

Fig. 32.4 Photographs of different ventilators commonly used in burn units in the United States. **(A)** The most commonly used is the servo type ventilator, which can be set to give volume- or pressure-regulated breaths with or without pressure support or positive end expiratory pressure (PEEP). The I:E ratios can also be reversed. **(B)** The second type is the volumetric diffusive respiration (VDR) ventilator, which delivers high-frequency percussive ventilation (HFPV) or as continuous positive airway pressure (CPAP). **(C)** The third type is the airway pressure release ventilation (APRV) ventilator, which can be set to all the servo settings as well as APRV.

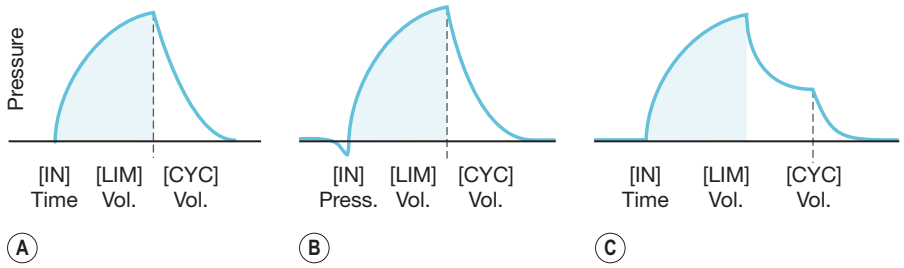

Fig. 32.5 Airway pressure curves illustrating the three mechanical functions: *IN*, initiation of the cycle; *LIM*, the preset limit (i.e., pressure or volume) imposed on the positive pressure cycle; *CYC*, the function (i.e., time or volume) ending the cycle. Each mechanical function is governed by one of four physical factors: volume, pressure, flow, and time. **(A)** A time-initiated, volume-limited mode. **(B)** A pressure-initiated (sub-baseline pressure produced by the patient's effort to breathe), volume-limited mode. **(C)** A time-initiated, volume-limited, time-cycled mode that extends inspiration beyond the time that the volume is delivered. A plateau is reached after flow has stopped but before the ventilator cycles into exhalation. (From Shapiro BA, Lacmak RM, Care RD, et al. *Clinical application of respiratory care*. St. Louis, MO: Mosby Year Book; 1991.)

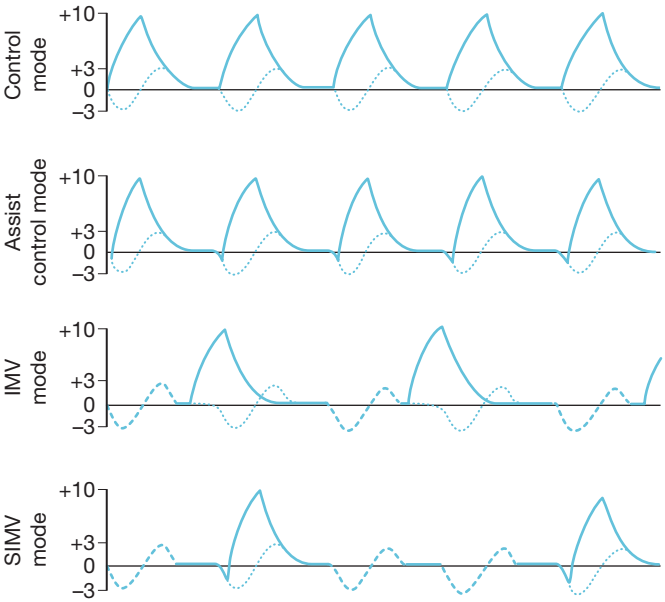

Fig. 32.6 Airway pressure tracings of four volume-cycled modes. The thick solid lines represent ventilator breaths. The thick dotted lines are spontaneous breaths. The thin dotted lines illustrate the spontaneous breathing pattern in the absence of ventilator breaths. *IMV*, intermittent mandatory ventilation; *SIMV*, synchronized intermittent mandatory ventilation. (From Shapiro BA, Lacmak RM, Care RD, et al. *Clinical application of respiratory care*. St. Louis, MO: Mosby Year Book; 1991.)

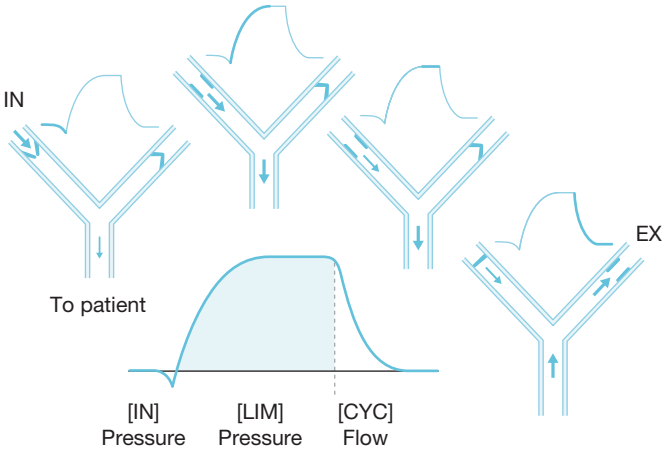

Fig. 32.7 Schematic illustration of pressure support ventilation. *IN*, initiation by spontaneous breath; *LIM* limit (pressure); *CYC*, cycle (derived from decreasing inspiratory flow); *EX*, expiration. (From Shapiro BA, Lacmak RM, Care RD, et al. *Clinical application of respiratory care*. St. Louis, MO: Mosby Year Book; 1991.)

Intermittent mandatory ventilation (IMV) allows spontaneous ventilation interspersed with volume-cycled or time-cycled pressure control mechanical ventilation. The addition of synchronization, in synchronized intermittent mandatory ventilation (SIMV), avoids placing a mechanical breath on top of a spontaneous patient breath, greatly improving this mode. It was hoped that maintaining some patient work in breathing would preserve respiratory strength while mechanical ventilation was required and that this mode would support weaning to progressively increasing patient effort while reducing mechanical support, although outcome data did not support a role in weaning (Fig. 32.6).

Pressure-support ventilation (also known as continuous positive airway pressure [CPAP]) is a patient-triggered pressure-limited flow-cycled ventilatory mode (Fig. 32.7). Each pressure support breath is triggered by patient negative-pressure effort and allows the patient to control his or her minute ventilation. This is a very comfortable mode for patients and effective for weaning; however it is not compatible with decreased respiratory drive. Care must be taken to ensure the patient does not develop progressive atelectasis with resultant decreases in compliance.

Inverse ratio ventilation (IRV) increases the MAP-O_2 thereby improving oxygenation in the setting of high A-a gradients. Conventional ventilation uses the time of inspiration and expiration at a ratio of 1 : 4 or 1 : 2, providing the greater time for expiration, as it is generally a passive process. IRV reverses this to give a longer inspiratory time (1 : 1 or 2 : 1) by using rapid inspiratory flow rates and decelerating flow patterns during the inspiratory phase. The prolonged inspiratory pressure increases MAP-O_2 dramatically to drive oxygen across a large diffusion membrane. Similarly to PEEP, this prolonged pressure recruits alveoli with long time constants. In severe lung disease, ventilation in the lung is unequal due to peribronchial narrowing. Thus some underventilated alveoli are actually open but unable to efficiently exchange gases, thereby increasing the intrapulmonary shunt and reducing arterial oxygenation. IRV can improve on this by selective air-trapping (intrinsic

PEEP) in these compromised air spaces. This can be done in either a volume-cycled or time-cycled pressure ventilation mode, but pressure-controlled ventilation is most commonly used to reduce peak airway pressures. Some studies show no benefit of IRV compared to conventional volume ventilation in terms of oxygenation.[108] These studies demonstrate some slight improvements in ventilation ($PaCO_2$). Furthermore this mode is not well tolerated by patients because they are unable to spontaneously breathe and thus tend to require heavy sedation. For these reasons, IRV cannot be recommended except in the setting of ARDS refractory to other therapies.

APRV delivers continuous positive airway pressure with a time-cycled pressure-release phase (to allow for expiration). Similar to IRV, it maintains high pressures within the airways for most of the respiratory cycle, thus allowing for very high MAP-O_2 to overcome high A-a gradients, recruitment of long time constant alveoli, and improved VQ matching. Unlike IRV, the patient can breathe spontaneously over the high and low pressures enabling greater patient comfort and synchrony, minimal sedation, and augmented minute ventilation. These characteristics allow for an open lung with extensive alveolar recruitment and thereby improved VQ mismatching.[109] This mode is best utilized in patients permitted to breathe spontaneously with negative pressure induced by diaphragmatic contraction, which aids in lung recruitment of areas previously atelectatic. This contrasts conventional positive-pressure ventilation, where positive pressure within the bronchus through the volume of air distributes preferentially down the path of least resistance to areas of the lung already well aerated, predisposing them to over-distension and barotrauma. Theoretically APRV is the ideal lung-protective strategy.

APRV gained popularity in the late 1990s and is becoming the preferred mode of ventilation in many centers, particularly in the setting of inhalation injuries. This open lung technique allows effective expectoration during the "dump" exhalation phases. Small prospective trials suggest APRV associates with fewer ventilator days, improved gas exchange, decreased atelectasis, improved hemodynamic performance, and decreased sedative administration compared to conventional modes in nonburned populations.[97] Some recent data in trauma patients refute this, although that paper suffered from a significant lack of statistical power.[109] Nonetheless this mode is being increasingly used in burn units around the world, but no prospective trials have yet been reported.

HFOV maximizes MAP-O_2 by maintaining airways at MAP-O_2 and delivering subtidal, high-frequency oscillatory breaths otherwise described as "CPAP with a wiggle." It is believed to maintain open alveoli by recruiting collapsed portions of diseased lung and applying the equivalent of CPAP used during conventional ventilation and driving oxygen into the blood with a high A-a gradient. HFOV maintains a maximal MAP-O_2 with a limited peak pressure while there is neither opening nor closing of alveoli. Thus this is a "lung-protective" mode preventing atelectotrauma, volutrauma, and barotrauma. Ventilation and CO_2 elimination are achieved via eddy currents mixing the air throughout the ventilator circuit, but poor CO_2 elimination is a major limitation of HFOV.[96] Because there is no exhalation, expectoration is minimal unless special maneuvers are employed.[110] A randomized prospective trial in adult patients with ARDS demonstrated that HFOV resulted in brief improvements in oxygenation, although mortality and complication rates were not different.[111] One center reported early success in reversing profound hypoxemia in burned patients with ARDS while facilitating early excision and grafting with intraoperative use.[112] However this same group recently showed that, in burned patients with inhalation injury, this method often failed secondary to hypercapnia rather than hypoxia.[113] HFOV appears to be effective in improving oxygenation in burned patients with inhalation injury, but the data without inhalation injury are murkier. In the recent OSCILLATE and OSCAR trials in unburned populations, no benefit and potential harm with HFOV was found.[85]

HFPV is a pressure-limited, time-cycled mode of ventilation delivering subtidal pressure-limited breaths at a high frequency (400–800 beats/min) superimposed on a conventional inspiratory and expiratory pressure-controlled cycle (10–30 breaths/min). The purported advantages are mobilizing airway secretions, casts permitting better expectoration and pulmonary toilet, and providing adequate gas exchange at lower airway pressures. First reported in 1989, HFPV has been tested primarily in burned patients with inhalation injury.[114] In this study, HFPV was used as a salvage therapy in one group of burned patients with inhalation injury and as the primary therapy in another. Improvements in oxygenation and a lower rate of pneumonia were observed. A subsequent study documented improvements in mortality in burned patients with inhalation injury treated with HFPV compared to historical controls.[115] Other outcomes in this study were significant decreases in the work of breathing and lower inspiratory pressures in addition to improvements in oxygenation and the pneumonia rate. This method of ventilation is advocated in the treatment of inhalation injury because it facilitates expectoration, particularly compared to HFOV.

In severely burned ventilated patients, a randomized controlled trial tested the effects of a low tidal volume conventional ventilator strategy against an HFPV ventilator strategy. This study found differences in improved oxygenation early in the course but no differences in mortality or other outcomes. However it demonstrated the need for ventilator "rescue" in only the HFPV group, defined as the need for changing ventilator modes due to inadequate oxygenation or ventilation despite maximizing the mode. Thus the data support HFPV in this population (e.g., less rescue indicated).[116] At a minimum, these data show HFPV as a useful tool in the burned patient population.

Nitric oxide (NO) is used to improve VQ mismatch in the setting of refractory hypoxemia. It is a short-lived gaseous product of endothelial cells that is a powerful local vasodilator. As a gas, this product can be delivered through the endotracheal tube to areas of ventilated lung where it can provide localized pulmonary vasodilation. Thus areas of ventilated lung can receive more blood flow to reduce intrapulmonary shunting and improve oxygenation. This compound has been used extensively to beneficial effect in neonates and children with hypoxemic respiratory failure. It has also been used in ventilated burned children to improve oxygenation.[98] Although NO therapy has received considerable attention as a potential therapeutic option in

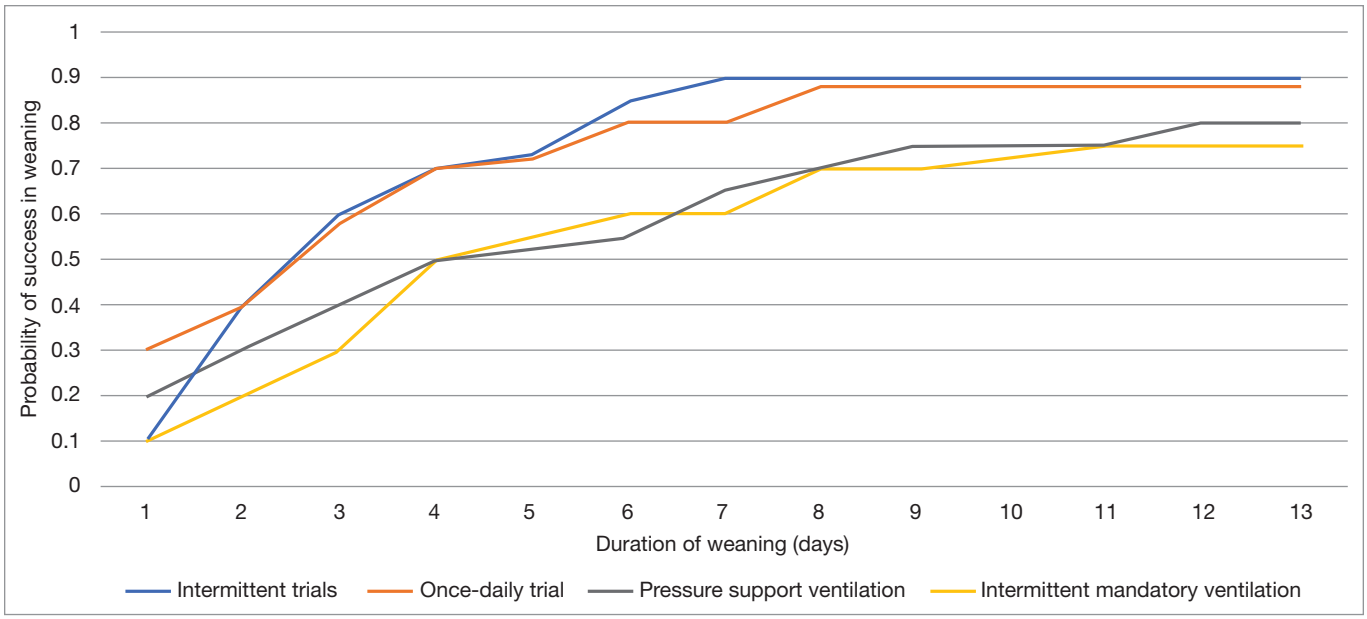

Fig. 32.8 The probability of successful weaning with intermittent mandatory ventilation, pressure support ventilation, intermittent trials of spontaneous breathing, and once-daily trials of spontaneous breathing (Kaplan–Meier curves). After adjustments for baseline characteristics (Cox proportional hazards model), the rate of successful weaning with a once-daily trial of spontaneous breathing was 2.83 times higher than that with intermittent mandatory ventilation ($P < 0.006$) and 2.05 times higher than that with pressure support ventilation ($P < 0.04$). (From Esteban A, Frutos F, Tobin MJ, et al. A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group. *The N Engl J Med.* 1995;332(6):345-350.)

severe pulmonary disease, no reports to date have documented improved mortality or other clinical outcomes in spite of improvements in oxygenation. *Inhaled prostaglandins* have a similar effect via an alternate mechanism. Some centers prefer using prostaglandins due to cost. Epoprostenol has been shown to be noninferior to inhaled nitric oxide with regards to ventilator-free days in ARDS.[117] Inhaled NO and aerosolized epoprostenol consistently improve oxygenation but have not yet been demonstrated to impact survival ventilator-free days or attenuation of disease severity. [118] Epoprostenol has also been successfully used in cases of inhalation injury with a nebulized heparin protocol.[119]

Weaning From Mechanical Ventilation. Regardless of the mode of ventilation, almost all patients surviving the initial insult will eventually need to be weaned off the ventilator. Clinicians continue to debate the advantages of weaning patients with various forms of mechanical ventilation. Some prefer using pressure support ventilation (PSV) with or without SIMV because of the ease with which the level can gradually be reduced. Others advocate that intermittent trials with abrupt cessation of ventilator support while also maintaining endotracheal intubation ("t-tube trials") result in more rapid weaning.[120] Between weaning trials it is important to provide sufficient support to re-recruit alveoli and prevent progressive atelectasis and the resultant loss of compliance, all of which make weaning more difficult. Weaning from ventilation depends on the rate at which the patient recovers from the condition requiring mechanical ventilation and the aggression of the clinician driving the weaning process. In practice, either method of weaning from the ventilator (gradually with pressure support or intermittently with t-tube or PSV trials) will be successful (Fig. 32.8).

The standard of care has shifted to perform protocolized daily sedation interruptions, spontaneous breathing trials, and assessment from extubation. This protocol has been shown to decrease ventilator days and mortality in randomized controlled trials (RCTs). An RCT has demonstrated one life saved for every seven patients treated with a spontaneous breathing trial protocol.[121] There is an argument that decreased sedation applied in these protocols increases self-extubation, which was found in the study. However the reintubation rate was not different, indicating that patients who were able to self-extubate tended to not require further intubation. Thus, in this study, self-extubation was a good weaning parameter.[121]

Monitoring of Mechanical Ventilation. For patients on mechanical ventilation, sedatives and paralytics for the endotracheal tube or other conditions often impair the normal physiologic regulation of ventilation and oxygenation. For these reasons, monitoring of ventilation and oxygenation by the clinician is required utilizing serial examination, chest X-ray, blood gas analysis, continuous SaO_2, and, preferably, $EtCO_2$.

LIMITING VENTILATOR-INDUCED LUNG INJURY. Mechanical ventilatory support is employed to provide supraphysiologic conditions to injured lungs otherwise unable to sustain life. Ultimately ventilator weaning is predicated on these lungs healing sufficiently to allow them to again sustain the patient's life without the supraphysiologic conditions the ventilator creates, such as positive pressure. Care must be taken to balance the systemic needs of the patient for gas exchange with the injurious nature of mechanical

ventilation in a supraphysiologic manner. VILI is the result of injurious ventilator settings that lead to a combination of barotrauma, volutrauma, atelectrauma (repeated opening and closing of alveoli), and chemotrauma (paracrine inflammatory effects). VILI is a common complication of mechanical ventilation and results in pneumothorax, pneumomediastinum, subcutaneous emphysema, interstitial emphysema, or pneumatoceles.[122]

In a volume-cycled mode, large tidal volumes, along with elevated peak and plateau pressures, have been implicated in inducing VILI. It is conceivable that limiting airway pressures may reduce morbidity. Early reports showed no clear benefit of pressure-limited ventilation, which was demonstrated by giving lower tidal volumes more frequently to maintain minute ventilation and accepting a higher $Paco_2$ value and lower arterial pH.[123]

This "permissive hypercapnia" is a compromise in the acceptance of a recoverable compensated systemic pathology to allow less injurious ventilation and hopefully permit the lungs to heal.[91] Criticism of these trials rests in their low enrollment and lack of power to show differences. As an answer to this critique, a large multicenter trial documented improved survival and increased ventilator-free days during the first 28 days in the ICU in patients with ARDS treated with low tidal volumes (6 mL/kg predicted body weight) versus traditional tidal volumes (12 mL/kg predicted body weight). In fact, the data safety committee halted the study early because the benefits incurred to the treated group were so clinically significant.[124] Suspected reasons for the improvements seen in this trial contrary to prior trials was the number of subjects enrolled as well as the defined protocol to limit both tidal volumes (volutrauma) and plateau pressures of less than 30 cm H_2O (barotrauma). Interestingly, this trial demonstrated decreased inflammatory markers, specifically IL-6, in the low tidal volume arm, suggesting a third possible mechanism of benefit (chemotrauma).

Theoretically the low tidal volume strategy subscribes to the theory of ARDS, which dictates that small healthy regions of lung exist adjacent to diseased and collapsed areas. In the conventionally treated group, higher tidal volumes and pressure are distributed only to open healthy alveoli; therefore the barotrauma of high pressures is delivered to this "healthy" lung, thereby increasing the damage there and worsening outcomes.[125]

In burned patients, decreased chest wall compliance, presence of smoke inhalation injury to the upper airways, and massive fluid administration coupled with increased CO_2 production due to hypermetabolism are just a few variables that make effective gas exchange challenging while optimally minimizing VILI. Prospective trials comparing modes of ventilation to minimize VILI are lacking in burn literature, making it difficult to ascertain which approach is best suited to this population. In 61 burned patients, one study showed no statistically significant differences between a pressure-limited strategy and a conventional strategy for mortality, pulmonary complications, or incidence of pneumothoraces.[126] In the trial comparing HFPV (a pressure-limited strategy) to an ARDSnet-based conventional strategy, a lower incidence of barotrauma was seen in the HFPV group. However there was no difference in inflammatory markers between the two modalities.[116]

It stands to reason that pressure-limited ventilation strategies (either conventional or high frequency) might be of benefit in burned patients in sufficiently powered studies. One outcome that should certainly be accounted for is the need for adjunctive therapies (rescue treatments), as implied earlier. Given current data, the best balance is struck by an experienced physician with a firm understanding of pulmonary physiology continuously weighing the systemic needs of the patient against the capabilities of available interventions and their potential pulmonary harm.

Epidemiology, Pathophysiology, and Treatment of ARDS. ARDS occurs as a result of injury to the lung, which can be direct through smoke inhalation or pneumonia or indirect through mediators associated with sepsis (Table 32.3). Until recently, most studies of ARDS reported mortality rates between 40% and 60%. Now, in trauma patients, the most recent mortality rate for ARDS was 14%; in addition, the incidence of ARDS fell by 50% in a matched patient population.[127] Thus we conclude that the incidence has gone down. What changed is the method of management, indicating that reducing the risk of further harm is the most effective treatment for this condition.

ARDS occurs because of damage to the endothelium and lung epithelium. It is speculated that the products of inflammation, such as cytokines, endotoxin, complement, and coagulation system products, induce the changes characteristic of ARDS.[122] The acute phase of ARDS is marked by an influx of protein-rich edema fluid into the air spaces as a consequence of increased permeability of the alveolar–capillary barrier (Fig. 32.9). The importance of endothelial injury and increased vascular permeability leading to the formation of pulmonary edema is well established. Epithelial injury is also of great importance. In fact, the degree of alveolar epithelial injury is an important predictor of outcome.

Neutrophils play a role in the pathogenesis of ARDS. Histologic studies of lung specimens obtained early in the course demonstrate marked accumulation of neutrophils in the alveolar fluid. However it must be stated that ARDS develops in patients with profound neutropenia, and some animal models of ARDS are neutrophil independent, implying that neutrophils may be nothing more than bystanders in the inflammatory process.[128]

The effects of ventilator injury on the development and progression of ARDS are now firmly established. Previous

Table 32.3 ARDS Risk Factors

Direct	Indirect
Pneumonia	Nonpulmonary sepsis
Aspiration of gastric contents	Major injury
Inhalation injury	Pancreatitis
Pulmonary contusion	Severe burns
Pulmonary vasculitis	Noncardiogenic shock
Drowning	Drug overdose
	Transfusion-related acute lung injury

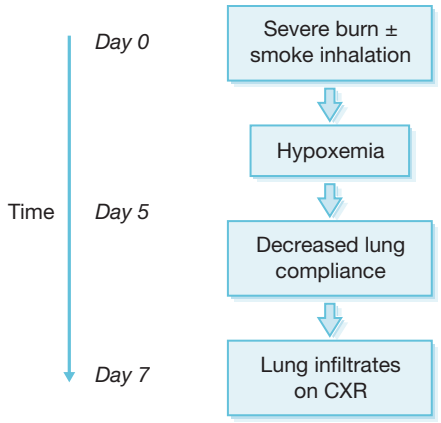

Fig. 32.9 Typical timeline for progression to acute respiratory distress syndrome (ARDS). Patients are typically intubated for airway compromise and operative intervention. At day 4 or 5 after severe burn, oxygenation will deteriorate, requiring higher inspired concentrations of oxygen. These measures will soon fail with the introduction of decreased lung compliance requiring higher inspired airway pressures. Only then will infiltrates begin to appear on the chest X-ray.

studies focused on the potentially damaging effects of high oxygen concentrations on lung epithelium and a prolonged F_{IO_2} of greater than 60% should be avoided.[129] Evidence suggests that mechanical ventilation at high pressures injures the lung,[124] causing increased pulmonary edema in the uninjured lung and enhanced edema in the injured lung.[130] Alveolar overdistension and cyclic opening and closing of alveoli associated with high ventilator pressures are also potentially damaging to the lung. High F_{IO_2} may predispose to this atelectrauma by displacing nitrogen from the alveoli. Nitrogen is then not absorbed and can serve as a stent maintaining airway patency.[90]

After the development of ARDS, some patients have a rapid recovery over a few days. Others progress to fibrotic lung injury; the alveolar space fills with mesenchymal cells, extracellular proteins, and new blood vessels. The finding of fibrosis on histologic analysis correlates with increased mortality.[131]

In nonfatal cases of ARDS, the lung heals by the proliferation of type II epithelial cells, which begin to cover the denuded basement membrane and differentiate into type I epithelial cells, restoring normal alveolar architecture, and increasing the fluid transport capacity of the alveolar epithelium. Alveolar edema is resolved by active transport of sodium from the distal airspace into the interstitium by intact alveoli. Soluble protein is removed primarily by diffusion between alveolar cells, while insoluble protein is eliminated by endocytosis and transcytosis by alveolar epithelial cells and phagocytosis by macrophages.

The severely burned are unique among patients who develop ARDS. Direct injury to the lung from smoke inhalation can cause respiratory insufficiency and relative hypoxia due to increased capillary permeability and interstitial edema increasing the A-a gradient, while ciliary dysfunction embarrasses expectoration. A few days later, the damaged and necrotic respiratory mucosa begin to slough, causing bronchial plugging and atelectasis, further worsening the clinical condition. However it is not typically until 4–8 days into the course of injury that severe hypoxemia and ARDS develop in burned patients, a scenario not unlike that in other types of patients who develop ARDS, such as after abdominal sepsis or multiple blunt trauma. While smoke inhalation is understandably associated with the development of ARDS, this affiliation is related to the inflammation corresponding to the injury in addition to that rendered by the burn wound. In fact, it was shown that the degree of inhalation injury was not associated with the development of ARDS in burned patients.[132] It may be, then, that smoke inhalation and ARDS are actually two distinct conditions that are related. Indeed, the preponderance of pathology in smoke inhalation is to the airways beginning proximally and decreasing in effect as you move more distally into the lung away from the source of smoke. Conversely the preponderance of damage in ARDS is alveolar, beginning distally and decreasing as it proceeds proximally.

Treatment of ARDS. Until the healing processes just described can be accomplished, the treatment of ARDS is largely supportive. A careful search for potential underlying causes should ensue, including attention to possibly treatable sources such as unexcised or open burn wounds, invasive burn wound infection, intraabdominal infections, pneumonia, line sepsis, or cholangitis, to name a few. Treatment of the inciting cause of ARDS and careful ventilator management aimed to limit further VILI while maintaining life-sustaining gas exchange are the core of ARDS treatment protocol. An improved understanding of the pathogenesis of ARDS has led to the assessment of several novel treatment strategies, including changes in mechanical ventilation strategies, fluid management, surfactant therapy, NO treatments, and antiinflammatory strategies.

The most appropriate method of mechanical ventilation for ARDS has been controversial for some time, although the picture is becoming clearer; the ARDSnet study provided much of this clarity.[124] They reported a 22% decline in mortality in patients with ARDS treated with tidal volumes of 6 mL/kg compared to those treated with conventional volumes of 12 mL/kg. In this study, peak airway pressures could not exceed 30 cm H_2O in the lower tidal volume group, and a detailed protocol was used to adjust the F_{IO_2} and PEEP. These results differed from those of smaller previous studies showing no improvement with pressure-limited ventilation. Potential reasons for the discrepancy between the National Institutes of Health (NIH) study and the others are as follows: the NIH study had the lowest tidal volume of the three studies and respiratory acidosis was allowed in the NIH study, with sodium bicarbonate treatment if necessary to maintain homeostasis. Furthermore the NIH study had more patients and so may have been more sufficiently powered to show differences between treatment groups.

The implementation and utility of low tidal volume protocols have been limited, likely due to the unique pathology of burn patients with hypermetabolism requiring greater gas exchange and inhalation injury requiring greater airway support and expectoration. In one study, one-third of burn patients failed to meet oxygenation and ventilation requirements when treated with low tidal volumes, and two-thirds failed when there was an inhalation injury.[85] Counter to the ARDSnet data, in a review of 28 years of 932 burned

pediatric patients with inhalation injury and stratifying for tidal volume, high tidal volume (15 +/− 3 mL/kg) was associated with significantly fewer ventilator days. This effect could reflect an interruption of events leading to lung injury following inhalation injury but could also evince the capacity of pediatric lungs to heal given their preserved stem cell function and ability to form airways de novo.[93]

PEEP has clearly been shown to benefit patients with ARDS; however the optimum level has been contentious. The best effects of PEEP are to increase functional residual capacity or the number of open alveoli at the end of expiration, as well as increase MAP-O_2 and thus oxygenation. However the use of prophylactic PEEP therapy in patients at risk for ARDS showed no benefit for the treatment group compared to controls.[89]

A study of PEEP therapy aimed at raising the level of PEEP above the lower inflection point on pressure–volume curves, thereby preventing alveolar closure, in conjunction with low tidal volumes and pressure-controlled IRV showed improved mortality compared to a control group managed with conventional ventilation.[133] Drawbacks to this study were the unusually high mortality (71%) in the control group; improvements in mortality for the treatment group compared to controls could only be determined at hospital day 28, which was not appreciated at hospital discharge.

Inhaled NO and prostaglandins are potent pulmonary vasodilators with effects localized to ventilated areas of the lung, thus directing more blood to the functional areas of the lung. The conceivable result, then, is to diminish the fraction of blood shunted through the lungs without oxygenation, thereby improving pulmonary venous oxygenation and reducing VQ mismatching. Observational studies suggest that inhaled NO might be beneficial in the treatment of ARDS by improving oxygenation without increased ventilatory pressures and reducing barotrauma. However randomized trials testing this hypothesis have, as of yet, been disappointing. In the most recent large study, inhaled NO therapy did not reduce mortality or the duration of mechanical ventilation. Improvements in oxygenation were seen, but the effects were not sustained.[134] The reported experience with this modality in burns is only anecdotal.

Prone positioning is another modality commonly used in BICUs for refractory hypoxemia, aimed to reduce VQ mismatch. This is based on the rationale that dependent areas of the lung in ARDS have the most blood flow and the most edema, thereby leading to a greater mismatch of blood flow and aerated lung and a greater shunting of blood past unaerated areas; hence blood returns to the heart unoxygenated. By placing the patient in the prone position for a prescribed period, the previously aerated lung now receives a greater portion of blood flow as directed by gravity. This approach almost always results in improved oxygenation, but, as with NO, has not been shown to be of benefit for mortality in prospective trials.[135] However two recent meta-analyses have demonstrated significant mortality benefit in those with severe hypoxemia.[99,136] Thus it appears that in certain subpopulations VQ mismatch therapies may be considered after carefully balancing risk versus benefit.

Ultimately if the lungs are too injured to provide the sufficient gas exchange required to maintain life, even with the support of mechanical ventilation and techniques aimed to minimize VQ mismatch, mechanical circulatory support must be considered. ECMO can be employed either in a venovenous method to only supplement gas exchange or in an arteriovenous method to also supplement cardiac function. Its use has the benefit of maximizing gas exchange while allowing total lung rest without need for further injurious ventilation techniques. There has been limited experience globally and no large trials to document any benefit to date. In a small series investigating ECMO, 60% of burned patients in the series survived and had significant improvements within 96 hours of ECMO administration.[137] This intervention must be regarded with great trepidation, given the need for anticoagulation and that cannulation prevents standard burn care and rehabilitation. This therapy can be life-saving, but it should be considered carefully and utilized only in the appropriate candidate. Often it is preferable to balance an injurious but survivable ventilation strategy with the other burn care needs of the patient.

Last, glucocorticoids have been used in the treatment of ARDS because of the inflammatory nature of the disease. There have been several trials with contradictory and equivocal data. To add fuel to the fire, the most recent large trial of glucocorticoid treatment of early severe ARDS showed an improvement in ventilator days and MOF scores.[138] Others have shown the benefit of glucocorticoids when used to good effect in the later fibroproliferative phases of the disease.[139] It is probable that some population with ARDS exists in which glucocorticoid treatment is of benefit, but we do not think it is burns. This type of therapy may be treacherous in burned patients at risk for invasive burn wound infection but might be considered upon complete burn wound closure. If steroids are used, high-dose vitamin A can be tried to ameliorate the wound-healing complications.[140]

GASTROINTESTINAL SYSTEM BURN CRITICAL CARE

Pathophysiologic Changes in the Gut After Burn

The gut, including the stomach, intestines, liver, and pancreas, plays six critical roles after burn injury: absorption of nutrients, mucosal barrier to invasive microbes, elimination of hydrophobic wastes, clearance of lactate, production of acute-phase proteins and coagulation factors, and an endocrine function able to drive toward anabolism. The gastrointestinal response to burn injury is highlighted by mucosal atrophy, changes in digestive absorption, and increased intestinal permeability. Changes in gut blood flow are related to changes in permeability. Intestinal blood flow was shown to decrease in nonresuscitated animals, a change associated with increased gut permeability at 5 hours post burn.[141] This effect was abolished at 24 hours. Systolic hypotension has been shown to occur in the immediate hours after burn in animals with a 40% TBSA full-thickness injury.

Clinical Changes in the Gut After Burn

Given these changes in the gut from burn, it is commonplace to observe some evidence of gut dysfunction after burn, as evidenced by feeding intolerance and mucosal ulceration and bleeding, particularly in the stomach and

duodenum.[5] Enteral feeding is an important means of providing nutrition to burned patients and has led to a decrease in mortality, but on occasion the gut will not cooperate. Reduced motility and ileus are common, as is diarrhea, at times requiring parenteral nutrition to meet caloric needs. At present there is no specific treatment for burn-induced ileus, but early enteral feeding prevents some of these potential complications.

The best management for the gut and the patient in total is sufficient enteral nutrition. Ascertaining the amount and type of nutrition is the subject of Chapter 28 on nutritional support. It is worth noting here that feeding the gut promotes mucosal barrier function, nourishes the patient, and promotes bile flow, elimination of hydrophobic wastes, and an anabolic hormonal release from the gut and pancreas.[142,143] In determining the amount to feed, measurement of resting energy expenditure is superior to equations used to estimate caloric needs, such as the World Health Organization (WHO), Schodield-HW, and Harris-Benedict equations and, as such, should be used to calculate feeding goals.[144]

Stress ulceration of the stomach and duodenum, on the other hand, can be prevented effectively with antacid therapy. In the 1970s, stress ulceration leading to life-threatening hemorrhage was common. The mechanism of injury corresponds to an imbalance between protective factors, such as mucus production, protective prostaglandin output, and bicarbonate secretion, and injurious factors, such as decreased blood flow and acid production. Gastric ulcers developed in the watershed zones between capillary beds, which are worsened by gastric acid-induced injury. With today's use of standard critical care techniques, including gastric acid suppression and expeditious wound closure, upper gastrointestinal bleeding is relatively rare. When it occurs, treatment is congruent with standard upper gastrointestinal bleeding protocols through identification of the bleeding source and control with local techniques or surgery when required.

Abdominal compartment syndrome has proved a significant risk. This is associated with massive volume resuscitation, inducing generalized edema in a relatively limited abdominal compartment. It eventuates in decreased gut blood flow and renal blood flow causing oliguria and bowel ischemia.[145] The tragedy is that the early sign of this condition is low urine output, which is commonly addressed by more intravenous fluid, which only worsens the case. The associated physical finding is abdominal distension. An estimate of intraabdominal pressure can be obtained by pressure monitoring of the bladder; pressures of greater than 30 torr are concerning and should instigate further investigation. Treatments are aimed at reducing intraabdominal pressures through drainage, sedation, and paralysis, or decompressive laparotomy if needed.[146] Unfortunately those with burns of greater than 40% TBSA are at highest risk for abdominal compartment syndrome and have a mortality rate approaching 100% when treated with decompressive laparotomy.[87] Therefore the best treatment for this condition is prevention through judicious resuscitation, as discussed in Chapters 8 and 9 on burn edema and resuscitation, respectively.

The liver also plays a critical role in the recovery from burn injury. Acute liver failure is a rare occurrence in burn injured patients and is more thoroughly discussed in Chapters 30 and 31 on MOF and the liver, respectively. It is related to ICU common causes such as preexisting cirrhosis, drug toxicity, or viral activation, but also to burn-specific issues such as hepatic steatosis, right heart failure, and/or fluid overload. High central venous pressures (CVPs) compromise the pressure gradient from the portal system that provides 75% of the oxygen delivery to the liver, thus creating an ischemic injury.[147] Treatment is to first remove hepatotoxic medications and reduce CVP to improve hepatic perfusion, then begin symptomatic treatment including monitoring and treating elevated ICP; treating hemodynamic failure, respiratory failure, and hypoglycemia; and replacing clotting factors.[148]

Pancreatitis also occurs, though rarely subsequent to burn injury. Its etiology tends to be ischemic in nature, with an incidence of 0.17% demonstrated in a pediatric series. It is associated with elevated mortality and thus should be taken seriously. It is diagnosed with elevated amylase or lipase in conjunction with abdominal pain, feeding intolerance, or radiographic signs. Treatment is feeding distal to the ligament of Trietz and, should this fail to abate the pancreatitis, bowel rest is advisable with parenteral feedings.[149]

RENAL BURN CRITICAL CARE

Pathophysiology

Acute kidney injury (AKI) is a potentially lethal complication of burns. Of note, AKI has supplanted the prior term (acute renal failure [ARF]). Despite substantial technical developments in dialysis to replace the function of the kidneys, mortality meets or exceeds 50% for all critically ill patients who develop ARF.[150] Interestingly mortality associated with AKI undergoing hemodialysis for frank renal failure in the critically ill has not improved significantly in more than 40 years. The same can be said for renal failure requiring dialysis, specifically in the severely burned. The cause of death in these critically ill patients was not uremia because of advances in dialysis, but primarily sepsis and cardiovascular and pulmonary dysfunction.[151]

With the advent of early aggressive resuscitation after burn, the incidence of renal failure coincident with the initial phases of recovery has diminished significantly in the severely burned. However another period of risk for the development of renal failure 2–14 days after resuscitation is still present and is likely related to the development of sepsis.[152] Transient hypotension, nephrotoxic medications such as antibiotics, hypovolemia from insensible fluid losses, and rhabdomyolysis are all also significant etiologies of AKI in the BICU.[153]

AKI, usually in the form of acute tubular necrosis (ATN), is characterized by deterioration of renal function over a period of hours to days, resulting in the failure of the kidney to excrete nitrogenous waste products and maintain fluid and electrolyte homeostasis. It may be caused by a number of factors interfering with glomerular filtration and tubular resorption. In burned patients, the causes can be generally narrowed to renal hypoperfusion, nephrotoxic insults from pharmacologic treatments (e.g., aminoglycosides or intravenous contrast agents), or sepsis.[153] Ischemic renal failure

is the more common of the three causes and is induced by hypoperfusion from an imbalance between vasoconstrictive and vasodilatory factors acting on the small renal vessels during low-flow states. Decreased flow to the renal cells directly alters endothelial cell function, reducing the production of and response to vasodilatory substances. The renal medulla is the portion of the kidney most sensitive to hypoxia, and the damage is initially to the renal tubular cells. The outer medulla and proximal tubules have high oxygen requirements, and the resulting ischemia causes swelling of tubular and endothelial cells, with necrosis, apoptosis, and inflammation evident on a histologic examination. These changes lead to further vascular congestion and decreased blood flow, resulting in more cell loss and further decrements in renal function. Characteristic tubular casts can be seen on urine microscopy that is diagnostic for ATN.

After the initiating event, tubular function and glomerular filtration rate (GFR) decrease to reduce urine production. The progression of AKI is commonly divided into three phases: initiation, maintenance, and recovery; it can be oliguric (urine output <400 mL/day) or nonoliguric (urine output >400 mL/day) in nature. Patients with nonoliguric AKI have a better prognosis than oliguric AKI patients, probably due in large measure to the decreased severity of the insult and the fact that many have drug-associated nephrotoxicity or interstitial nephritis.[151]

Once AKI is established, pharmacologic improvement of renal blood flow will not reverse the injury. Agents such as dopamine, which was commonly used in the past to dilate renal arterioles and increase renal blood flow via dopamine receptors, have been shown to be mostly ineffective.[154] Recently the potent dopamine-1 receptor agonist fenoldopam has garnered some interest as an agent to improve renal perfusion and outcomes. A meta-analysis of randomized controlled trials demonstrated that low-dose fenoldopam (0.03–0.09 μg/kg per minute) may be of benefit in reducing the need for renal replacement therapy and hospital mortality when used in septic patients with either established AKI or at high risk for AKI in a mixed ICU population.[155] Its use in this setting has been reported in a noncontrolled study in burned patients, with improvement in renal function (increased urine output and decreased serum creatinine) and without any hypotension at the low dose.[156] Further work will need to be done in the burn population to fully determine its efficacy.

Diuretic therapies, such as mannitol and loop diuretics, have been used extensively in patients with AKI to increase urine flow and protect the kidney from further ischemic damage. Mannitol can reduce cellular swelling in the proximal tubule and increase intratubular flow, thus potentially decreasing intratubular obstruction and further renal dysfunction. Mannitol has been previously recommended along with vigorous volume replacement and sodium bicarbonate for the treatment of early myoglobinuric acute kidney injury. However recent evidence suggests a lack of benefit and a need to reevaluate this practice.[157] Loop diuretics also increase intratubular flow rates and can convert an oliguric state to a nonoliguric state, thereby facilitating clinical management of renal failure. While patients with nonoliguric AKI are generally easier to manage from a volume standpoint, there is no evidence that conversion from an oliguric to a nonoliguric state improves outcomes.

Table 32.4 Laboratory Tests to Distinguish Prerenal from Intrinsic Renal Failure

Examination	Prerenal	Intrinsic Renal
Urine osmolality (mmol/kg)	>400	<400
Urinary sodium (mEq/dL)	<20	>40
FENa (%)*	<1	>2

*FENa, fractional excretion of sodium, calculated as (U/PNa/U/PCr) × 100, where U is urinary concentration, and P is plasma concentration. Na is sodium and Cr is creatinine.

The initial care of patients with AKI is focused on reversing the underlying cause and correcting fluid and electrolyte imbalances. Renal failure is heralded by a decrease in urinary output. Volumes of urine of less than 1 mL/kg per hour may indicate the onset of AKI. This failure may be due to a prerenal cause, which is typically due to decreased renal blood flow from hypoperfusion, or intrinsic renal causes, which are associated with medications, rhabdomyolysis, or sepsis. Differentiation between these etiologies can be made with laboratory examinations (Table 32.4). Prerenal etiologies are associated with concentrated urine (urine osmolarity >400 mmol/kg), decreased urinary sodium concentrations, and decreased fractional excretion of sodium. Intrinsic renal causes will be associated with a more dilute urine with higher sodium concentrations. These tests should be performed before diuretics are administered because this treatment will increase urinary sodium and decrease urine osmolality even in prerenal conditions. In general, urine osmolarity and urinary sodium concentrations are primarily used for these determinations because of the ease of measurement. In terms of clinical utility, renal dysfunction is often a mixture of prerenal and intrinsic causes, making treatment decisions difficult.

Should these tests reveal a prerenal cause, volume optimization should ensue to prevent further renal ischemia, although in the fluid overloaded patient with heart failure inotropes may be necessary. Physical examination and invasive monitoring, if deemed appropriate, should guide this volume replacement. The decision to administer or remove fluids may prove difficult, however, because both strategies have detrimental consequences if followed inappropriately. Although volume replacement is ineffective in restoring renal function once tubular necrosis is established, it remains the most effective prophylactic strategy, and so is generally the place to start at the onset of renal failure.

Owing to the wide variation in the definition of AKI, reporting an accurate incidence, as well as resultant outcomes, has been problematic. In an effort to resolve this and standardize the classification of AKI, the Acute Dialysis Quality Initiative (ADQI) developed and reported the Risk, Injury, Failure, Loss of function, End-stage (RIFLE) renal disease criteria.[158] More recently, the Acute Kidney Injury Network (AKIN) proposed a modified version of the RIFLE system because of a number of identified limitations. These revised criteria are intended to simplify the definition and make it more clinically applicable. According to the AKIN

criteria, stage 1 AKI is delineated by "an abrupt (within 48 hours) reduction of kidney function currently defined as an absolute increase in serum creatinine of more than or equal to 0.3 mg/dL, a percentage increase in serum creatinine of more than or equal to 50% (1.5-fold from baseline), or a reduction in urine output (documented oliguria of less than 0.5 mL/kg per hour for more than 6 hours)." Stages 2 and 3 are the same as RIFLE—Injury and Failure, respectively.[159]

In burned patients, investigators showed that the incidence and outcomes of greater than 20% TBSA burned patients with AKI using RIFLE criteria was 24% (12% Risk, 8% Injury, and 5% Failure). Associated mortality was 14%, which increased directly with each RIFLE class (7% normal, 13% Risk, 40% Injury, and 83% Failure). Renal dysfunction occurred within 7 days in 55% of affected patients and completely recovered in all survivors; pulmonary dysfunction was present in all. Sepsis was a possible aggravating factor in acute kidney injury in 48%. They concluded that AKI is common after severe burn, develops within days of injury, and parallels other organ dysfunction.[160] These data confirm earlier studies showing that the development of renal failure is associated with dismal outcomes. Minor dysfunction does not necessarily correlate to progression and mortality, giving hope to therapies designed to maintain renal function after severe burn.

Another study examined the incidence of renal dysfunction in burned patients, defined by serum creatinine levels of greater than 1.4 mg/dL. Thirty-nine percent of patients admitted to the BICU developed renal insufficiency, of which 33% underwent renal replacement therapy. Associated mortality in those with renal insufficiency was 44%. Those who developed renal insufficiency within 5 days of thermal injury had a higher mortality than those with later onset. Of interest, all survivors regained normal renal function later in their course.[153] The next study investigated early markers of renal dysfunction and found that elevations in urinary microalbumin and malondialdehyde (both three- and fourfold) were present in all burn patients with eventual renal dysfunction.[161] These may come to be indicators of risk for injury that can be acted upon early to prevent progression to more severe degrees of failure and thereby improve outcomes.

The last study investigated the role of continuous venovenous hemofiltration (CVVH) in the treatment of renal dysfunction after severe burn. Investigators compared a population of patients treated with high-volume CVVH (at least 50 mL/kg per hour) compared to nontreated historical controls and found that both 28-day and mortality improved by 50% with this therapy.[162] A multicenter RCT comparing early high-volume CVVH (70 mL/kg per hour) to standard care is under way in this high-risk population (ClinicalTrials.gov Identifier: NCT01213914).

After ensuring adequate volume status, every effort should be made to prevent other causes of renal injury. All nephrotoxins should be discontinued or avoided. Hyperkalemia may develop and can be treated with resins, glucose and insulin, and sodium bicarbonate in the presence of metabolic acidosis. Medications eliminated through the kidney should be adjusted. Once the diagnosis of AKI is established, consideration can be given to diuretic therapy or the early initiation of CVVH, especially if it is determined that the patient is volume overloaded. Reducing the volume of fluid given can also alleviate volume overload in burned patients. These patients have increased insensible losses from the wounds that can be roughly calculated at 3750 mL/m^2 TBSA wound plus 1500 mL/m^2 TBSA total. Reducing the infused volume of intravenous fluids and enteral feedings below the expected insensate losses may alleviate some of these problems.

However it is important to continue sufficient nutritional delivery to the patient and balance this against the renal function, utilizing diuretics and even dialysis to ensure an excessive nutrient debt does not develop. Reducing potassium administration in enteral feedings and giving oral bicarbonate solutions can minimize electrolyte abnormalities. Almost invariably, severely burned patients require exogenous potassium because of the heightened aldosterone response resulting in potassium wasting. Therefore hyperkalemia is rare, even with some renal insufficiency. Indeed, spironolactone is generally a wise adjuvant to loop diuretics in burn patients due to this potassium wasting.

Intermittent dialysis remains a viable replacement therapy for severe AKI in the hemodynamically normal ICU patient, although this is changing. The indications for dialysis are edema and volume overload, electrolyte abnormalities not amenable to other treatments, or refractory acidosis. In recent years, continuous renal replacement therapies (CRRT) have emerged as another option for critically ill patients with AKI. The advantages of continuous over intermittent treatment include more precise fluid and metabolic control, increased hemodynamic stability, and the enhanced ability to remove injurious cytokines. Additionally many BICU surgeons perform CRRT without use of nephrologists or dialysis nurses, thus making the timely application of CRRT practical as a component of burn critical care. Disadvantages constitute the need for heightened surveillance, heavy resource and nursing utilization, and slower overall clearance compared to intermittent dialysis.

Peritoneal dialysis (PD) is another option for AKI in burned patients.[163] Catheters can be placed at the bedside with near-continuous exchanges to improve electrolyte and volume overload problems. The capital required for this treatment is minimal and surgeons unable to perform CRRT can easily place a catheter and begin PD. Hypertonic solutions are used to remove fluid volume, and the concentrations of potassium and bicarbonate are modified to produce the desired results. The dwell time is usually 30 min, followed by 30 min of drainage. This treatment can be repeated in cycles until the problem is resolved. For maintenance, 4–6 such cycles a day with prolonged dwell times (1 h) is usually sufficient during the acute phase. This treatment is known to be useful in burned patients but has not received a significant amount of study.

HEMATOLOGIC BURN CRITICAL CARE

Burn patients are subject to major blood loss due to phlebotomy and surgery. As such, they can suffer intravascular hemolysis in burn wounds. They also suffer hematopoietic suppression or modulation from inflammation and adrenergic causes. Coagulation factors and platelets can be consumed, creating a consumptive coagulopathy. Resultantly transfusion is a standard component of burn critical care.

The threshold for transfusion in the euvolemic patient has been lowered over the past decades through sequential studies. Concomitantly the indication for transfusion in the setting of active hemorrhage has been expanded. In a landmark study in the *New England Journal of Medicine,* Holst et al. demonstrated in septic shock a transfusion threshold of 7 mg/dL.[164] Lelubre et al. subsequently showed this to be a safe threshold in burn patients, although they did note a 5.9% rate of protocol suspension for myocardial ischemia in 1.2% of burn patients or life-threatening bleeding in 3.7%.[165] Palmieri and Greenhalgh similarly demonstrated that restrictive blood transfusion does not adversely impact outcomes and causes significant savings.[166] In a series of greater than 60% TBSA burned children with inhalation injury, Jeschke and Herndon determined high transfusion patients (>20 units PRBC/>5 FFP) had their risk of sepsis increase from 8% to 58%, and they concluded that the immunocompromising effect of blood transfusion may be the etiologic factor.[167] Collectively these data support the practice of restrictive transfusion in the euvolemic burn patient without active hemorrhage.

In patients undergoing active hemorrhage, those who are at risk of or are in hemorrhagic shock, transfusion is critical. This occurs commonly during burn excision or in the postoperative resuscitation. These patients should be actively and rapidly transfused, as would be done in any trauma, with a goal of maintaining euvolemia, hemoglobin, clotting factors, normal pH, and temperature. U.S. Army data have demonstrated that whole blood transfusion is associated with improved survival compared to resuscitation with blood components for hemorrhagic shock. However whole blood is not yet available in the civilian world; groups are working to develop a civilian equivalent with storage stability at 4°C for 15 days.[168]

The current standard is to transfuse blood components in a 1 : 1 ratio of red cells to plasma. Pidcoke et al. did find the amalgamated transfusate samples administered to burn and soft tissue excision patients produced abnormally weak clots and have inferior platelet functions, thus concluding the transfusates were not hemostatic.[169] Regardless, given the currently available products, these component-based therapies are the standard of care.

In addition to meticulous and rapid techniques, epinephrine, thrombin, and direct pressure, antifibrinolytic therapy has also been used to limit intraoperative hemorrhage during burn excision. In the CRASH-2 trial, tranexamic acid (TXA) was shown in a double-blind RCT to reduce all-cause mortality and severe blood loss in traumatic bleeding.[170–172] However TXA use has only been defined topically in one burn case study, although a clinical trial is currently examining its parenteral value in burn wounds.[33]

Finally, transfusions of albumin or fresh frozen plasma (FFP) are key components of resuscitation, both in the acute burn setting and also in the critical care setting. As discussed extensively in Chapter 8 on burn edema, large-volume resuscitation with crystalloid damages the endovascular glycocalyx, thereby encouraging edema. This damage is limited with colloidal resuscitation, particularly plasma.[173] In select patients where interstitial or pulmonary edema is of significant concern, resuscitation with plasma transfusion may thus be indicated.

Burn wounds create a hypercoagulable environment due to the procoagulant effects created by the release of subendothelial collagen and also of tissue thromboplastin leading to a high risk of venothromboembolism (VTE). Data from a University of Michigan study demonstrated a substantial incidence of deep venous thrombosis (DVT) in 23% of their burned population with TBSA of less than 30%.[174] Several methods have been advocated to reduce the incidence of complications, including DVTs and capillary thrombosis, from this hypercoagulable state. One treatment, first proposed by Leyvraz, maintains a prothrombin time (PTT) of 1.2 times normal values using a sliding scale unfractionated heparin protocol.[175] This can be achieved via either a subcutaneous route or IV route; our institution prefers to use the intravenous route with monitoring of the PTT, starting with a dose of 5 units/kg per hour. Other methods include standard prophylaxis with low-molecular-weight heparin (LMWH).[176] The altered pharmacokinetics of burn patients benefit from factor Xa monitoring to assure prophylactic anticoagulation with LMWH. In a meta-analysis of RCTs involving 7226 ICU patients, those receiving any heparin-based VTE compared with placebo demonstrated reduced rates of DVT (relative risk [RR] 95%; confidence interval [CI] 0.41–0.63) and pulmonary embolism (PE) (RR 0.28–0.97), but not symptomatic DVT (RR 0.59–1.25), major bleeding (RR 0.56–1.21), or mortality (RR 0.78–1.02). LMWH was more effective compared to unfractionated heparin reducing rates of PE (RR 0.39–1.00) and symptomatic PE (RR 0.34–0.97), but not DVT (RR, 0.74–1.08), symptomatic DVT (RR 0.60–1.25), major bleeding (RR 0.75–1.26), or mortality (RR 0.82–1.04).[177] Overall, specifically in patients not actively hemorrhaging or where prophylaxis is contraindicated, VTE prophylaxis should be addressed.

ENDOCRINE BURN CRITICAL CARE

The role of the endocrine system in burn injury was thoroughly addressed previously in Chapter 23, so here we will focus on the practical critical care implications. Hyperglycemia and insulin resistance are common in the critically ill, and the burned patient is no exception. In 2001, Greet van den Berge reported in a landmark trial that intensive insulin treatment with continuous infusions of insulin aimed at normalizing blood glucose levels between 80 and 110 mg/dL reduced bloodstream infections and acute kidney injury and improved mortality.[178] This study was among the first to show some benefit of a treatment for all critically ill patients. Since this study, most intensivists throughout the world have targeted glucose control in a more normal range through the use of insulin. This may have other beneficial effects because investigators have shown an anabolic benefit of insulin treatment in burned patients in terms of muscle mass.[179] Intensive insulin treatment significantly decreases sepsis and infections, as well as reducing organ dysfunctions, thereby reducing IL-6 and acute-phase proteins. There was a trend toward reduced mortality; however the study was not sufficiently powered for this outcome.[180]

The particular range to which glucose should be controlled has not been firmly established, however, as the latest large-scale study on glucose control in the ICU did not

find a benefit to keeping glucose in the normal range, but rather indicated a higher range might have been even more beneficial.[181] The caveat to this analysis is that, on a post-hoc basis, injured patients had better outcomes with a normal glucose range rather than higher. However a growing body of evidence has demonstrated that hypoglycemic episodes (<60 mg/dL) cause increased length of stay, more infections, sepsis, MOF, and mortality.[182] Interestingly these negative outcomes and mortalities were not an acute result of the hypoglycemia, thus indicating there are lasting negative effects of transient and even successfully treated hypoglycemias. As such, the Society of Critical Care Medicine tolerates higher blood glucoses, in the 150–180 mg/dL range.[71] Methods to balance the benefits of euglycemia with the risks of hypoglycemia remain an active area of study in critical care.

In another landmark trial, cortisol levels were found to be low in many critically ill patients, and a mortality benefit accrued with physiologic replacement with hydrocortisone.[183] This study highlighted that hypocortisolemia is, at the very least, associated with septic shock and hypotension, and that replacement with hydrocortisone at 50 mg every 6 h improves outcomes. The same was seen in burned patients in the ICU.[184,185] This occurs despite the demonstrated fact that burn patients are in a hyperadrenal state.[186] It must be noted, however, that the benefits seem to be limited to those with relative adrenal insufficiency assessed by corticotropin stimulation, as seen in the follow-up CORTICUS trial.[187] Regardless, in the case of hypotension unrelated to hypovolemia in burn patients, cortisol levels and adrenal stimulation can be performed to determine whether relative adrenal insufficiency exists.

Venet et al. performed a placebo-controlled, double-blind RCT testing hydrocortisone in BICU patients suffering from refractory shock, defined as greater than 0.5 μg/kg per minute of norepinephrine. They found a significant reduction of norepinephrine treatment duration. Of note, 78% of these patients had a negative corticotropin stimulation test. They concluded low-dose hydrocortisone in burn patients with refractory shock reduces vasopressor administration.[188] These data thus obviate the value of cortisol stimulation tests. In a subsequent study, Winter et al. demonstrated that a hydrocortisone bolus of 100 mg followed by a 0.48 mg/kg per hour infusion improved norepinephrine dosing in burn survivors, but not in nonsurvivors.[185]

Burn surgeons are typically reticent to risk the negative wound healing and immunosuppressive complications of glucocorticoids. However, in the setting of refractory shock, a trial of steroids can prove diagnostic and therapeutic. Furthermore high-dose vitamin A can be utilized to ameliorate the wound-healing complications.[140]

INFECTIOUS DISEASE BURN CRITICAL CARE

Sepsis is a leading cause of mortality in burn patients and is the subject of Chapter 11. Sepsis has two potential causes: infection or inflammation without infection. Reliable detection of those patients with some component of infection is crucial. Our difficulty in severe burns is delineating this because traditional screening indicators for infection, such as temperature and white blood cell count, are unreliable because of the massive hypermetabolism and inflammation associated with recovery and healing.[189,190] The current standard for diagnosis is a high index of suspicion and frequent culturing of wounds, lines, blood, airways, urine, and any other potential source. Suspicion must as well be maintained for invasive yeast and molds, viruses (most especially herpetic viruses), and, of course, bacteria.

Potential does exist for elevations in procalcitonin (PCT) to be associated with a higher risk of infection, this being linked to pathogen infection presumably through PAMPs rather than DAMPs. An interesting study from Iran examined the role of white blood cells, sedimentation rate, C-reactive protein, and PCT in diagnosing sepsis in the severely burned. The authors found that PCT was the only test with any distinguishing capacity and accuracy.[191]

In a recent meta-analysis of 566 patients from nine trials of sepsis in burn patients, PCT demonstrated a sensitivity of 0.74 and a specificity of 0.88.[192] In a subsequent study, a protocol was instituted utilizing PCT to determine duration of antibiotic therapy in 46 burn BICU patients. Antibiotic duration was significantly reduced without relapse of infection, increase in mortality or organ failure, or increase in length of stay.[193] PCT has not yet become a standard of care; however data continue to support its utility in the burn population.

Prevention of Organ Failure

This brief outline of the potential pathophysiology and causes of burn-induced critical illness and MOF demonstrates the complexity of the problem. Prevention of organ failure is the subject of Chapter 30. Because different cascade systems are involved in the pathogenesis, it is currently impossible to pinpoint a single mediator or system that initiates the event. Thus because the mechanisms of progression are not well known and specific treatments cannot be accurately devised, it seems that prevention is the best solution. Current recommendations are to prevent the development of organ dysfunction and provide optimal support to avoid the conditions that promote its onset. In burned patients this can be accomplished most reliably through expeditious wound closure, rapid mobilization of the patient, and prompt identification of and treatment of early infections.

Conclusion

Burn critical care is predicated on seven key factors: sufficient goal-directed fluid resuscitation; early burn excision and wound coverage; aggressive antimicrobial and source control of sepsis; aggressive nutritional support; active warming; aggressive physical, occupational, and respiratory therapy; and aggressive and continuous support of organ failures until such time as the patient can heal. This care has reduced mortality over the past three decades, in large part through the development of specialized units for the care of burned patients. These units are equipped with the personnel and equipment to deliver state-of-the-art care. Better understanding of the processes of critical illness and MOF has led to effective prevention strategies and treatment modalities. Further advances in the understanding of

the mechanisms of the progression from SIRS to MOF might engender new breakthroughs that can be expected to further improve the outcomes of burned patients.

33 Burn Nursing

DEBRA A. BENJAMIN and MARY JACO

Introduction

The bedside nurse caring for the severely burned patient is given more responsibility than in most types of serious illness. It is extremely important that the nurse be an integral part of the team of people caring for the burned patient.[1] This is as important when modern burn care began as it is today. Care begins with the immediate resuscitation of the patient in the emergency department and continues until discharge, through rehabilitation and surgical reconstruction, until the patient is completely recovered and reintegrated into society. During the acute hospitalization, the nurse caring for the burned patient spends more time with the patient than any other member of the burn team. Because of this, especially during the acute hospitalization, the nurse is the best person to notice changes in patient condition and status and must continuously keep various team members updated on changes. Physical changes can include fluid balances, cardiovascular changes, neurological status changes, and tolerance of nutritional feedings. The nurse may also be the best person to act as patient advocate for psychosocial needs such as pain control, anxiety, and the like.

Emergency Needs: Resuscitation and Pulmonary Priorities

One of the first priorities in caring for the burn patient after assuring that the patient's airway is secure is to address cardiovascular needs. After a patient receives a severe burn injury, a leakage of fluids into the area of the burn injury causes swelling and may prevent circulation to that and distal areas. Circumferential burns especially need to be monitored to ensure there that is adequate circulation to the surrounding tissues and areas distal to the burn. Pulses must be checked hourly, and any diminished or absent pulses should be reported to the physician immediately. Another complication is circumferential third-degree burns around the chest and neck, which often cause restrictive defects. The increased amount of edema, combined with decreased chest excursion, may greatly decrease tidal volume. This condition may progress and can become life threatening, in which case chest escharotomy may be necessary to release the constricting eschar. The procedure may be done at the bedside or in the operating room. Equipment includes sterile drapes, scalpel, and electrosurgical unit (to control bleeding).

As fluids shift from the cardiovascular system to the interstitial regions of the burn, there may be a subsequent drop in blood pressure and organ perfusion and a decrease in urine output. It is the responsibility of the nurse, who is always with the patient, to monitor the patient's vital signs and urine output and notify the physician of changes to ensure an adequate fluid and cardiovascular status. An adult should maintain a urine output of 0.5 cc/kg per hour and a child should maintain a urine output of 1.0 cc/kg per hour. Lower urine volume rates may indicate hypovolemia, which can lead to cardiovascular collapse. Resuscitation fluids are to be started as soon as the patient first comes in contact with medical personnel. This is normally accomplished with IV fluids using resuscitation formulas designed for adults or children, or through oral ingestion of fluids.[2] The goal is to provide adequate fluid resuscitation to maintain a normal cardiovascular status, perfusion of organs and tissues, and an adequate urine output.

Inhalation injury continues to be the most serious and life-threatening complication of burn injury. Early diagnosis and treatment greatly impact the outcome of care. Impaired gas exchange is a potential problem for patients who have face and neck burns and/or inhalation injury. Inhalation injury may include carbon monoxide poisoning, upper airway injury (heat injury above the glottis), lower airway injury (chemical injury to lung parenchyma), and restrictive defects (circumferential third-degree burn around the chest). Upper airway edema causes respiratory distress and is the primary concern during the initial 24- to 48-hour postburn phase. Tracheobronchitis, atelectasis, bronchorrhea, pneumonia, and adult respiratory distress syndrome (ARDS) may occur during the acute postburn stage either related or unrelated to inhalation injury.

Nursing care of a patient with inhalation injury begins with a detailed history of the accident. Inhalation injury is suspected when the accident occurred in a closed space. Close observation of the patient and frequent respiratory assessments are made throughout the initial and acute phase postburn. Initially the patient is observed for hoarseness and stridor, which indicate narrowed airways. Emergency equipment is placed at the bedside to facilitate intubation if necessary. Observing an increased frequency of cough, carbonaceous sputum, and increased inability to handle secretions may indicate possible inhalation injury and the potential for impaired gas exchange. Other important observations include respiratory rate, breath sounds, the use of accessory muscles to aid in respiratory effort, nasal flaring, sternal retractions, increased anxiety, and complaint of shortness of breath. Disorientation, obtundation, and coma may be due to significant exposure to smoke toxins such as carbon monoxide or cyanide. These conditions are managed emergently with 100% oxygen.

Bronchoscopy may be done early to diagnose inhalation injury as well as to facilitate airway clearance. Humidified oxygen should be readily available and applied to patients who have evidence of impaired gas exchange (especially

pediatric patients). Aggressive nasotracheal suction may be indicated if the patient has difficulty managing secretions either because of the increased amount of secretions and/or the decreased effectiveness of the cough. In addition, aggressive pulmonary toilet, including turning, coughing, deep breathing, and up and out-of-bed rocking in mother's arms may be done regularly and frequently. Elevation of the head of the bed, unless contraindicated, will also support and possibly improve ventilation. Trends and changes should be correlated with laboratory results and shared with the team.

Intubation and mechanical ventilation may be required to improve gas exchange. Tube placement should be checked and documented frequently and verified daily by X-ray. Securing the endotracheal tube requires a standard technique for stabilization and prevention of pressure necrosis. Adequate humidity is necessary to prevent secretions from drying and causing mucous plugging. Remember to provide pre-/postsuctioning hyperoxygenation. Sterile technique is used when suctioning to prevent infection. Attention to the details of oral hygiene will provide comfort for the patient and may reduce the occurrence of ventilator-associated pneumonia related to colonization in the oral pharynx.[3]

Criteria for extubation depend on the reasons that the tube was inserted initially, but, overall, stable vital signs and hemodynamic parameters will support the plan for extubation. The patient should be awake and alert in order to protect the airway; therefore pain medications may be reduced before extubation. Ventilatory measurements and blood gas analysis should be within normal limits.

Immediately following extubation, the nurse must be alert for signs and symptoms of respiratory distress, administer suction as needed, monitor blood gas measurements, and provide optimal positioning for ventilation, as well as provide reassurance and support to decrease anxiety.

Age, burn size, and the presence of inhalation injury and pneumonia have been identified as major contributors to mortality.[4] Thus vigilant nursing care (frequent nursing assessments, aggressive pulmonary toilet, etc.) combined with anticipating potential problems and being prepared to deal with those problems will add to the team effort and possibly improve patient outcome.

Acute Care of the Burn Wound

The primary goal for burn wound management is to close the wound as soon as possible. Prompt surgical excisions of the eschar and skin grafting have contributed to reduced morbidity and mortality in severely burned patients.[5–7]

Wound care in the burn unit has become a specialized art of burn nursing practice. It can be extremely challenging and complicated, and, for a new nurse, it can be the most difficult and misunderstood part of burn nursing. The complexity exists because of the variety of wound types, each of which requires different interventions in relation to time postburn or time postoperative. Wound assessment and care is a learned skill that develops over time. These skills must be taught by experienced nurses to new burn nurses. Assessment of the burn wound takes place in the hydrotherapy area, the operating room, and at the bedside.

Wounds may consist of eschar, pseudo eschar, skin buds, autografts, donor sites, hypermature granulating tissue, blisters, and exposed bone and tendons. In addition to the many kinds of possible wounds, there are many topical antibacterial agents available for managing wounds. These choices raise many decisions for the team to address. Topical antimicrobial creams and ointments include mafenide acetate, silver nitrate, silver sulfadiazine, petroleum and mineral oil-based antibacterial products, and Mycostatin powder. Wounds may be treated in the open fashion (topicals without dressings) or closed fashion (topicals with dressings or soaks). There are several techniques for applying dressings to different areas of the body that need to be able to withstand exercise, ambulation, and moving around in bed. Biological dressings, such as homografts or heterografts, may be used as temporary wound coverage. Dressings may also be synthetic or biosynthetic or silver-impregnated. Selection is based on the present condition of the wound and the expected outcome.

Secondary goals of wound care are to promote healing and to maintain function of the affected body part. These goals are accomplished by preventing wound infection, treating wound infection, preventing graft loss and tissue necrosis, providing personal hygiene, and maintaining correct positioning and splinting throughout hospitalization. To prevent burn wound infection, the burn nurse must cleanse the wound with soap and water; débride the wound of loose necrotic tissue, crusts, dried blood, and exudate; apply topicals or dressings; and ensure that dressing changes are ordered and done. The nurse must inspect the wound for evidence of infection: cellulitis, odor, increased wound exudate, and/or changes in exudate; changes in wound appearance; and increased pain in the wound. The physician should be notified so that changes in wound care can be made. Cultures and biopsies may be ordered to identify the type and count of organisms, and infected wounds are treated with a specific systemic antibiotic, topical dressing, soak, or a combination of all treatments. The wound is often the source of bloodstream sepsis. The five cardinal signs of sepsis are hyperventilation, thrombocytopenia, hyperglycemia, disorientation, and hypothermia.[8]

Preventing graft loss is another wound care challenge for nursing. Usually the patient returns from the operating room in a position that is maintained for 3 or 4 days. Any interaction with the patient during this time of graft immobilization requires creativity and care in order to prevent shearing of the graft. Postoperative dressings on the thighs and back are protected with Polysporin/polymyxin and a fine-mesh gauze to prevent soiling by feces and to minimize cleanup. The dressings are continuously monitored for increased drainage and odor, which would indicate possible wound infection. If infection is suspected, then the postoperative dressings may be removed early for a closer inspection of the wound.

Donor sites will also require additional care to prevent infection. Of course, the postoperative care depends on the coverage of the donor site. If the donor site is covered with fine-mesh gauze, initial care is to ensure homeostasis and adherence of the gauze to the wound. Therefore the postop pressure dressing remains intact for 6–12 hours and is then removed. The focus of managing the donor site is to keep

the wound dry. If grafts/donor sites are on the back or backs of the legs, the patient is placed in a Clinitron bed for 4–5 days to promote drying. If the donor site remains wet, additional drying techniques (hair dryers, external heaters) may be used periodically during the day.[9]

If the donor site is covered with a synthetic or biological dressing, the same principles apply. Basically, a pressure dressing is applied to ensure adherence to the wound for a short period of time postoperatively and then the wound is exposed to the air to support drying. A bed cradle is used to keep bed linen from contacting wounds. The location of the graft, donor site, and eschar may all be on the same extremity, which again requires creativity to accomplish all three interventions of care.

Nurses must always be vigilant when it comes to skin assessment; early detection and prevention is the key ingredient in preventing pressure ulcers in major burn patients. Pressure ulcers are no longer treated as a burn wound. There is evidence to support nursing practices in the prevention of pressure ulcers in burn patients. Burn patients have many risk factors that predispose them to developing pressure ulcers. Initially hypovolemic shock with blood flow shunted away from the skin to preserve vital organ function is a factor. Additional injuries may increase the risk for pressure ulcers, such as inhalation injury, which may require intubation and use of paralytic agents to manage the airway. Fluid resuscitation may contribute to massive edema in both burned and unburned areas. The edema is maximized at about 2–3 days postburn, which also decreases the blood flow to the skin and adds weight to all parts of the body.

Maintaining systemic hydration can continue to be a problem long after the patient has received adequate resuscitation for burn shock. Continued fluid therapy to replace fluid loss through the burn wound is essential. If systemic hydration is not maintained, even normal skin may be at risk. To complicate this situation, the quantity of fluid lost through the burn wound may increase the moisture on normal skin adjacent to the burn wound. This moisture may cause the normal skin to break down and predisposes the skin to further compromise.

All patients, except those with skin grafts postoperatively, will benefit from a bath or shower. Large acute burns are placed on a shower cart and the wounds are gently showered with warm water. The overhead heater is turned on, and the room temperature is maintained at 85°F (29°C) or higher. Large acute burns are not immersed in a tub of water to prevent autocontamination and electrolyte imbalance.[10] Hydrotherapy can be used for careful assessment of wounds, as well as for personal hygiene such as shampooing, mouth care, face care, and perineal care.

Hydrotherapy is an excellent opportunity for the nurse to teach the patient and family about wound care and dressing application. As the patient gets closer to discharge, families are required to do more of the care. The trend for earlier release from the hospital poses additional challenges for nursing since it reduces the time available to prepare the patient for discharge. The better the patient and family are educated, the better the outcome. Early involvement with patient and family helps identify potential obstacles at discharge and facilitates care coordination in the discharge process.

Surgical Care

The perioperative setting combines a number of professionals with different levels of experience and expertise, all directed toward patient care. Each team member has a specialized role: the surgeon provides surgical intervention, the surgical technician supports the surgeon, the anesthesiologist or certified registered nurse anesthetist (CRNA) provides life support functions, and the circulating nurse's role is to provide safe patient care by ensuring that all team members adhere to professional standards and guidelines. The perioperative nurse is a professional registered nurse who provides nursing care to patients in the preoperative, intraoperative, and postoperative phases of surgery. Perioperative burn nursing care can be described as hot, intense, and demanding. Burn nursing, in fact, represents one of the profession's most challenging specialties.

Once surgery is completed, perioperative nurses provide postoperative care and assessment. This phase of nursing care can also be challenging for the nurse caring for the patient during the immediate postoperative period. Nursing care and plan for care depend on many factors: amount of blood loss, surgical time, and the site(s) and extent of excision and grafting. The postanesthesia nurse caring for the burn patient must be knowledgeable about the medications and procedures used during surgery to provide appropriate safe nursing care.

Many burn-injured patients will make repeated trips to the operating room for surgical excision of the burn wound and grafting, with grafts taken from unburned areas. These procedures may require the patient to be anesthetized for long periods of time. Patients are at risk for pressure ulcers in the operating room; thus proper positioning and the use of pressure-reducing devices is essential to reduce the risk of pressure ulcer formation. During these operative procedures the patient may lose large quantities of blood, resulting in decreased tissue perfusion, and the patient may develop shock. Vasopressors and fluid resuscitation are the usual treatments for shock. Low-flow states and the use of vasopressors may also result in decreased tissue perfusion and increased risk of pressure ulcer formation.

Postsurgery, the patient or surgical area is often immobilized with large bulky dressings and splints to protect the grafts. These dressings need to be applied with enough pressure to stop bleeding from the grafted wound and the donor site. But if the dressings are applied too tightly, or if edema develops after dressing application, this may cause increased pressure on the skin.

To prevent wound bed desiccation, antimicrobial ointments or soaks are used to maintain moisture in the grafted wound and to aid in decreasing wound colonization with bacteria. This moisture, when in contact with adjacent normal skin, may increase the risk of tissue breakdown.

Inadequate nutrition prior to or after the burn injury is potentially a significant problem. The hypermetabolic response in the burn-injured patient leads to protein malnutrition if caloric intake is compromised. To reduce the risks of systemic infection and to promote wound healing, enteral hyperalimentation is most frequently used and the patient is fed by nasogastric or nasojejunal tubes.

In summary, burn patients are among the high-risk populations for pressure ulcer development. The physiology of the burn injury combined with many of the therapies and treatments used during hospitalization impacts the burn patient's risk for pressure ulcers.

Nutrition and Metabolic Changes

Hypermetabolism, or metabolic stress, is the direct response to a burn injury. The amount of stress increases proportionally to the extent of the injury and strongly influences a patient's nutritional requirements. This response can magnify the normal metabolic rate by 200%. Malnutrition, starvation, and delayed wound healing will result if calories are not provided consistently to meet nutritional requirements. Children require more calorie and protein replacement than do adults because they have additional nutritional demands to support growth and development.

Managing nutritional intake and monitoring output are among nursing's primary responsibilities. An accurate record of intake and output is critical to patient care because potential problems can be detected early and alternate options of care can be individualized to help the patient achieve his or her goals. Accurate weights, daily or as ordered, are also important. Remember to record whether dressings, splints, or linens are included in the weight. Obviously, including additional elements does not reflect an accurate weight, but trends in weight either up or down may be identified and may be helpful in the overall management of the patient.

Typically when patients cannot consume enough calories by mouth, then enteral feedings are begun. Sometimes enteral feedings are started before the patient is given the option of eating because the amount of calories is so great and/or the condition of the patient is unstable. Parenteral nutrition is used when enteral nutrition fails to deliver adequate nutrition. The goal is to provide adequate nutrients, calories, and protein. A nasogastric tube is inserted initially and used to decompress the stomach until bowel sounds return. Then tube feedings are started at a very low volume per hour to act as a buffer against ulcer formation. The nasogastric tube allows for checking hourly gastric residuals, gastric pH, and guaiac. If the gastric pH falls below 5, or if the guaiac is positive, Maalox and Amphojel are given every 2 hours, alternately every hour.

Aspiration of stomach contents is a potential complication and always a concern. Gastric residuals are checked before suctioning to prevent the patient from vomiting and possibly causing aspiration. Another precaution is to keep the head of the bed elevated. A Dobbhoff tube is also inserted initially, and feedings are begun as soon as 6 hours postburn. The rate starts slowly and is advanced as tolerated to meet the calculated amount of nutritional replacement. Tube feedings continue until the patient can take the required amount of calories by mouth.

Another potential problem with both tubes is dislocation; therefore it is important to check placement periodically throughout the day. When gastric residuals start climbing, it may be because the Dobbhoff tube has slipped into the stomach or the patient is septic. Tube feedings may become contaminated and become a source of infection for the patient, leading to significant morbidity. Routine procedures should be established to prevent this occurrence, and care should include sterilization of the blender and limiting to 4 hours the amount of time that tube feedings can be hung at the bedside. The tubing and container should be changed every 4 hours.

Sometimes when patients are encouraged to begin taking food by mouth, tube feedings may be discontinued during the day and be used only at night. Not scheduling painful activities around meal times and providing frequent mouth care will also contribute to improved oral intake.

Regular bowel patterns are expected in the postburn period. Patients are given many medications during hospitalization that may contribute to either diarrhea or constipation. Patients are expected to have at least one bowel movement per day. If not, then a bowel evacuation regimen should be considered. If diarrhea is the problem and the volume exceeds 1500 mL/day, then bulking agents and/or antidiarrhea medication may be useful to promote routine bowel elimination.

The importance of monitoring and documenting the many parameters of intake and output cannot be overemphasized. Established clinical protocols and guidelines facilitate the implementation and evaluation of the nutritional program.

Other strategies to support the hypermetabolic phenomenon of the burn patient are to keep the room temperature higher than 85°F (29°C) and to keep the room door closed to prevent drafts. Also frequent rest periods must be provided during the day. Nursing generally makes the schedule of activities for the day, so including frequent rest periods is just as important as anything else that needs to be done during the day. Adequate sleep during the night is also very important: often this makes the difference between a good day and a bad day. A quiet comfortable environment without sensory overload (lights and noise) is essential for the patient to sleep.

Nurses are the grand communicators of progress and/or problems. Nurses work closely with dietitians, physicians, patients, and families to ensure that optimal metabolic and nutritional support is achieved during the postburn period.

Pain and Anxiety Assessment and Management

Throughout the acute phase of care the burn patient is predisposed to pain and anxiety. Pain in the burn wound and fear of pain cause patients to try not to move. Careful titration of anxiolytics and narcotics can result in an alert patient who is relatively pain-free, but this requires intense attention to detail from the nursing staff. The expected outcome for pain and anxiety management is for the patient to achieve a balance between successful participation in activities of daily living and therapies and being comfortable enough to rest and sleep as needed. The ultimate goal is for the patient to be satisfied with the pain management plan as it is implemented. Assessment of pain and anxiety provides a baseline for evaluation of pain and anxiety relief measures. Pain and anxiety scales are essential to quantify painful episodes and to evaluate effectiveness of medication. Knowing when and how much to intervene is guided

by knowing the baseline pain and anxiety rating for the individual. Patients and families should be given information upon admission on how to use the assessment scales and to identify an acceptable level of pain and anxiety.

Intravenous administration of opioids and anxiolytic agents is essential to manage pain and anxiety during the initial stage of injury due to the altered absorption and circulation volume following a major burn injury. A patient-controlled analgesia (PCA) pump is useful for children older than 5 years and adults. It is important to manage background pain as well as procedural pain, for which medication should be given 15–30 minutes prior to a painful procedure. Nursing-driven protocols for sedation and analgesia have been developed for the burn ICU and were reported to be effective in controlling pain. Nurses positively supported the introduction of the protocol but junior nurses seemed to be more uncomfortable with its use than more senior nurses.[11]

Constipation is frequently a complication of pain management; thus a bowel management program should be instituted at the same time.

Relaxation, guided imagery, music therapy, hypnosis, and therapeutic touch are adjunct techniques to complement analgesia and reduce anxiety.[12] Virtual reality is a relatively new technique used for pain control and has been quite successful.[13] It involves a computer software program with which the patient actively interacts, thereby transferring the patient's attention away from the painful event. Emotional support and patient and family education decrease fear and anxiety, thereby enhancing the pain management plan.[14]

Patient and Family Education

In order for nurses to be competent teachers, they must be competent practitioners with solid theoretical foundations. Continuing education to maintain competency is key for clinical staff because of their role as educators of patients and families. Reinforcement of the educational process (assess, plan, implement, evaluate, and document), characteristics of patient populations, updates on educational strategies, age-appropriate interventions, and ways to evaluate learning are topics that will sharpen educator competency.

Discharge planning and education begins upon admission. It begins with a thorough assessment of the patient's life prior to the injury. Identifying knowledge deficits and barriers to education, prioritizing strategies for education, and providing supplemental educational handouts and/or classes, as well as developing a plan for evaluating the effectiveness of the teaching opportunity are integral parts of the educational process.

Assessment provides essential information for planning an educational program to meet the specific individual needs of each patient and family. It is also done periodically during different stages of the educational process to determine if the plan remains valid or changes need to be made.

The assessment findings become part of the educational plan in that the plan is tailored to meet the needs and concerns of the patient and family. The plan includes the learning objectives, strategies for education, and learning materials. All of these parts of the educational goal are agreed upon by the patient, family, and educator.

Implementation of the plan is the next step, followed by a thorough evaluation of the effectiveness of learning and/or determination of whether the educational goal is being accomplished. Alterations in the original plan may be needed at any time during the educational process depending on unforeseen situations or unanticipated changes in conditions.

The benefits are many. This process ensures communication of educational topics among the team members, provides a historical account of education, and documents progress and/or changes in the plan. It benefits the patient and family by making them competent in their role as care provider when discharged from the hospital. Knowledge allays anxiety about the unknown and aids in compliance with recommended care after discharge, thus improving the long-term outcomes.[15] Patients and families can be empowered to become active participants in the burn care team early in the postburn course through a well-structured educational plan.

Rehabilitation of the Burn Patient

A major burn is one of the most devastating injuries, both physically and emotionally, known to man. After weeks of being an invalid, undergoing repeated surgeries, fighting infection, having the body ravaged by the metabolic consequences of injury, and enduring pain and anxiety, the patient now faces months of continued physical therapy to regain the level of function that he or she had known before the injury. Most patients who have sustained a major burn will continue to have a higher than normal metabolic rate for more than a year and thus find that they do not have the stamina to easily regain their lifestyle.[16] In addition to the catabolic effects of burn injury, being hospitalized and in bed with minimal activity for many weeks or months causes loss of muscle and bone weakening. Children are more prone to fractures.[17] During the rehabilitation phase these patients must continue to exercise to prevent contractures, but they may not have the physical strength or endurance necessary to actively participate in such programs. In addition, these patients frequently become depressed as they face an altered self-image and a forced physical dependence on others. They fear that they will never look normal and that they will not be able to return to a normal life. For adults, the concerns of whether they will be able to return to work or have to change occupation is also a factor. What is the role of the nurse at this phase of treatment? Although nurses have been very involved in the care of the patient in the early phases of care, the role of the nurse changes at this stage. The transition from the hospital to home care is often difficult for both the patient and family. It is important prior to discharge that the patient and family be educated in the care of open wounds, healed skin, itching, pain, and anxiety before they leave the hospital. They also need information about the normal depression that occurs posthospitalization and resources in their home community to which they have access. This is where the nurse case manager becomes an integral part of the patient care team. Hospital-based nurse case managers can begin to work with the

patient and family soon after admission to assess the patient's future needs and coordinate these with outside agencies to ensure that the transition goes smoothly. Often case managers from workmen's compensation carriers or health maintenance organizations (HMOs) are involved during the early phase as well. Coordination of activities between case managers is important to provide seamless care. With children, it is important for the nurse case manager to begin working with the school nurse or community health nurses to provide for this seamless transition in care.

Although the rehabilitation therapist plays an important role in providing referrals to community therapists and psychologists, and social workers frequently make referrals to community mental health providers, the nurse case manager should be involved in the overall coordination of these and other services to foster a unified approach. The free flow of communication among all providers is necessary for optimal rehabilitation of the patient.

WORK-HARDENING PROGRAMS FOR ADULTS

For adult patients, work-hardening programs have been shown to more rapidly return the patient to his or her optimum level of functioning.[18] These programs may be available through community rehabilitation facilities, vocational rehabilitation agencies, HMOs, hospitals, or health centers with cardiac rehabilitation programs or through workmen's compensation carriers. The major concern for the nurse case manager and the burn team is early identification of which patients need these programs and at what point the patient will benefit most from such intensive programs.

Assessment

Burn patients, like those recovering from coronary heart disease and surgery, find themselves deconditioned. Even 3 weeks of bedrest in a healthy subject can result in a 25% decrease in maximal oxygen consumption. Thus burn patients who are hospitalized for 2 or more weeks may need to be considered for such programs. Burn patients should be first assessed for risk factors associated with coronary heart disease. Such risk factors include:

- age and sex
- elevated blood lipids
- hypertension
- cigarette smoking
- physical inactivity
- obesity
- diabetes mellitus
- diet
- heredity
- personality and behavior patterns
- high uric acid levels
- pulmonary function abnormalities
- ethnic race
- electrocardiographic abnormalities during rest and exercise
- tension and stress

Cardiac stress testing is usually recommended prior to beginning an exercise program. If the patient has several risk factors, the exercise program can be tailored to fit the patient's needs.[19]

Planning

What is available? Often the major issue is what is available and who will pay for this care. When an adult is injured on the job, this is often arranged and paid for by the compensation carrier since they have a vested interest in returning the patient to work as soon as possible.

Implementation

Once the details are worked out, the next hurdle is to get buy-in from the patient and family. Some programs require the patient to be in a facility some distance from the home; this may present issues for both the patient and family. Similarly if the program is in the local community, daily visits to the rehabilitation facility may pose transportation issues, especially if the patient is unable to transport him- or herself. These details can usually be worked out with cooperation of all caregivers and the family involved. Motivation and determination are often the most difficult factors to overcome. This is especially true if the patient is suffering from depression. The nurse case manager can be very instrumental in rallying the burn team and caregivers in the community to help the patient and family to see this as a way to return the patient to more normal function.

Evaluation

Success in such programs requires that all involved have the same goals and that these goals result in measurable outcomes. The goal of such programs is not only to increase the patient's tolerance to exercise but also to improve his or her psychological and social functioning and to return the patient to work or to the same level of functioning as before the injury.

EXTENSIVE EXERCISE IN CHILDREN

Children may suffer from the same deconditioning as adults, especially if they have suffered total body surface area (TBSA) burns of 40% or greater. Cucuzzo et al. have shown that children with greater than 40% TBSA burns have bone demineralization.[20] This deconditioning can lead to low energy, decreased motivation, and depression. This can make it difficult for the child to return to school, where he or she must be alert and attentive for 6–8 hours a day. Younger children learn much about their environment and world through play and various activities. Limitations in movement from burn scars or low energy may decrease their rate of learning. Also, children learn much about socialization through their participation in sports activities. Physical limitations in sports may provide a type of isolation from their normal group of peers. Treatment of these patients with long-term anabolic agents and intensive exercise programs to improve strength and endurance can return the patient's metabolic status to normal and help with the patient's reintegration back into his or her normal preburn activities more quickly.

Assessment

Children and their family situation should be evaluated to determine what exercise program is best for their burn

injury and their family situation. Generally, children 7 years of age and older can participate in an intensive exercise program. This is an estimated age based on the child's size (ability to use exercise equipment that is manufactured for adults) and maturity (ability to follow direction so that a safe environment can be provided). For larger burns (60% TBSA and greater), a 12-week exercise program is prescribed. For smaller burns, a shorter period of time of about 6 weeks may be sufficient. The best time to start such a program depends on the patient's family situation. The program can start immediately after discharge or can be delayed for a few months to allow the family to return home and prepare for the next phase of intensive exercise rehabilitation care. As with adults, individualized programs that consider the pediatric patient's current general state of health are necessary. Because the child is under the care of and dependent on the parent, it is important for the parent or a responsible adult member of the family to be involved. This may be a significant factor in when the patient is able to start such a program. For children younger than 7 years of age, more creative interactive play and exercise programs have been developed utilizing music therapy as a stimulus for children to participate in the exercise program. These activities can include riding tricycles, playing sports games, obstacle courses, racing, dancing, stretching, and any activity that can be made into a game that promotes strength and endurance. The use of activities set to music can increase stamina, actively stretch scar tissue, and increase joint mobility.

Planning

Although cardiac rehabilitation programs and the like may be readily available in most major towns and cities in this country, often they do not admit children. Children's hospitals often have rehabilitation units or outpatient programs for children that can offer programs similar to those in adult cardiac programs. Children's hospitals are usually found in major cities; thus these programs may not be as accessible as programs for adults. In some communities, school-aged children may be able to obtain help within the school sport programs, especially if they have qualified athletic trainers. Children aged 4–6 may have more difficulty finding programs outside of children's hospitals. Some early childhood intervention and pre-kindergarten programs may be available for younger children.

Another issue is to determine who pays for this care. Unlike the adult with insurance or workman's compensation insurance, children are often without funding for this rehabilitative care. State programs for children with special needs (e.g., Title V programs) are one avenue to explore. Other sources of funding may come from private or public charities, school-mandated programs, or vocational rehabilitation programs for the older teenager.

Implementation

Motivating the child and parent can be a major task. Often the parent and child have spent weeks or months away from home during the acute phase of care. If there are other children in the home or if the parent normally works outside the home, the parent may not feel that he or she can be away from home an additional 2–3 months. The child may also not want to leave the safety of the home environment. Thus motivating the child and parent is often difficult. Helping the parent see this as a valuable program will require the whole burn team to work together with the patient and family. Alternatives may be available for older children within the community by utilizing local gyms or fitness centers. Communicating a prescription for exercise to the local facility and maintaining regular follow-up of progress can be as effective as having the patient remain within the larger hospital system.

Evaluation

The outcome of these programs for the child can be measured in increased exercise tolerance and improved psychological and social adjustment. A major function of these programs is to convince the child and parent that the patient is a normal child and can succeed mentally and physically. If the child returns home and can keep up with his or her peers, this alone improves the child's self-esteem.

Reconstructive Care

ASSESSMENT

The role of the nurse in the reconstructive care phase may include clinic visit assessments, physical care associated with surgical procedures, education related to reconstructive care and expectations, and care coordination, including social and financial support. The nursing role of patient advocate may be the most important for the patient and family. Due to a lack of knowledge or understanding, patients and families may have unrealistic expectations for reconstructive surgery. They may have the hope that plastic surgery can "fix" the burn scars and make the patient look the same as before the burn. The nurse's role in the outpatient clinic or physician's office is to listen to the patient and family and to understand their hopes and expectations. The nurse can take this opportunity to provide education about the expected course of burn care and realistic expectations for scars left from the burn injury. Often when the surgeon discusses what should or could be done to improve the patient's appearance or function, the patient and family member are reticent to ask questions or to describe what they want. Patients' priorities are often different from the surgeons, and this leads to dissatisfaction. This is when the nurse should help the patient ask questions or voice concerns.

PLANNING

The timing of reconstructive surgeries often varies between surgeons. Many surgeons prefer to wait until the scar has matured to begin reconstructive surgery, but occasionally surgery will be attempted if the scar tissue is interfering with function. This is especially true where scar tissue may cause bone deformity if left until it has matured. In children, some reconstructive procedures are best postponed until the child has matured. Surgery is often better accepted by the child at the beginning of high school or just prior to starting further education. The nurse case manager can be instrumental in helping the family find the funding and resources to provide reconstructive surgery for the patient.

If the patient is working or in school, planning the procedures should accommodate the patient's school or work schedule as much as possible. For children, funding through Services for Children with Special Needs may be available. Working with insurance companies and HMOs can be complicated if the surgery is presented as cosmetic rather than corrective surgery.

IMPLEMENTATION

Preparing the patient for surgery is the responsibility of the nurse and physician. Providing the patient with realistic expectations is often difficult, but educating the patient about the surgical procedure and expected timelines for healing and utilizing photographs of similar burn wounds improves understanding. Many times, immediately after the surgery, the area will look worse and the patient may feel dissatisfied and depressed. Preoperative preparation of the patient and family may allay some of these issues. Surgery itself is frightening enough for the patient and family. In children as well as adults, this can be especially frightening because it may bring up memories of their original burn injury, hospitalization, and the pain associated with it. Postoperatively the nurse's role is to teach the patient and family how to care for the wound to prevent infection, promote healing, and prevent further scarring. Throughout the reconstructive and rehabilitation phase the nurse is supportive of the patient and family as the scar matures. The nurse's role during this time is one of education, support, and encouraging the patient to continue with exercise, splints, and pressure garments, as ordered.

EVALUATION

Whose body is it anyway! A line from a famous play actually sums up the evaluative process for reconstructive surgery. As professionals, we may see great improvement in the patient's condition after surgery. But if the patient is not satisfied with his or her appearance, little has been gained by the surgery. This is the reason that the patient and family must have realistic expectations prior to surgery. On the other hand, the patient may be perfectly happy with his or her scars and how they look and not desire any surgery. And although a surgeon may have a great deal to offer with reconstructive surgery, the patient's decision must be respected.

Recovery and Social Reintegration

Nursing covers the spectrum of providing care from health to illness and hopefully back to wellness, including the physical, psychosocial, and spiritual realms, and the same concept applies to burn nursing. Nursing care must continue past the physical healing of the burn wound. Complete healing must also include the psychosocial and spiritual domains of the patient. Helping the patient to accept his or her "new me" is paramount to recovery. After any traumatic event in an individual's life, the person often claims to be different or changed, whether physically or psychologically. Often burn scars cause patients to avoid public situations where people may gaze at them for looking different. Support should be provided, and the patient should be encouraged to realize that he should not be defined by his physical body. Who they are is defined by what is in their minds, hearts, and souls. Through family support, professional counseling, and/or peer support the burn survivor can be taught to accept him- or herself and set a path for life. Some choose to cover their scars, some accept them as they are, and some wear their scars as badges of honor for the personal war they have triumphed over. Training is available for those who are uncomfortable with being out in public settings. Continued support from the burn team, the family, and support groups can help with the reintegration process.

Conclusion

Burn nursing is a unique field of practice. In the United States, there are currently only 127 burn centers, and only 67 of those are verified burn centers. Hospital burn units are often much different from other care units in a hospital because they frequently house a wide range of patients, young to old, with minor burns to critically ill patients with major burns, to patients receiving rehabilitation or reconstructive care. It can be difficult for the nurse to change patient assignments from one day to the next considering the wide range of care needed and to maintain skills in all areas. Nursing shortages can be common among burn units due to the general shortage of nurses and the challenging area in which they work.[21] It is important that nurses are made an active part of the burn care team to utilize the special insights that they have concerning the patient's physical condition and the psychosocial needs of the patient and family. Utilizing a nursing workload measurement for burn care may help provide information on staffing needs to ensure adequate staffing is made available for the burn unit. Assessing patients' daily wound care needs and medication/IV fluid needs can be utilized to assess nonintensive or intensive needs and then rank patients into categories by the levels of care demanded.[22] Finally it is important to give patient care nurses the opportunity to become involved in other areas of burn care. A great way for nursing to become involved with the burn team is for a nurse to become involved in better understanding an issue or in improving burn care. This can be done through research activities or through quality improvement activities. Nurses can often identify areas for improvement but may not have the resources to encourage change. Providing education opportunities to nurses can create a culture for change and improvement. Education can include in-services, publications,[23] and mentoring to support the nurse who is interested in this area. Research and quality improvement initiatives can make changes and improvements in care, including improving nutritional intake, decreasing pressure sores, decreasing infections, decreasing pain, and improving patient satisfaction. The burn nurse is an invaluable member of the burn care team. Her unique insights offer important information to the successful outcome of the burn patient. Active participation in the

physical care of the burn patient, attending to the psychosocial needs of the patient and family, and continually observing for ways to improve care are paramount to the ultimate success of the burn team.

Introduction

Approximately 8% of women experience trauma during their pregnancies.[1] Trauma in pregnancy is the most common cause of nonobstetric-related death;[2] more generally, trauma is the leading cause of death in the age group under 40 in the United States.[3–5] Women in their reproductive years are the population at the greatest risk of trauma.[3] While it is rare to see a pregnant woman in the burn ICU in industrialized nations, burn trauma is a great risk to pregnant women in developing countries. Correspondingly, recent literature regarding the care of burned pregnant patients more commonly comes from journals in these developing countries[6] and consists mainly of small studies and case reports. Burn injury during pregnancy tends to happen in the home environment.[7] In developing countries, this may be in part attributable to the large proportion of women who attempt suicide via self-immolation.[8]

Due to the particular paper paucity pertaining to pregnant patients, there is no great consensus on the population of burned pregnant women, size of burn disease burden in the population, or mortality of mother and fetus.[6,9–14] However, what does exist in the literature reveals that the maternal mortality rate exceeds 50% and has been reported at 100% when total body surface area (TBSA) burned exceeds 40–60%.[10,12] This statistic remains unchanged from Rode's study in 1990 showing that when TBSA was greater than 50%, maternal survival "was unlikely."[13] These appalling mortality data contrast a contemporaneous study by Herndon et al. that determined the lethal burn size for 50% (LD50) of pediatric patients reached 98% TBSA burned.[15] Despite progress made in survival rates of other burned populations, pregnant burned victims suffer the same mortality rates as in the 1960s. In a recent study, 60% of burned pregnant burned patients died, with an overall 50% mortality rate of the fetus.[16] As could be predicted, fetal survival greatly depends on maternal survival, although there is a high spontaneous labor rate among burned pregnant patients. While pregnancy does not greatly influence treatment protocols, it might factor into maternal outcome following thermal insult, given the enormously high mortality rate of pregnant women with severe burn injury when compared to the mortality rates of nonpregnant women and men with comparable burn wound sizes. However, more study is obviously necessary.

Mortality Factors

A consensus in literature exists: burn size correlates most significantly with the mortality of both mother and fetus. Large burn size is the single most predictive indicator for mortality.[10,13,17–21] The odds of mortality of the mother rise by 1.08 per percentage of TBSA burned ($P < 0.0001$).[22] Furthermore, there is an association between mortality, TBSA burned, and the incidence of intentional burns. Women who attempt suicide via self-immolation had greater TBSA and resultantly higher mortality rates,[17] especially those with greater than 50% TBSA burned. Rode reported a direct relationship between the size of burn and the frequency rates of spontaneous abortion and premature delivery.[13] Rezavand et al. demonstrated that, in every trimester, maternal TBSA burned positively correlated with fetal death as well as maternal demise.[12] Agarwal found fetal loss occurred at a higher rate than maternal death even at greater maternal TBSA burned.[17]

The second strongest predictor of mortality of both mother and fetus is smoke inhalation,[10] the treatment of which remains controversial. Maternal fatalities and mothers with fetal losses were more common in those with concurrent inhalation injuries.[10] The resultant hypoxia strongly correlates with maternal and fetal death.[23] Closed and structural fires emit smoke potentially imbued with cyanide (CN) and carbon monoxide (CO) gases. Upon inhalation, CO and CN demonstrate synergistic effects; furthermore, they concentrate at higher levels in the fetus than the mother[24] as fetal hemoglobin binds CO and CN more avidly than maternal.[5] As such, providers must treat two patients with awareness of potential effects of CO and CN poisoning on both mother and child.[24] Facial burns, large burns, and self-inflicted, intentional burns all strongly associate with inhalation injury. Significant thermal injury in the pregnant patient population can have not only direct but indirect effects on the pulmonary system. Unique to the pregnant burn patient, vital lung capacity decreases while mucosal edema,[25] oxygen consumption, and minute ventilation increase.[26] As with the severely burned nonpregnant patient, should a pregnant burn victim be suspected of suffering from inhalation injury, emergent intubation ought to be instituted. Given the known physiologic changes of pregnancy, which are compounded by burn edema, early intubation in the severely burned pregnant patient should be strongly considered. Hydroxycobalamin, the cyanide antidote[27] recommended in Chapter 32, is a pregnancy

category C drug and should only be used if the benefits outweigh the risks because cyanide crosses the placenta and will poison the fetus to a greater extent than the mother.[24,28]

Gestational age was also a factor reported in several studies.[16,17] Argawal found fetal survival in the third trimester correlated less to maternal survival but rather strongly to gestational age.[17] Liu determined gestational age-specific risk of birth to be greater among the population of injured mothers than noninjured in each gestational week until week 38, irrespective of medical condition.[29] Gestational age is not the sole criteria for neonatologists and obstetricians in determining viability of a fetus. The fetal weight benchmark of 500 g has been adopted, which is the lower size limit at which intubation is feasible.[30,31] Given the potentiality of obstetric intervention, it is imperative to precisely ascertain the gestational age and weight of the fetus via fetal ultrasound and menstrual and sexual patient history data early in the management of acute burns.

Hypovolemic shock[7] and sepsis[32] have also been found to be complications resulting in maternal and fetal death.[22] Recurrent septicemia is a major challenge in the management of a severely burned obstetric patient. Intraabdominal hypertension and abdominal compartment syndrome develop in most severely burned patients within 48 hours of injury.[33] Intraabdominal hypertension is present when intraabdominal pressure measures in excess of 12 mm Hg, and abdominal compartment syndrome exists when intraabdominal pressure is greater than 20 mm Hg, particularly if additional organs display dysfunction.[34] Pregnancy induces physiologic changes in all major maternal organ systems, mimicking early perturbations seen in multisystem organ dysfunction (MOD).[35] All these complications potentially lead to MOD, compounding the existing state present in the pregnant population and further jeopardizing severely burned obstetric patients.

Fetal Viability

Managing obstetrical complications provides an additional challenge to the burn team. Second to death of the mother, placental abruption is the most common cause of the death of the fetus following trauma.[3] Due to the intense kinetics undergone by a pregnant patient postburn, the fetus often spontaneously delivers.[12] In layman's terms, this is a miscarriage. Consistently studies show that fetal mortality rates were highest during the first trimester in the setting of major burns.[16,17] However, with aggressive fetal monitoring, appropriate obstetrical intervention can preserve the life of the fetus earlier in the course of pregnancy. Studies indicate this approach starts approximately in the 22nd week of gestation.[36] Determining the gestational age[6] and weight[37,38] of the fetus enables the healthcare team to most effectively guide this care. In a large study, Linder et al. demonstrated that early preterm, low-risk deliveries increased the risk of fetal complications with higher rates of neonatal ICU (NICU) admission, sepsis, and antibiotic treatment as compared to late-term neonates or the gestational control population.[39] While the study only began evaluation at gestational week 37 of low-risk singleton deliveries, it did show that neonatal morbidity risk corresponds with early term deliveries. The burn, obstetric, and neonatal teams must collectively weigh the risks of preterm delivery against the risks of the fetus remaining in utero and besieged by the expected effects of severe burn trauma.

Table 34.1 Indications for Emergent Caesarian Section in the Setting of Severe Burns when the Fetus is in Distress

FETAL DELIVERY IN THE SETTING OF SEVERE MATERNAL BURN		
Fetal Stage	**Gestational Age**	**Delivery Indicated**
Previable	0–21 weeks	No
Periviable, weight <500 g	22–26 weeks	No
Periviable, weight ≥500 g	26–28 weeks	Yes
Early viability	26–28 weeks	Yes
viability	28–32 weeks	Yes
Preterm	32–37 weeks	Yes
Term	37–40 weeks	Yes

PRACTICAL MANAGEMENT ALGORITHM

Adverse pregnancy outcomes are not associated with incidents of minor trauma during pregnancy.[40] However, severe burns are major trauma. As a practical matter, management of the pregnant burn patient can be divided into five phases: previablity, periviability, early viability, viability, and term (Table 34.1). Obstetrical complications (e.g., uterine rupture and placental abruption) are potential mechanisms of preterm delivery following acute maternal trauma.[29] During the period of previability, defined as the period in the pregnancy from conception to gestation week 22 or 23[31,36,41] and a fetal weight of less than 500 g,[30] the fetus cannot survive independent of the mother.[31] While the previability stage of pregnancy is currently defined at gestational week 24 by the American College of Obstetrics and Gynecology,[42] neonatologists and maternal fetal medicine specialists have extended the gestational age of periviability to 22 weeks.[36] However, this is dependent on a fetus of 500 g.[30,37,38] Most obstetricians will attempt resuscitation at 22 weeks,[36] but 24 weeks and 500 g remains the benchmark for viability because fetal mortality at 22 weeks remains incredibly high. Providing total burn care to the mother will make her womb the optimal incubator, thereby managing fetal care as best as is possible. The data indicate that there is a high spontaneous abortion rate;[12] however, there is no proven advantage to performing a termination of the pregnancy unless maternal death seems likely otherwise.[12] Effort should be exerted to avoid medications known to be hazardous to the fetus but not to the extent that the mother succumbs to shock and/or sepsis, which have very high rates of fetal loss.

The multidisciplinary team must balance burn care among several factors during periviability (22–26 weeks) and early viability (26–28 weeks). Prophylactically, antenatal corticosteroids should be administered upon admission in the setting of a severely burned obstetric patient. Demonstrated to be the optimal interventions to reduce morbidity and mortality in premature neonates, these also promote

organ growth[43,44] and can be administered for fetuses as young as 23 weeks.[45,46] Betamethasone (two 12-mg doses given 24 hours apart) and dexamethasone (6 mg every 12 hours in four doses) are the most commonly used antenatal corticosteroids.[43,47] There is no benefit to shorter dosing intervals, and it is recommended that the first dose be applied even if administration of a second dose is unlikely.[43] However, antenatal corticosteroids remain contraindicated when the risk to mother and child is greater by prolonging the pregnancy than is emergent delivery. Effective to forestall labor for up to 48 hours, tocolytic therapy is particularly useful in situations needing to delay labor until after the administration of antenatal corticosteroids or transfer of the patient to an appropriate burn center.[43,48] In the setting of severe burns, tocolytic therapy may be indicated prior to viability to inhibit contractions incited by intra-abdominal surgery.[47,48] Many different drug classes have been employed (e.g., calcium channel blockers, β-mimetics, and magnesium sulfide), but a recent study showed prostaglandin inhibitors to be the optimal first-line tocolytic agents to delay labor with the lowest maternal side-effect profile.[48–50] Calcium channel blockers potentially have the best neonatal outcomes of the tocolytic therapies.[51,52] While traditionally used to inhibit acute preterm contractions,[53] predelivery administration of magnesium sulfate conveys neuroprotection[54,55] and has been shown to be ineffective as a tocolytic agent.[56] Transdermal nitroglycerin for pregnancies of less than 28 weeks is not recommended due to its significant side-effect profile.[57] Because these medications can exacerbate the burn shock besetting a patient, coordination among critical care, obstetrics, neonatologists, and pharmacists is critical to guide therapy and avoid further risk to mother and child.

The dilemma of delivery and resuscitation must be measured against the fetus's odds of survival and chances of leading a normal life. If the perceived risk to the child remaining in utero exceeds the risk in the NICU, the infant should be delivered and cared for ex utero. During in utero critical care, the fetus must be monitored and medications chosen to avoid fetal harm. If toxic medications must be given, the risk should be balanced against the risk of fetal harm. Additionally, if intrauterine fetal death results, irrespective of the reason, the uterus should be evacuated. Retained stillbirth, septic abortion, and missed abortion can lead to disseminated intravascular coagulation (DIC).[58,59] Correlating with high rates of maternal morbidity and mortality, DIC induced by fetal loss is best prevented by prompt evacuation of the dead conceptus.[60,61] It is ethically reprehensible to attempt resuscitation on a child who has or will soon perish regardless of measures taken.

Treatment

It is widely acknowledged that burn patients suffer from altered pharmacokinetics that make them unique among trauma victims. While it could be presumed the treatment protocols would alter significantly given the fetus, they do not (Fig. 34.1). Early wound excision and coverage, aggressive fluid resuscitation, antibiotic administration (though limited in options), and sufficient nutrition are the foundation of managing burned pregnant patients.[17] However, emergency responders and the burn team may be unaware a patient is pregnant. Thus, the first simple and requisite precaution in treating reproductive-age female burn victims is to suspect pregnancy until proven otherwise.[3] Immediately upon determination of pregnancy, high-risk obstetric consultation must be sought, even before excision of the wound. Fetal heart tones must be established and an ultrasound performed to corroborate gestational age obtained from patient menstrual history to determine fetal viability. If the fetus is deemed viable, administer antenatal corticosteroids to mature the lungs for delivery, regardless if the fetus displays signs of distress. This also delays delivery, enlarging the time for stabilization and prep of the mother, and it improves outcomes for the child. After these consults and corticosteroid treatments, initiate antibiotic therapy and coagulopathy support prior to wound excision and/or emergent delivery.

As with nonpregnant burned patients, early wound excision is key in managing severely burned pregnant patients. Surgical interventions include escharotomies, as indicated, and coordination with an obstetrics team if fetal distress is evident. The burn team must proceed with the awareness that two patients require care. Studies have demonstrated that maternal demise strongly correlates to fetal death.[3] We advocate early excision of abdominal eschar to prevent abdominal compartment syndrome and decrease the risk of infection. Should the fetus be viable and in distress, excision of the burn wound can proceed immediately upon delivery. However, early wound excision with fetal survival is rare in the setting of major burns. If early wound excision is indicated and the fetus is not of gestational age or sufficient weight to support emergency caesarean section (e.g., at least 22–24 weeks by either ultrasonographic measurements and/or patient history of last menstrual period[31,36] and measured fetal weight of 500 g by ultrasound[36]), published data and our experience indicate that the mother will not carry the fetus to term. The best chance of both fetal and maternal survival is to deliver the fetus upon signs of distress and manage the maternal burn injuries. If the fetus shows no signs of distress, proceed with early excision and wound coverage and monitor the fetus. In this setting, should the fetus become distressed, perform an emergent caesarean section. If the fetus does not display distress, the mother remains the best incubator, but diligent monitoring is required. Even if the fetus is not viable gestationally, the burn team must proceed with the burn wound excisions because the mother would be subjected to an unacceptable risk of shock and sepsis. The care of the mother must take precedence over that of the child.

The anatomical and physiological changes brought about by pregnancy drastically increase the difficulty in the anesthetic, obstetric, and surgical management of burn patients. "Normal" vital signs and labs in pregnant patients sometimes differ from those of nonpregnant individuals. Current early warning system triggers used to evaluate deteriorating patients are based on nonpregnant values and thus require refinement for the pregnant population.[62] Therefore, awareness of the differences and consultation with appropriate specialists are fundamental to proper care. The changing cardiovascular profile includes increases in cardiac output, uterine blood flow, and blood volume as the fetus matures.[9] Crucially, pelvic blood flow autoregulation

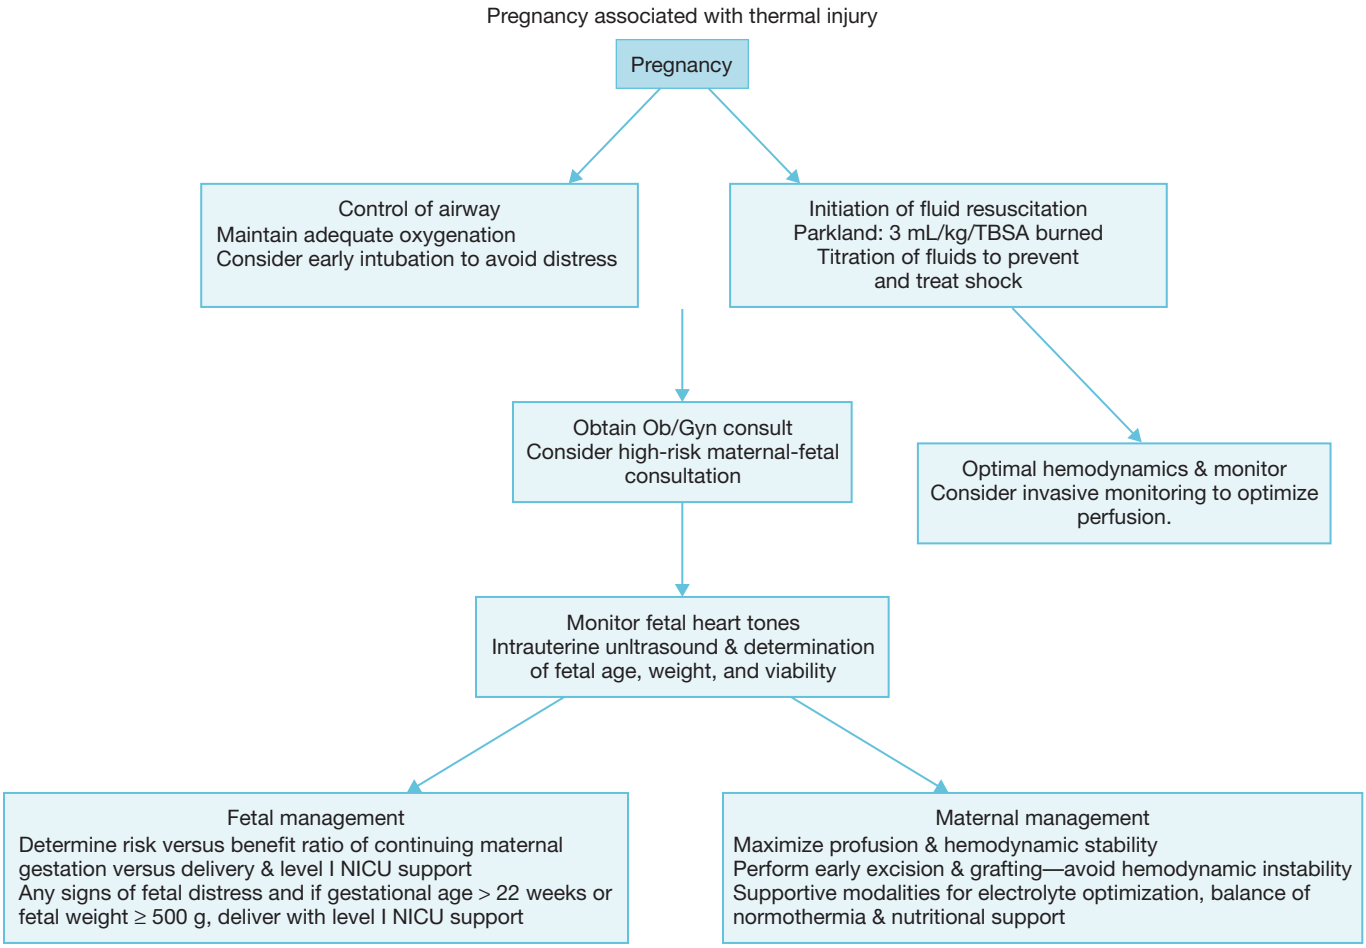

Fig. 34.1 Algorithm of the optimal treatment of the burned pregnant patient.

is absent because pregnancy maximally dilates the uterine vasculature. Resultantly, uterine blood flow depends solely on maternal mean arterial pressure. Furthermore, dilutional anemia of pregnancy may complicate assessments of blood loss and sufficiency of the oxygen-carrying capacity in burn patients.[4] Aggressive fluid resuscitation is vital in the early stages of maternal and fetal salvage. Early interventions during resuscitation include close monitoring of hemodynamics and perfusion indices to evaluate how those respond to initial resuscitation. We further recommend institution of a Foley catheter, central venous catheter, and an arterial line with advanced hemodynamic monitoring upon admitting a severely burned obstetric patient to determine adequate volume status and perfusion. The approach to fluid resuscitation remains the same in the pregnant population as in the nonpregnant group, with the goal to support fluid and plasma loss, early recognition of hypoperfusion, and prompt management of shock while avoiding hypoxia. We use a modified Parkland formula to begin resuscitation at 3 mL/kg per TBSA burned and titrate accordingly, with a targeted urine output of 0.5 mg/kg per hour. Careful monitoring of hemodynamics as well as of blood pressure, hematocrit, and heart rate should tailor resuscitation. Interestingly, one recent case report suggested that it is optimal to decrease the infusion volume of fluid resuscitation, especially following the delivery of the fetus, should that be necessitated,[6] but this has yet to be corroborated. After the 8th week of gestation, pregnant women should present with physiological dilutional anemia,[63] which, if absent, is an early marker of hemoconcentration (Hg > 13 g/dL)[64] and hypovolemia.[65] During the third trimester, instituting an intra-abdominal bladder pressure monitor for resuscitation is a necessary precaution to monitor those patients receiving in excess of 5 mL/kg per TBSA burned. The inability to accurately and timely assess for intra-abdominal hypertension and compartment syndromes in severely burned pregnant patients presents an additional challenge to the burn team. Care must be taken to ensure the pregnant patient does not develop acidemia, hypoperfusion, hypoxia, or thromboembolic complications stemming from high levels of coagulation factors common to pregnant women.[3] Supportive modalities include serial electrolyte and hematologic monitoring to support normalization of electrolyte levels, monitoring of hemoconcentration and fluid balance, and maintaining normothermia. Should such complications arise, the life of the fetus could be jeopardized. When that occurs, a review of the literature reveals that the pregnancy will most often spontaneously abort.[6,9,18] Should obstetrical intervention be indicated, such action must be taken expeditiously to preserve the lives of both mother and child. However, greater study is merited to determine the most efficacious triggers for obstetrical

intervention as well as the optimal amount for fluid resuscitation.

The U.S. Food and Drug Administration (FDA) classified drug recommendations by five grades (A, B, C, D, and X) according to the possible side effects for the fetus when administered to pregnant and/or lactating women[66] (Table 34.2). Animal studies showed no adverse reactions to grade B drugs (e.g., macrolides, cephalosporins, penicillins, lincomycin, and clindamycin), and these are presumed safe to treat pregnant women.[6] In fact, benzylpenicillin remains

Table 34.2 Available Pharmaceuticals for Pregnant and Lactating Women and Their Recommendations

DRUG RECOMMENDATIONS FOR PREGNANCY AND/OR LACTATION IN BURN PATIENTS (*LR = LOW RISK)				
Drug	**Pregnancy Category**	**Pregnancy Recommendations**	**Lactation Recommendations**	**Comments**
A. Topicals				
Bacitracin-like products	C	Compatible	Compatible	Limited fetal exposure would be expected after topical use
Dakin's solution (Na hypochlorite 0.125%, 0.25%, 0.5%)	_	May use during pregnancy; no human data available; risk of fetal harm not expected based on limited systemic absorption	Safety unknown; inadequate literature available to assess risk; caution advised	
Mafenide	C	No human data; should not be withheld because of pregnancy	No human data	
Miconazole	C	Avoid vaginitis treatment in the 1st trimester or application to large areas at any time during pregnancy		
Mupirocin	B	No human data; probably compatible	No human data; probably compatible	
Nystatin	C	Compatible	Compatible	
Silver nitrate	C	None	No human data	
SSD	B	No recommendations		
B. Antibiotics				
Aminoglycosides	D	Human data—LR	Compatible	Streptomycin linked to hearing loss in newborns and should be avoided, unless specific benefit established. Short-term use of others in class acceptable with monitoring, if benefits outweigh the risk
Penicillins	B	Compatible	Compatible	Generally safe to use
Carbapenems (meropenem)	B	Probably compatible	Probably compatible	Use with caution only when penicillins or cephalosporins not an option
Cephalosporins (all generations)	B	Compatible	Compatible	Generally safe to use; use ceftriaxone with caution at term due to risk of kernicterus
Clindamycin	B	Compatible	Compatible	Appears to be safe and effective
Daptomycin	B	Limited human data; animal data—LR	Limited human data; probably compatible	May use if benefits outweigh risks
Vancomycin	B	Compatible	Limited human data; probably compatible	Safe and effective
Metronidazole	B	Human data—LR (see comments)	Hold breastfeeding (single dose); see comments	Contraindicated 1st trimester; lactation is potentially toxic for divided dose; "topical" metronidazole should be avoided
Linezolid	C	Compatible	No human data; potentially toxic	May use if benefits outweigh risks
Sulfamethoxazole, trimethoprim	C	Human data suggest risk in 3rd trimester	Limited human data; potentially toxic	Avoid in 1st trimester due to major congenital malformations. Sulfamethoxazole should be avoided after 32 weeks' gestation due to risk of kernicterus

Table 34.2 Available Pharmaceuticals for Pregnant and Lactating Women and Their Recommendations—cont'd

DRUG RECOMMENDATIONS FOR PREGNANCY AND/OR LACTATION IN BURN PATIENTS (*LR = LOW RISK)				
Drug	**Pregnancy Category**	**Pregnancy Recommendations**	**Lactation Recommendations**	**Comments**
B. Antibiotics				
Tetracyclines	D	Contraindicated in 2nd and 3rd trimesters	Doxycycline; compatible	Should be avoided
Tigecycline	D	Contraindicated in 2nd and 3rd trimesters	Limited human data; probably toxic	Avoid in pregnancy unless benefits outweigh risks
C. Antifungals				
Fluconazole	D/C	Associated with fetal mortality and congenital abnormalities	Compatible	
Posaconazole	C	Animal data suggest risk of skeletal malformations	No human data; potential toxicity	
Voriconazole	D	Animal studies have demonstrated fetal harm	No human data; potential toxicity	
Micafungin	C	Animal data revealed embryotoxic effects but have not been replicated in adults	No human data; probably compatible	
Amphotericin	B	Observational data suggest rate of human birth defects is similar to that of the general population	Not recommended	
D. Pain Medications				
Codeine	C	Human data suggest risk	Limited human data; probably compatible	Although the AAP has classified codeine as compatible with breastfeeding, data suggest that, for some women, codeine can not be considered safe during nursing, especially if therapy is >1–2 weeks
Fentanyl	C	Human data suggest risk in 3rd trimester	Compatible	Neonatal withdrawal, respiratory depression
Hydrocodone/APAP	C	Human data suggest risk in 3rd trimester	Limited data; potential toxicity	
Morphine	C	Human data suggest risk in 3rd trimester	Limited human data; probably compatible	
Oxycodone	C	Human data suggest risk in 3rd trimester	No human data; probably compatible	
Tramadol	C			

the most commonly antibiotic administered to pregnant women.[67] Categories C, D, and X have been demonstrated to generate negative side effects in fetal development. In cases where the benefits of treating a pregnant woman with a grade C drug, such as quinolones and fluconazole, greatly outweigh the risks associated with the drug or no alternative exists, they are warranted for use in pregnant women.[6] Drugs belonging to class D will rarely warrant administration, and only if the risk of harm is strongly outweighed by the benefit. Category X should only be administered in instances where fetal loss is assured or an accepted ramification of using the medication to preserve the life of the mother.[66] Adding to the complexity, recommendations vary depending on trimester or for a lactating burn patient. As part of the multidisciplinary team, the clinical pharmacist plays an integral role in assuring safe and effective pharmacological therapy for each patient in the burn unit. A pharmacist should be knowledgeable and current on the changing recommendations of all drugs safe for administration to pregnant and nursing patients, from antibiotics to renal dosings. As such, the clinical pharmacist is indispensible in advising the team on the optimal therapy for burned pregnant patients.

It comes as no surprise that pregnancy increases the mother's metabolic requirements. Early enteral nutrition remains key to the management of the severely burned pregnant patient. Within 48 hours of admission to our hospital, we initiate dietary consultation and estimate caloric need. Special considerations that can develop with severely burned pregnant patients include postoperative ileus with caesarean delivery and surgical interventions. For those in this patient population who may have undergone an emergent caesarean section, the risk of developing acalculous cholecystitis is elevated. Management of acalculous

cholecystitis complications can be complex given a postpartum surgical abdomen.

Additional Considerations

HEMATOLOGY AND COAGULOPATHY

In the severely burned patient, DIC can develop.[68] DIC is defined as an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization originating from and causing damage to the microvasculature, potentially leading to MOD by the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis.[69,70] In the early, acute phase of burn, DIC presents as the fibrinolytic phenotype; later in the course of burn pathophysiology, DIC is often sepsis induced.[68,71–73] The syndrome is characterized by excessive thrombosis, unchecked inflammation and MOD, insufficient anticoagulation mechanisms, and increased fibrinolysis.[72] Massive transfusions are common in patients with DIC.[74] Management of coagulopathy in the severely burned pregnant patient includes transfusions of fresh frozen plasma, packed red blood cells, cryoprecipitate, and platelets while in the operative theater and for patients at risk of significant bleeding. This is covered in greater depth in Chapter 22 on hematology, hemostasis, thromboprophylaxis, and transfusion medicine.

Pregnancy normally induces a hypercoagulable state that is compounded by thermal insult. This presents an additional challenge for supportive and screening therapies throughout the course of care. Prophylaxis administration of heparin, specifically low-molecular-weight heparins, is recommended. Routine weekly Doppler exams are suggested, given the high suspicion of thrombosis in the pregnant population. Extensive findings of deep vein thrombosis (DVT) in conjunction with the inability to fully anticoagulate a severely burned pregnant patient require the burn team to weigh the risks versus the benefits of placing an inferior vena cava filter device, as thrombosis is likely to further propagate.

PSYCHOLOGICAL ISSUES

Pregnant burn prevalence is greater in developing countries. Furthermore, the etiology of traumatic injury differs between industrialized and developing countries: a far greater numbers of women are likely to deliberately set themselves on fire in mostly futile suicide attempts in developing countries.[12,75] However, a noted rise in self-inflicted burns in industrialized countries exists.[76] This bespeaks a lack of psychiatric and social support for expectant mothers that, were it better addressed, might help prevent such incidences.[23] Underreporting of suicide is perennially problematic because no standard method exists to evaluate pregnancy at time of death.[77] The high incidence of thermal insult found in the uneducated or illiterate populations of obstetric patients illustrates the benefit that education imparts in reducing burn injuries.[23,75] Greater education and access to psychological support is needed.

Perinatal loss resultant from burn injury compounds the already traumatic psychological effects of burn patients. Women are adversely impacted by the image-altering effects common to burn survivors, especially from severe burns.[78] Shepherd showed a positive correlation between trauma symptoms and appearance concerns.[79] Cumulatively complicating recovery, mothers may also experience depression,[80–82] posttraumatic stress,[83] and anxiety[84] following fetal loss. These may also be experienced by any potential partner[82] in addition to the psychological distress experienced by spouses and close relatives of burn and trauma survivors,[85] resulting in notable adverse sequelae for the couple.[86] All these may profoundly and detrimentally impact any potential recovery of the mother. The inclusion of psychiatric consultations should be a standard part of burn care protocols, especially given the profound psychological upheaval following traumatic and unexpected fetal loss for both the maternal survivor and any spouse or partner. In developing countries, greater psychiatric and social work support for expectant mothers should be made readily accessible to better prevent suicides and suicide attempts by self-immolation.[23]

In the case where the fetus survived despite maternal complications, we observed a disassociation bond between mother and child. Supportive modalities in keeping with the multidisciplinary approach included recognition of maternal signs of depression and anxiety by consequently referring the patient to psychiatry for pharmacologic and other therapies to address her posttraumatic and adjustment stress disorders. In our experience, early family interaction has been instrumental for a patient's recovery from traumatic injury, along with early initiation of infant bonding.

Also to consider are support modalities for the multidisciplinary team. Managing the care of pregnant patients, especially those who have suffered traumatic injuries, and fetal demise can create stressors within the critical care medical and nursing staff that must be managed to avoid provider burnout.[87]

NONSEVERE BURNS

The text of this chapter has dealt with the care of the severely burned obstetric patient. The approach to the nonseverely burned pregnant victim is much the same (Fig. 34.1). Obtain a high-risk obstetric consult upon admission of the pregnant burn patient. Establish and monitor fetal heart tones. Perform an ultrasound to determine fetal viability and gestational age, as well as acquire patient history regarding last menstrual cycle. Optimize fluid resuscitation and perfusion, beginning with the Parkland formula. Utilize the multidisciplinary team to maximize management of the burned pregnant patient. In contrast with the treatment of the severely burned pregnant population, early wound excision can be balanced between the risk and benefit to both patients of surgical intervention versus topical treatments. Protocols must be established regarding critical care, perinatal support, lactation consultation, and nursing monitoring should the fetus be viable and delivered; anesthetic consultation and support should surgical intervention be indicated; nutrition optimization; clinical pharmacist consultation regarding recommendations for optimal medications; DVT prophylaxis initiated and aggressive screening established to monitor the hypercoagulable

state native to pregnant women; and physical therapy regimens.

Conclusion

Given the dearth of data, the burn surgeon must respond to the challenge presented by a pregnant burn victim by coordinating the best practices of burn, surgical, and critical care in a team approach with a high-risk obstetrician, neonatologist, and clinical pharmacist. What exists in literature points to the positive association between maternal death and TBSA burned, that, fetal survival depends on maternal survival, and that, despite the massive physiological and anatomical changes induced by pregnancy, the care of a burned pregnant patient is similar to that of a nonpregnant burned victim. Indeed, the standard of care remains as follows: aggressive fluid resuscitation, early wound excision and coverage, empiric but class-restricted antibiotic administration, and adequate nutrition. Patients should be carefully resuscitated based on standard resuscitation algorithms, titrating infusion to urine output and hemodynamics. Burn wounds should be excised early and wounds grafted as quickly as practical. Severely burned pregnant women are ideally treated in burn centers specialized to handle severe burns and concurrently manage neonatal deliveries.[1] The fetus must be monitored continuously for signs of distress in order to guide obstetric intervention should it be warranted. Each additional week of gestation gained corresponds to significant decreases in neonatal morbidity and mortality.[88] For burns occurring after gestational week 28, the risk to the child from premature birth is moderate. Ideally, these children can be carried to term with close monitoring. However, a very low threshold for delivery should be maintained to avoid fetal harm from episodes of shock, sepsis, toxins, or infections. For a fetus younger than gestational week 22, care must focus on maintaining the mother in the hope the fetus can survive in her womb. Between 22 and 26 weeks, the gray period of neonatal survival, the womb is the preferred environment, but, should the fetus begin showing signs of distress, collaboration with a high-risk obstetrician and a neonatologist is imperative to attempt to preserve the lives of both mother and child. The coordinated efforts of a multidisciplinary team whose members include burn, trauma, critical care, obstetric, neonatal, and psychiatric specialists are requisite to provide the best management of the physiological and psychological challenges presented by severely burned obstetric patients. Further systemic research into the care of mother and fetus following thermal insult is necessary to better refine treatment algorithms.

35 Special Considerations of Age
THE PEDIATRIC BURNED PATIENT

OMAR NUNEZ LOPEZ, WILLIAM B. NORBURY, DAVID N. HERNDON, and JONG O. LEE

Introduction

According to the National Burn Repository, burn injuries are responsible for 40,000 annual hospital admissions, of which one third are pediatric patients.[1] Despite the steady decrease of burn injuries over the past three decades, children continue to represent a disproportionately high proportion of this population. The pattern of burn injuries affecting children differs from the pattern observed in adult burns.

House fires are among the leading causes of burn injuries and burn-related deaths in the United States, with approximately 2,600 deaths and 13,000 injuries reported per year.[2] Children under 5 years of age are at a greater risk. Deaths due to house fire among preschool children are at a rate of more than twice the national average for all ages (29.6 deaths/million children, or an average of 20% of all home fire deaths).[2,3] In addition, scald burns constitute the most common mechanism of injury in the pediatric population, representing approximately 71% of all burn injuries nationwide.[3] Scald burns are more frequently observed in children 6 years or younger. Scald injuries may be due to household accidents or can be deliberate abuse. More than half of these burns are attributable to hot liquids related to cooking, including spilling hot coffee or water, or to children reaching up to countertops, pulling pot handles or cords attached to cooking appliances, and spilling the contents onto themselves. Other causes include unknowingly putting body parts under a hot water faucet or climbing into a bathtub with hot water and intentionally or unintentionally being placed into or brought in contact with a hot substance by another individual. According to epidemiologic studies, minorities and children living in areas with lower incomes are disproportionately more affected by burn injuries.[4,5] Notably, flame burns are the dominant cause in adolescents and are associated with increased severity and increased need for hospitalization when compared to other burns.[4,6]

Drastic changes in burn care over the past decades, which include aggressive and early fluid resuscitation, prompt excision and grafting of burn wounds, improved infection control, modulation of the hypermetabolic response, and management of inhalation injury, have promoted a substantial decline in in-hospital mortality after burn injury.[7] This overall improvement in mortality is most perceptible in children. For example, in 1949, a pediatric patient (aged 0–14) with a burn covering 50% of total body surface area (TBSA) had an expected mortality rate of 50%; today, a similar mortality rate is expected in a pediatric patient (same age group) with a 98% TBSA burn.[8,9]

A retrospective study involving 103 children with burns covering more than 80% of TBSA over a 15-year period reported an overall mortality of 33%. Mortality was significantly higher in children under 2 years of age and in those with more than 95% TBSA burn (Figs. 35.1 and 35.2).[10] Delay in obtaining intravenous (IV) access was an additional predictor of mortality (Fig. 35.3). Aggressive fluid resuscitation during the first hour after burn increased survival. The mortality rate also increased significantly with inhalation injury, sepsis, and multiorgan failure.[10]

In addition to biological derangements, a severe burn produces tremendous psychological challenges to a child. Anatomical differences specific to the pediatric population make procedures and interventions more challenging.

Initial Evaluation

First, the burn patient needs to be removed from the source of thermal injury expeditiously and clothing and jewelry removed immediately. Pouring cold water onto the burn can cause hypothermia in large burns and should be avoided. After the burning process is stopped, the patient should be kept warm by covering with a sterile (if available) or clean sheet or blanket. If the burn is chemical, the patient should be removed from the chemical immediately, and the burn should be irrigated with copious amounts of water for at least 30 min. If the chemical is powder, it should be brushed off first prior to irrigation.[11,12]

Burn patients should be assumed to be trauma patients, and any potential life-threatening injuries should be identified and treated. The airway should be assessed first. One-hundred percent oxygen should be administered if inhalation injury is suspected. In addition, arterial blood gas and carboxyhemoglobin levels should be measured: pulse oximetry readings will be falsely normal in patients with elevated carboxyhemoglobin levels because carboxyhemoglobin is read as oxyhemoglobin by the pulse oximeter.[13]

Tachypnea, stridor, and hoarseness indicate an impending airway narrowing due to inhalation injury or edema, and immediate intubation should be considered. A full-thickness circumferential chest burn can interfere with ventilation. Chest expansion should be observed to ensure adequate air movement. If the patient is on a ventilator, airway pressure and P_{CO_2} should be monitored. If ventilation is compromised, escharotomy of the chest should be performed to improve ventilation.

Blood pressure measurement may be difficult in patients with burned extremities. These patients may require an arterial line to monitor their blood pressure. A radial

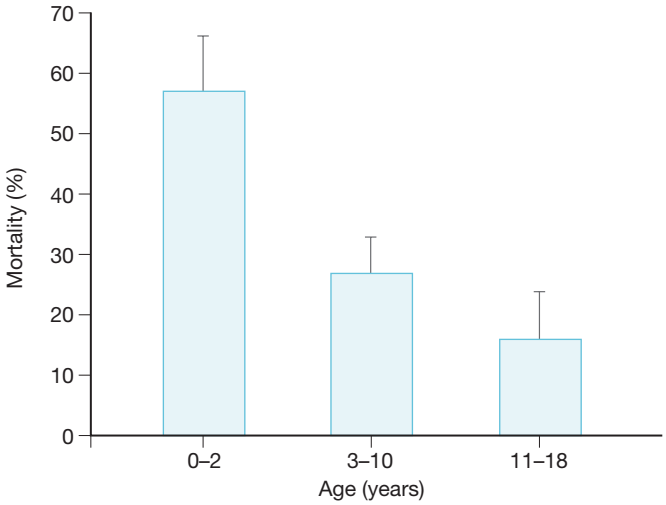

Fig. 35.1 Mortality in burns of more than 80% total body surface area for various ages.

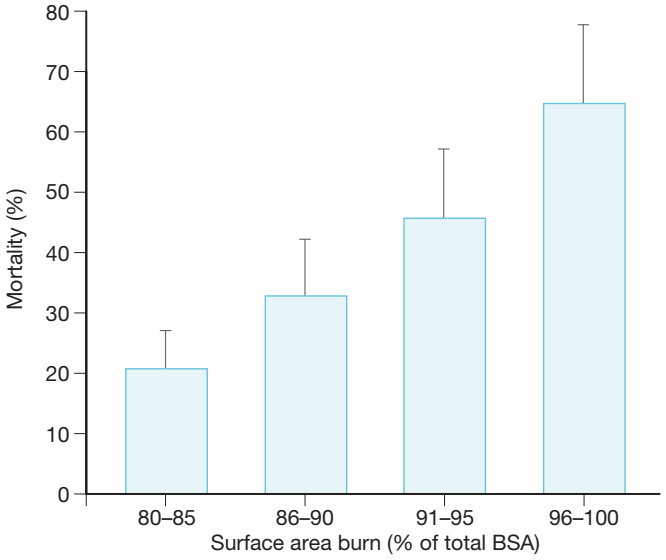

Fig. 35.2 Mortality for increasing burn size.

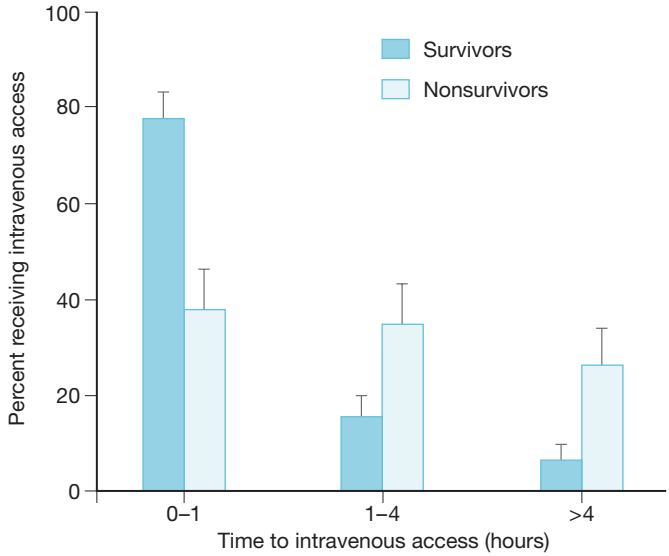

Fig. 35.3 Time to intravenous access in survivors and nonsurvivors. Mortality increases with delays in starting an intravenous line and instituting volume resuscitation.

arterial line may not be reliable in pediatric patients with extremity burns and may be difficult to obtain. A femoral arterial line may be more reliable and easier to secure.

An urinary catheter is placed to monitor urine output as a measure of successful resuscitation. Placement of a nasogastric tube is recommended in patients with severe burns because they can develop gastric ileus. Persistent tachycardia should alert a clinician to a missed injury or underresuscitation. Accurate and prompt determination of burn size is fundamental for the proper management of burn injury.

Resuscitation

There is a systemic capillary leak after a major burn, which increases with burn size. Intravenous access should be established immediately for the administration of fluids. Delays in commencement of resuscitation of burned patients result in worse outcome.[14] Therefore it is vital that IV access be obtained as early as possible. Due to the small circulating volume in children, resuscitation should be started immediately; even short delays increase the risk of shock. Peripheral IV access is preferred, and it must go through burned skin if necessary. IV access should be well secured. When peripheral IV access is not available because of severe extremity burns, a central venous line must be placed. Children with large burns should have two large-bore IV lines for fluid administration. The presence of two IV lines provides a safety margin if one stops functioning.

When vascular access is unobtainable, the intraosseous route is a viable option. Fluid volumes in excess of 100 mL/h can be administered directly into the bone marrow.[15] Intramedullary access can be utilized in the proximal tibia until IV access is accomplished. A 16–18-gauge bone marrow aspiration needle, spinal needle, or commercially available intraosseous needle can be used to cannulate the bone marrow compartment. Although previously advocated only for children younger than 3 years of age, intraosseous fluid administration can be safely performed in all pediatric age groups.[16,17] The proximal anterior tibia, medial malleolus, anterior iliac crest, and distal femur are preferred sites for intraosseous infusion. The needle should be introduced into the bone, avoiding the epiphysis, either perpendicular to the bone or at a 60-degree angle, with the bevel facing the greater length of bone (Fig. 35.4). The needle has been properly inserted when bone marrow can be freely aspirated. Fluid should be allowed to infuse by gravity drip. The use of pumps should be discouraged in case the needle becomes dislodged from the marrow compartment.

Fluid losses are proportionally greater in children owing to their small body weight-to-body surface area ratio. Normal blood volume in children is approximately 80 mL/kg body weight and in neonates 85–90 mL/kg, compared to an adult whose normal blood volume is 70 mL/kg. The

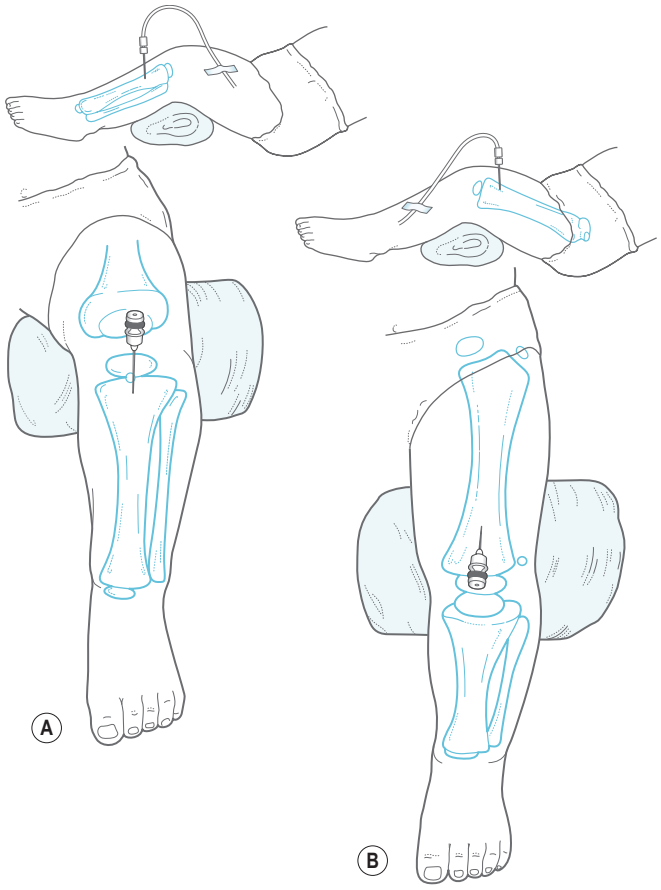

Fig. 35.4 Intraosseous line placement in the proximal tibia (A) and distal femur (B). (From Fleisher G, Ludwig S, eds. *Textbook of Pediatric Emergency Medicine*, 2nd ed. Baltimore: Williams & Wilkins; 1988: 268.)

commonly used "rule of nines," useful in adults and adequate in adolescents, does not accurately reflect the burned body surface area of children under 15 years of age (Fig. 35.5). The standard relationships between body surface area and weight in adults do not apply to children because infants possess a larger cranial surface area and a smaller area in the extremities than adults. The use in children of the most popular resuscitation formulas (initially designed for the adult population) can easily result in suboptimal resuscitation (Table 35.1).

Pediatric burned patients should therefore be resuscitated using formulas based on body surface area, which can be calculated from height and weight using a standard nomogram (Fig. 35.6) or formulas (Table 35.2). The commonly used resuscitation formula in pediatric patients calls for the administration of 5000 mL/m^2 TBSA burned plus 2000 mL/m^2 TBSA for maintenance fluid given over the first 24 hours after burn, with half the volume administered during the initial 8 hours and the second half volume given over the following 16 hours.[18] The subsequent 24 hours, and for the rest of the time their burn wound is open, the requirement is 3750 mL/m^2 TBSA burned or remaining open area plus 1500 mL/m^2 TBSA for maintenance. The fluid requirement decreases as a patient achieves more wound coverage and healing. As in the adult patient, resuscitation formulas offer a guidance for the amount of fluid necessary for replacing lost volume, and the amount of fluid should be titrated according to the patient's response. Resuscitation formulas have been incorporated into manual calculators, electronic devices, and smartphone applications in order to decrease the risk of error and increase the speed of calculation.[19] Hyponatremia is a frequently observed complication in pediatric patients after the first

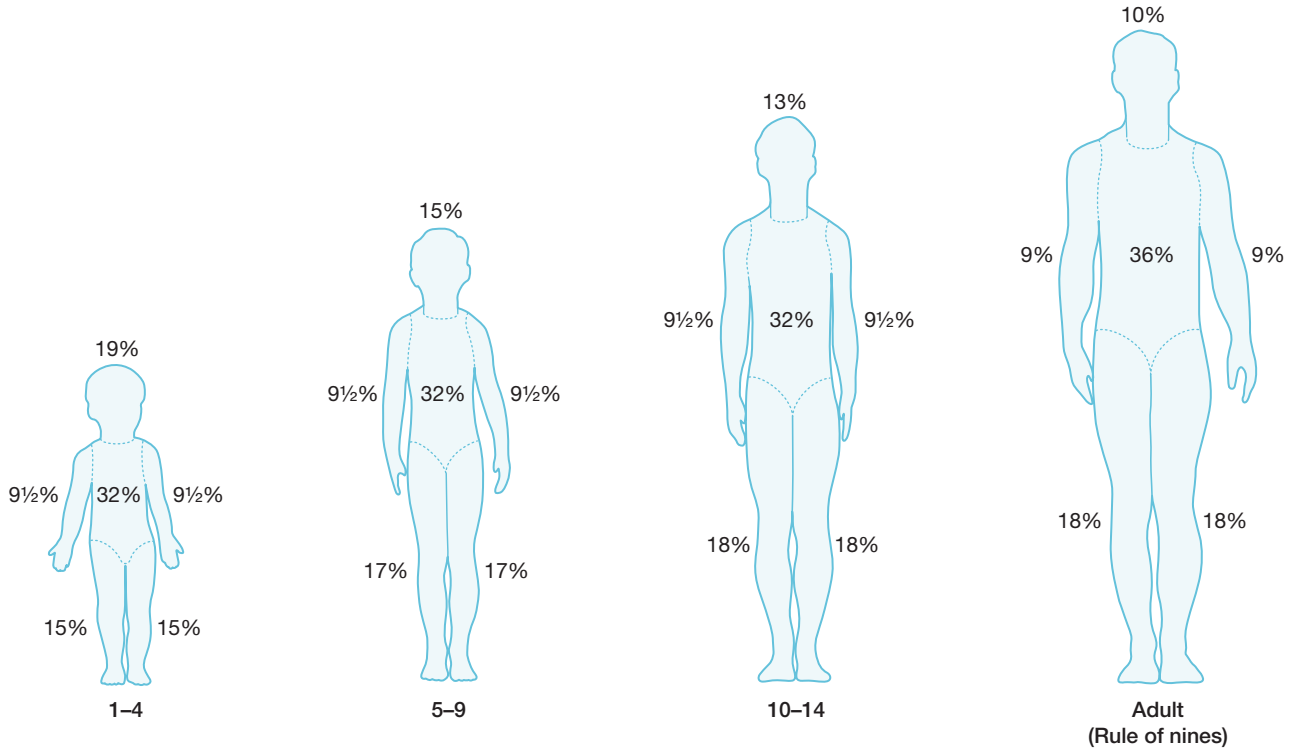

Fig. 35.5 The "rule of nines" altered for the anthropomorphic differences of infancy and childhood.

Table 35.1 Resuscitation by the Parkland Formula Only Compared to Maintenance Fluid Requirements Alone

	CALCULATED NEEDS		REPLACEMENT BURN LOSS		
Example	**% Burn**	**Resuscitation***	**Maintenance†**	**mL**	**mL/kg/%**

Table 35.2 Formulas for Calculating Body Surface Area (BSA)

Dubois formula	BSA (m^2) = ht (cm)$^{0.725}$ × wt (kg)$^{0.425}$ × 0.007184
Jacobson formula	BSA (m^2) = [ht (cm) + wt (kg) − 60]/100

48 hours post burn. Frequent monitoring of serum sodium is necessary to guide appropriate electrolyte and fluid management. Children under 1 year of age may require more sodium supplementation because of higher urinary sodium losses. Hypernatremia can also develop, and it has been identified as an independent predictor of mortality in adult burn patients.[20] Potassium losses are usually replaced with oral potassium phosphate rather than potassium chloride, as hypophosphatemia is frequent in this population.[21] Calcium and magnesium losses also must be supplemented.

Intravenous resuscitation fluid should be isotonic and replace lost electrolytes. Lactated Ringer's solution is the most commonly used resuscitation solution for the first 24 hours post burn. Children less than 1 year of age should also receive a separate maintenance fluid solution containing dextrose to prevent hypoglycemia because their glycogen stores are limited.

Assessment of Resuscitation

The routine clinical signs of hypovolemia in adult burn patients, such as low blood pressure and decreased urine output, are late manifestations of shock in the pediatric patient, and tachycardia is ubiquitous. Due to their cardiopulmonary physiologic reserve, pediatric patients do not show overt signs of hypovolemia until a decrease of at least 25% of the total blood volume occurs; at this point, hemodynamic decompensation occurs abruptly. Changes in distal extremity color, capillary refill, pulse pressure, and mental status reflect volume status. Capillary refill is a good indicator of volume status in pediatric patients. Decreased capillary refill should warn a clinician of imminent cardiovascular collapse. Measurements of arterial pH, base deficit, and lactic acid are of particular importance in this age group, reflecting decreased tissue perfusion. Improvements in base deficit or lactic acid show successful resuscitation.[22]

Normal blood pressure range varies according to age, with a systolic blood pressure of 100 mm Hg or less considered normal in patients younger than 9 years (Table 35.3). Renal compensatory mechanisms for hypovolemia (e.g., tubular concentration) are not well-developed in young children, contributing to hypovolemia with sustained urine production despite reduced intravascular volume.

An indwelling urinary drainage catheter is essential for burns of greater than 20% during resuscitation. During the early phase of resuscitation, urine output should be assessed hourly and the resuscitation fluid adjusted appropriately. Fluid administration should be titrated to achieve a urine output of 1 mL/kg/h in children and 2 mL/kg/h in infants. Initial fluid boluses should be administered in amounts appropriate to the size of the child and should be less than 25% of the total blood volume (20 mL/kg).

Overresuscitation must be avoided because it can lead to congestive heart failure, pulmonary edema, abdominal and extremity compartment syndromes, and cerebral edema in burn patients. In children, cardiac output depends mainly on the heart rate due to the low compliance of the heart, which limits increase in stroke volume. In addition, the heart is more susceptible to volume overload. Cardiac output can be measured using transpulmonary thermodilution devices, which are less invasive than a pulmonary artery catheter and only require an arterial catheter and a central venous line.[23] Transthoracic or transesophageal echocardiograms should be used early to assess cardiac function in patients who are not responding to conventional therapy. Children are particularly prone to the

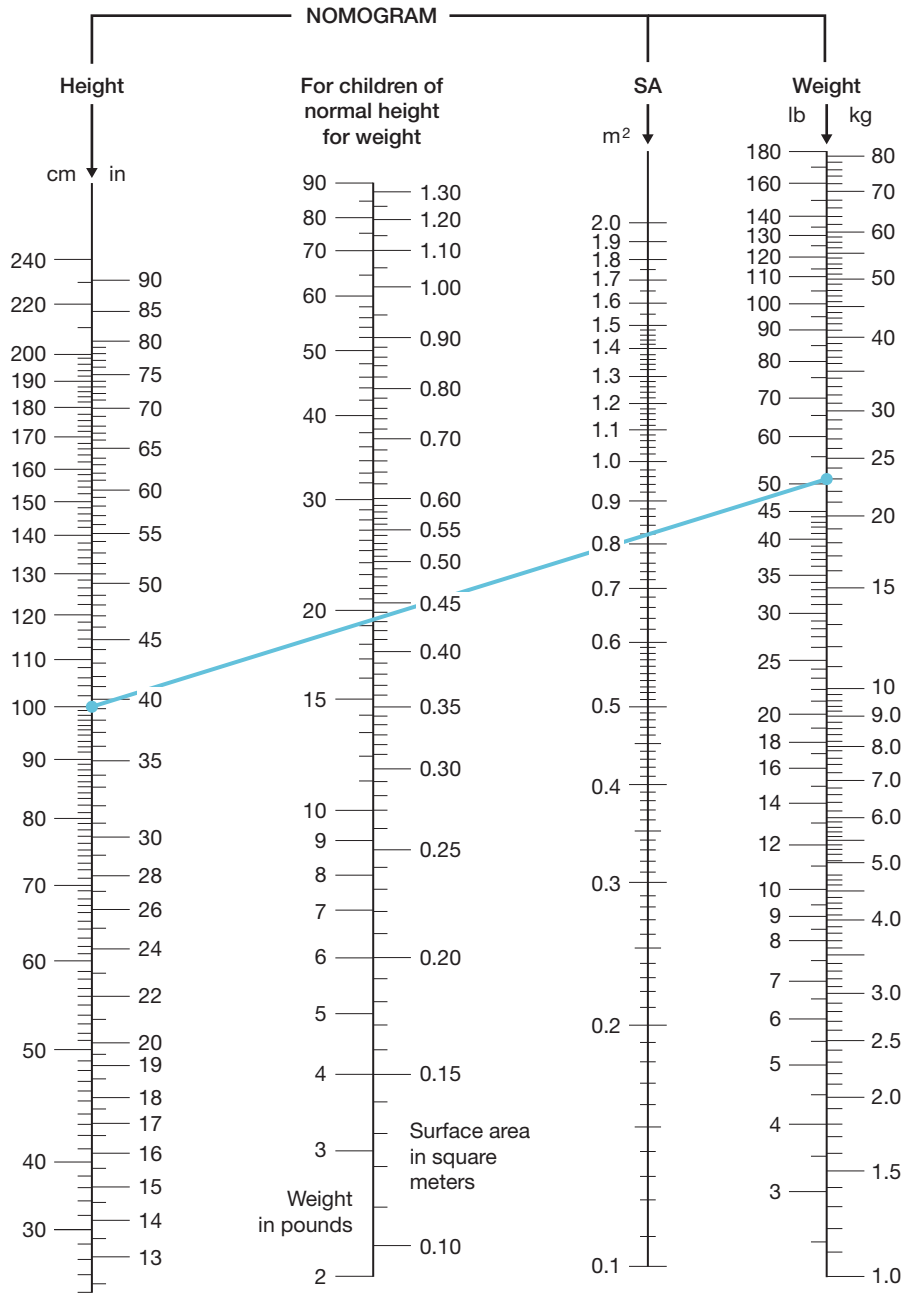

Fig. 35.6 Standard nomogram for the determination of body surface area based on height and weight. The example depicted is for a child of 100 cm in height and 23 kg in weight. (From Eichelberger MR, ed. *Pediatric Trauma: Prevention, Acute Care and Rehabilitation*. St Louis: Mosby Year Book; 1993: 572.)

Table 35.3 Normal Pediatric Vital Signs

Age	Minimum Heart Rate (beats/min)	Systolic Blood Pressure (mmHg)	Respirations (breaths/min)	Minimal Hemoglobin (g/dL)	Minimal Hematocrit (%)
<2 years of age	100–160	86–106	30–40	11.0	33.0
2–5 years of age	80–140	89–112	20–30	11.0	33.0
6–9 years of age	70–120	97–115	18–25	11.5	34–5
9–12 years of age	70–115	102–120	18–25	11.5	34–5
>12 years of age	60–110	90	12–20	12.0	36.0

development of edema from both vasogenic and hydrostatic sources. Vasogenic edema occurs in the early post-burn period when vascular integrity is impaired. The maintenance of intravascular osmotic pressures reduces the likelihood of edema development. In difficult resuscitation, colloids such as albumin can be used. Albumin can be expected to remain in the intravascular space if administered more than 8 hours after burn.

Evaluation and Management of Airways

Airway evaluation and management must be given priority. Children are more prone to obstruction due to the smaller aperture of their trachea. Airway edema causes disproportionate increments in resistance with concomitant reduction of the cross-sectional area.[24] Inhalation injury can lead to delayed airway edema after administration of massive resuscitation fluids.

Potential hemorrhage and edema make emergency intubation difficult. Hence, early intubation should be considered when a long transfer is anticipated, severe inhalation injury is present, or a patient has a large burn that likely will develop airway edema secondary to the large amount of fluid resuscitation. Concurrent placement of an endotracheal tube (ETT) over the bronchoscope should be considered at the time of bronchoscopy. A readily available estimate of airway diameter is the width of the patient's little finger, an age-based formula (age + 16)/4, or the use of a Broselow tape.[25]

The ETT must be well secured. In a child, exudative wounds and moist dressings can make this task difficult. One successful approach is to attach the ETT with tape around the back of the head, both above and below the ears. An additional piece of tape over the top of the head, secured to the tape behind the head, will prevent accidental extubation in most children.[26] In addition, commercially available endotracheal tube holders exist; however securing the tubes with tape strips of sufficient length and width has proved superior to two different commercial tube holders.[27]

Inhalation Injury

Inhalation injury is one of the main contributors to burn mortality.[28,29] The mortality rate of children with isolated thermal burns is 1–2%, but increases to approximately 40% in the presence of inhalation injury.[30,31] Expectedly, inhalation injury is associated with longer hospital stay and increased risk of pneumonia.[32] Carbon monoxide poisoning coupled with hypoxia is the most frequent cause of death due to inhalation injury. Any patient with a flame-related injury, particularly if confined in a closed space, should be evaluated for inhalation injury. If inhalation injury is suspected, arterial blood gas and carboxyhemoglobin levels should be obtained, and the patient should be placed on 100% oxygen. Signs of potential inhalation injury include facial burns, singed nasal vibrissae, carbonaceous sputum, abnormal mental status (agitation or stupor), respiratory distress (dyspnea, stridor, hoarseness, wheezing), or an elevated carboxyhemoglobin level of greater than 10%, especially in a closed-space fire.[33,34] The initial carboxyhemoglobin level should be calculated from the time the admission level is drawn, back to the time of the burn injury. A carboxyhemoglobin level of greater than 60% has a greater than 50% chance of mortality. Diagnosis is made by visualization of the airway with fiberoptic bronchoscopy (Table 35.4).

Table 35.4 Carbon Monoxide Poisoning

Carboxyhemoglobin (%)	Symptoms
0–10	Normal
10–20	Headache, confusion
20–40	Disorientation, fatigue, nausea, visual changes
40–60	Hallucination, combativeness, convulsion, coma, shock state
60–70	Coma, convulsions, weak respiration and pulse
70–80	Decreasing respiration and stopping
80–90	Death in less than 1 hour
90–100	Death within a few minutes

Table 35.5 Airway Maintenance, Clearance, and Pharmacological Management

Turn side to side	q2h
Sitting or rocked in chair	As soon as physiologically stable
Ambulation	Early
Chest physiotherapy	q2h
Suctioning and lavage (nasal/oral tracheal)	q2h
Bronchodilators	q2h
Aerosolized heparin/acetylcysteine	q2h alternating
Heparin 5000–10,000 units with 3 mL NS	q4h
Alternated with acetylcysteine 20% 3 mL	q4h

Treatment modalities for inhalation injury include airway maintenance, secretion clearance, and pharmacological management (Table 35.5). Further care is mainly supportive and includes ventilator support as needed, vigorous pulmonary toilet, humidification of inspired air, and antibiotics for documented infection. A combination of nebulized heparin and N-acetylcysteine has been shown to decrease the duration of mechanical ventilation after inhalation injury.[35–37]

Hypermetabolism

Profound hypermetabolism is a classic feature of children with large burn injury. No other pathological state produces

as dramatic an effect on the metabolic rate as burn injury.[38,39] Hypermetabolism slows wound healing, prolongs generalized weakness, and can lead to loss of lean body mass.

The hypermetabolic response increases with increasing burn size. There is an upregulation of catabolic agents, such as catecholamine, cortisol, and glucagon, which induces a hyperdynamic cardiovascular response; elevated oxygen consumption; increased energy expenditure; proteolysis, lipolysis, and glycogenolysis; loss of lean body mass; delayed wound healing; and immune suppression.[40–43]

Pharmacological agents have been used to attenuate hypermetabolism in burn injury. In order to minimize lean body mass loss, several therapeutic agents have been used in pediatric burned patients: anabolic hormones such as recombinant human growth hormone, insulin, and insulin-like growth factor-1 (IGF-1); anabolic steroids such as testosterone and synthetic analogue oxandrolone; and adrenergic antagonists such as propranolol.[44–50]

THERMOREGULATION

Hypothalamic dysregulation induced by various inflammatory cytokines and pain causes elevation of core body temperature after a major burn even in the absence of infection. Burn patients strive for temperatures of around 38°C. Low temperature is more likely indicative of overwhelming sepsis or exhausted physiological capabilities. The augmented heat loss secondary to epidermal loss after a major burn makes conventional methods of heat conservation inappropriate in burn patients.[51,52] In addition, low muscle mass in young children and their limited shivering capacity are factors that increase the risk of hypothermia in this population.[53]

Every effort should be made to reduce heat loss. Environmental temperature should be maintained at 30–33°C in order to reduce energy demands and evaporative water losses. Bathing should be performed expeditiously, with avoidance of unnecessary environmental exposure.[54]

Hypothermia produces numerous consequences. The heart is particularly sensitive to temperature, and ventricular arrhythmias are not uncommon. Hypothermia also increases the susceptibility of the myocardium to changes in electrolyte concentrations. The oxyhemoglobin dissociation curve is shifted to the left by decreased body temperature, impairing peripheral oxygenation. In extreme cases, hypothermia produces central nervous system and respiratory depression, coagulopathy, and loss of peripheral vasomotor tone.[41]

NUTRITIONAL SUPPORT

Nutritional support becomes an essential part of treatment of acute burn patients. Early enteral nutrition is used to accomplish nutritional support of the hypermetabolic response in severely burned patients. Early enteral nutrition preserves gut mucosal integrity, improves intestinal blood flow and motility, and can abate the hypermetabolic response to burn.[55,56] Patients with smaller burns should receive a high-protein, high-calorie diet to support their metabolic response. Those with burns covering more than 30% of the TBSA benefit from enteral feedings to supplement their diet.

Table 35.6 Nutritional Requirements for Children

	Galveston	Modified Curreri
Infant burn	2100 kcal/m^2 + 1000 kcal/m^2 burn	BMR + 15 kcal/%
Toddler burn		BMR + 25 kcal/%
Child burn	1800 kcal/m^2 + 1300 kcal/m^2 burn	BMR + 40 kcal/%
Adolescent burn	1500 kcal/m^2 + 1500 kcal/m^2 burn	

Feeding tubes can be placed beyond the pylorus and enteral nutrition initiated within a few hours of admission. Most children will tolerate enteral feedings as early as 1–2 hours post burn. Several studies have demonstrated the efficacy of early alimentation and its additional salutary effects.[57,58] Enteral feedings can be given through a flexible nasoduodenal or nasojejunal feeding tube, bypassing the stomach.

Several formulas are available to estimate caloric requirements in burn patients. Since caloric demands are related to burn size, caloric support should be given in amounts calculated based on total and burned body surface areas in burned children. A series of different formulas based on body surface areas have been developed to meet the differing requirements of the various age groups.[59–61] The Curreri formula has likewise been amended to reflect the differing demands of the pediatric group (Table 35.6).

Growth Delay

Increased protein degradation has been reported up to 9 months after major burns. Growth delay and osteopenia can persist up to 2 years in children.[44,62,63] Despite adequate nutritional support, children with greater than 40% TBSA burn have a linear growth delay of height and weight and a decrease in maximal exercise capacity during the first year after burn, which slowly resolves to near normal distribution by post-burn year 3.[64] Administration of propranolol and oxandrolone has been shown to ameliorate growth delay secondary to burn injury in children.[50]

Management of Burn Wound

One of the most important advances in the care of burn patients is the early surgical excision and grafting of the burn wound. Improvements in the treatment of burn wounds with the practice of early excision and grafting, along with improvements in fluid resuscitation and the general care of burn patients, have reduced the incidence of sepsis in burn patients.[65] Prior to early excision and grafting, third-degree burns were treated by removing small amounts of eschar at a time followed by grafting. Commonly, eschar was allowed to separate through lysis by bacterial enzymes, which led to a high incidence of invasive

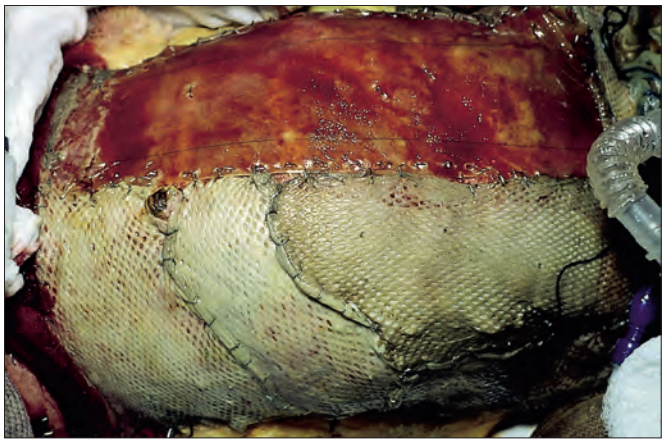

Fig. 35.7 Dermal and skin substitutes can be used as temporary cover for severe burns. Integra, a bilaminar skin substitute, can replace homografts as temporary cover. The Silastic superficial layer can be removed after 3 weeks and a super-thin autograft then placed on top. The entire wound can be covered with Integra, which is subsequently autografted when donor sites are available. (From Barret J, Herndon DN, eds. *Color Atlas of Burn Care*. London: WB Saunders; 2001: 107,„late 6.95.)

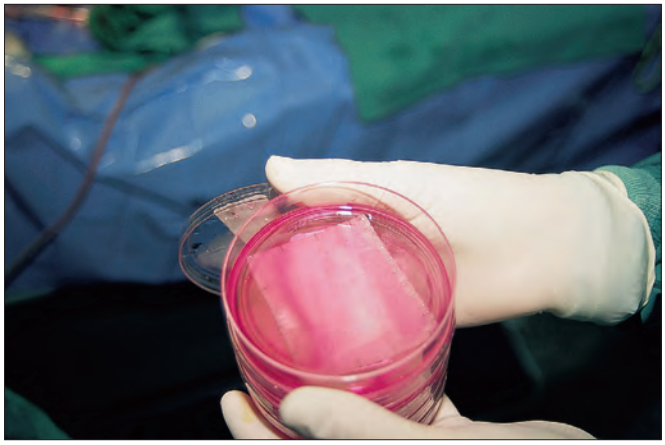

Fig. 35.8 The cultured epidermal autografts are ready to use 18–21 days later. Extreme care with handling is needed because of the fragility of the cultured cells. (From Barret J, Herndon DN, eds. *Color Atlas of Burn Care*. London: WB Saunders; 2001: 106, plate 6.89.)

infection, wound sepsis, increased length of hospital stay, and increased mortality. Currently, massive excision can be easily managed in children and contributes to shortened length of hospital stay and reduced mortality.[66,67] Early excision of massive burns in the first 24 hours is safe and effective.[68]

By using skin substitutes such as allograft, xenograft, and Integra (Fig. 35.7), the burn wound can be covered and protected until donor sites are available for procurement. Cultured epidermal autografts (CEA) are available for massive burn injuries (Fig. 35.8). Although it is an effective way to cover large burns where donor sites are limited, it may not be the most cost-effective approach. A group of patients treated with CEA had greater hospital costs, a longer hospital stay, and required more reconstructive surgical admissions when compared to patients who received conventional treatment with meshed autograft skin.[66]

Fig. 35.9 Superficial and small areas of deep second-degree scald burns before topical treatment: 25% total body surface area. (From Barret J, Herndon DN, eds. *Color Atlas of Burn Care*. London: WB Saunders; 2001: 79, plate 5.39.)

Traditionally, topical antimicrobials were the most commonly used treatment in partial-thickness burns. One of the drawbacks of using topical antimicrobials in burn wounds is the pain associated with dressing changes, especially in children. Immediate application of Biobrane is one of the treatment options for partial-thickness burns, primarily scald burns covering less than 30% of the TBSA. Biobrane can be safely used in children, including infants. When applied within 48 h of burn, there is no difference in infection rates between Biobrane and topical antimicrobials. Furthermore, Biobrane application leads to less pain, shorter hospitalizations, and shorter healing times compared to topical antimicrobials.[69–71] Other silver-based dressings such as Acticoat, Aquacel, Silverlon, and Mepilex Ag are available for partial-thickness burns that can be left on for several days, thus decreasing the number of dressing changes and the associated pain.[72–74]

It may be difficult clinically to determine the precise depth of scald burns during the early post-burn period because the wounds may be indeterminate and contain a mixture of superficial and deep partial-thickness burns and sometimes even full-thickness burns. Indeterminate-depth scald burns covering less than 20% of the TBSA in young children are best managed with delayed surgical intervention instead of early excision. Unless the wound is clearly full thickness, the scald burn should be conservatively managed for approximately 2 weeks to allow the wound to heal or demarcate (Figs. 35.9 and 35.10). This delayed surgery results in a smaller area of wound being excised and less blood loss.[75]

Large scald burns can be treated with allograft or xenograft, which significantly reduces the pain involved with dressing change and wound care. Scald burns covering more than 20% of the TBSA and of indeterminate depth were randomized to treatment with allograft skin versus topical antimicrobial therapy. Treatment with allograft skin led to faster healing and less pain.[76] In another study, patients with greater than 40% TBSA burn were randomized to treatment with allograft skin or topical antimicrobials. Patients who received allograft skin had a significantly shorter length of hospital stay.[77]

Fig. 35.10 Deep second-degree burns treated for 10 days with silver sulfadiazine. Note that the edges are regenerating. Pseudo-eschar challenges the evaluation of the wounds. Foul smell, discoloration, surrounding cellulitis, and eschar separation are signs of infection. (From Barret J, Herndon DN, eds. *Color Atlas of Burn Care.* London: WB Saunders; 2001: 77, plate 5.31.)

Pain Management

Therapeutic interventions such as wound care, surgical interventions, and physical therapy cause significant pain.[78,79] Despite advances in burn care, procedural pain continues to be severe and undertreated.[80] Well-controlled pain in the post-burn period has been associated with improved clinical outcomes (i.e., wound healing, re-epithelialization rates).[80–82] Conversely, poorly managed pain is associated with dysesthesias, chronic pain, and debilitating psychological conditions.[83]

Pain assessment in pediatric patients must be individualized to the patients' age, clinical conditions, and preferences. Verbal pain scales that assess pain severity are the most commonly used assessment tools.[84] Published studies report that burn patients preferred face and color scales over visual analogs and adjective scales.[85] When factors related to the injury or the treatment limit the capacity of the patient to communicate, the evaluation of the patient's behavior is a valid alternative. However it is recognized that these patients are at increased risk for inadequate treatment of their pain.[86]

The intravenous route is the preferred mode of analgesic administration in the acute phase post-burn. Significant changes in the metabolism of nonopioid medications (altered volume distribution due to carrier protein changes, alterations in receptor sensitivity) have been reported after burn injury.[87–89] Morphine sulfate and lorazepam pharmacokinetics seem to remain unaltered after burn injury; however it has been reported that their clearance rates increase after massive burns (>80% TBSA burn).[90–92] Morphine sulfate is one of the most commonly used analgesic in pediatric burn patients.[93] Fentanyl is another safe and efficacious alternative. Despite enthusiasm and increased interest, the routine use of intravenous local anesthetics is not advocated.[94]

Fentanyl Oralet (10 μg/kg) has been used successfully in the outpatient setting for dressing changes and wound care. Most outpatients are treated with hydrocodone/acetaminophen, and some require longer-acting narcotics such as methadone.

Nonpharmacological methods, including hypnosis, distraction techniques, and the use of virtual reality can be used in combination with pharmacological options for the treatment of pain and anxiety.[78,95–98]

Rehabilitation

One of the integral parts of successful treatment of burn injury is rehabilitation. During the acute phase of burn care, splints and proper positioning are used to minimize joint deformities and contractures. Splints are fabricated and adapted to meet individual needs and used preferably from the first day of hospitalization. Bedside therapy, including passive and active range of motion, is started early. Patients with leg grafts are kept on bed rest after the operation, but on postoperative day 3 they are allowed and encouraged to ambulate. Early physical therapy and ambulation are the keys to success in the long-term rehabilitation of burned children. When patients are discharged from their acute-care hospitalization, they follow rigorous outpatient treatment plans that include stretching, range of motion, and strengthening exercises.

Prevention

Prevention remains the single best way to reduce pediatric burn injuries. National prevention and education efforts have significantly decreased the number of pediatric burns each year. Lowering the temperature set point on water heaters and educating families to check the bath water temperature before placing a child in the bath have reduced scald burns. Prevention groups have worked with water heater companies and the Consumer Product Safety Commission (CPSC) to provide education to raise gas water heaters 12 inches above the ground, which significantly reduces the risk of accidental explosions and fires.

Three-quarters of "child fire play" involves matches or lighters. All matches and other ignition sources must be placed out of reach of children. A positive step toward prevention occurred in 1994 when the CPSC put into effect a child-resistant lighter to protect children. The importance of placing smoke detectors in multiple areas of the house cannot be overstated. Current prevention education focuses on children and especially infants who are not able to remove themselves from a fire. Educating children as early as possible that fire is dangerous is imperative. Providing safe environments for children and providing appropriate education is the responsibility of healthcare providers, the adults who care for them, and the community.

36 Care of Geriatric Patients

GABRIEL HUNDESHAGEN, JONG O. LEE, WILLIAM B. NORBURY, and DAVID N. HERNDON

Introduction

The quality of life in developed countries has improved over the past 50 years, increasing the average lifespan by nearly 30 years.[1] Individuals aged 65 years and over account for 13% of the U.S. population. This "elderly" population is projected to double from 40.2 million in 2010 to 88.5 million by 2050. Such population aging is unprecedented.[2] By 2050, the number of older adults persons in the world is expected to exceed the number of young for the first time in history.[3] This trend presents a special challenge because older adults will constitute an ever-growing segment of the average surgeon's practice and will influence clinical decisions, ethical decisions, and healthcare costs.

A multicenter study conducted in Tokyo found that 25% of burned patients were older than 65 years of age.[4] A systematic review of more than 186,500 patients in Europe showed that 10–16% were in this age range.[5] In the United States, geriatric patients constitute about 10% of the major burn population. The anticipated rise in the geriatric population makes understanding age-related physiological and metabolic changes even more important for burn care professionals.[6–8] The elderly and the very young are most likely to die from severe burns.[9–13] Adults older than 65 years old have a mortality rate from burns that is five times the national average.[9,13] Treatment of these patients remains a greater challenge than treatment of middle-aged and younger patients because lower physiological reserves and higher underlying comorbidities reduce the margin for error.

Epidemiology

Contact with flame is the main (54%) cause of burn injury.[13] One third of injuries result from cooking accidents: scalds in 22% of cases and contact with hot objects in about 6% of cases.[6–8,13,14] The latter cause is more prevalent in older adults, reflecting increased psychological and physical disability. This fact is also reflected in the rate of fire-related deaths in individuals older 75 years old, which is four times the national average. The male-to-female ratio decreases progressively as age increases, with women exceeding the number of men in the 75 years and older group (compared with the 5:1 male-to-female ratio for young adult burn patients).[13] Most burns in older adults occur at home; therefore, prevention must be focused in the home environment.[13,15] Prevention should also focus on the fact that 30% of geriatric patients are the victims of self-neglect, and at least 10% are the victims of elder abuse.[14]

Outcome

Mortality rates have diminished among all age groups in recent decades.[5,13,16] Technological progress as well as advances in fluid resuscitation, early burn wound excision, skin grafting, and pharmacotherapy have improved survival.[17] The Baux score is calculated as a sum of age and percent total burn surface area (TBSA) and illustrates both the influence of age on outcome and the improvements in burn care: When compared over time, the score at which the survival rate reaches 0% has steadily increased from 100 in the 1940s to 130–140 in the early 2000s.[18] However, mortality and morbidity rates remain higher in geriatric burn patients.[1,2,10,13,17,19] A large registry study of Jeschke et al. reported the LD50 (50% mortality) for 50-year-old patients at burn sizes of 50% TBSA. This LD50 considerably drops to 30–40% TBSA for patients older than 65 years to only 25% for those older than 70.[17] Pereira et al. have found in a large study of mortality trends and autopsy data that LD50 for older adults has remained steady at 35% for decades, which is disconcerting in the light of the overall improvement of burn care. Lung injury and sepsis were the most common primary causes of death noted in burn patients, and an increase in the weights of heart, lung, spleen, and liver was noted in all age groups postmortem.[16] Pomahac et al. reported that increased levels of creatinine at the time of admission were associated with increased mortality in older adults.[20]

Age, TBSA burned, and inhalation injury are associated with increased mortality rates. The mortality rate is 7.4% for all patients with burn injury aged 60–69 years, 12.9% for patients aged 70–79 years, and 21% for patients older than 80 years of age.[13]

Geriatric patients also experience greater long-term disability after burn injury. Only about 50% of elderly patients with a major burn return home within the first year,[7,16,21] and any loss of function, strength, or independence is more difficult to recover than in the younger patient population.[22] The unique risk factors present in this population explain these statistics.

Risk Factors

A number of well-recognized risk factors are present in older adults. Increased risk of infections, pulmonary diseases, and sepsis as well as the variability of comorbidities present in these patients increase morbidity after a burn. Some of the more prominent factors are shown in Box 36.1.

Box 36.1 Risk Factors in Elderly Patients

- Chronic illness (e.g., diabetes)
- Effects of aging (e.g., presbyphagia)
- Cardiovascular disease (e.g., previous infarct)
- Pulmonary reserve (decreased with age)
- Infections (e.g., pneumonia and urinary tract infection)
- Unintentional weight loss
- Decrease in lean body mass
- Impaired nutrition with presence of deficiency states in energy, protein, and macronutrients
- Decreased endogenous anabolic hormones
- Skin aging (thin, decreased synthesis)

Box 36.2 Aging of Skin

- Decreased epidermal turnover
- Decrease in skin appendages
- Thinning of dermis
- Decreased vascularity
- Decreased collagen and matrix
- Decreased fibroblasts and macrophages

DECREASED CARDIOPULMONARY RESERVE

Aging reduces pulmonary reserve for both gas exchange and lung mechanics.[23] Elderly patients are more prone to pulmonary failure, one major cause of burn-related death. The presence of atherosclerosis, coronary artery disease, and previous myocardial infarction is also common.

INFECTIONS

Pneumonia and urinary tract infections are the most prevalent complications in elderly burn patients.[13] The development of pneumonia seems to correlate with male gender, TBSA burned, and the presence of inhalation injury and contributes to higher mortality rates.[19]

MALNUTRITION AND DECREASED LEAN BODY MASS

Aging leads to progressive decreases in lean body mass, and some degree of protein–energy malnutrition is found in more than 50% of elderly burn patients on admission.[24–27] Any preexisting loss of lean body mass will result in increased morbidity, early onset of immune deficiency, organ dysfunction, weakness, and impaired wound healing.[25,28,29] Losses are caused by multiple factors, including impaired nutrition; swallowing disorders (presbyphagia); reduced mobility; and age-related decreases in endogenous anabolic hormones, human growth hormone, and testosterone.[23,25,30]

Decreased anabolic activity prolongs recovery time and greatly delays restoration of muscle. Importantly, older adults respond to exogenous anabolic stimuli such as testosterone analogs, human growth hormone, and resistance exercise similarly to the younger population. At the same time, daily protein requirements are higher in older adults than in the younger population.[31] Therefore, exercise, high-protein nutrition, and anabolic agents are essential for recovery.[32–34]

AGING SKIN AND WOUND HEALING

Aging produces significant changes in the skin. Because of these changes, burns tend to be deeper in older than in younger patients.[35–37] After the age of 65 years, the turnover rate of the epidermis decreases by 50%. A flattening of the rete pegs and fewer epidermal-lined skin appendages are present. These properties significantly delay healing of partial-thickness burns.[36,37]

Additionally, a progressive thinning of the dermis occurs, along with a decrease in both collagen content and other extracellular matrix proteins, especially glycosaminoglycan, which lower skin turgor. There are also decreases in vascularity, macrophages, and fibroblasts, resulting in deeper burns, an impairment of all phases of wound healing (Box 36.2).[36,37]

IMMUNE RESPONSE

It is hypothesized that aging leads to a state of "chronic inflammation" with increased baseline levels of proinflammatory cytokines that increase the vulnerability of elderly patients to negative outcomes after insults.[38,39] A recent study evaluated the unique characteristics of the inflammatory and immune response in elderly burn patients. Stanojcic et al. were able to show an uncoordinated overactivation of proinflammatory and antiinflammatory cytokines that occurred delayed by 2 weeks postburn.[40] This functionally impaired "cytokine storm" is followed by a phase of depletion and a dampened immune reaction in nonsurviving patients. The study concludes that because of the delay in the characteristic cytokine response, it cannot be used as a predictor for mortality in older adults as opposed to adults and children.[40]

Treatment

The increased complications seen in elderly burn patients may to a certain degree result from more cautious and less aggressive treatments. This is due to existing beliefs that elderly burn patients cannot tolerate eschar excision as well as their younger counterparts, resulting in a greater delay in the excision of burn wounds.[41] However, despite these risk factors, elderly patients have repeatedly been shown to tolerate multiple, early surgical procedures, and early wound closure corresponds to a better outcome in these patients.[41–43] In general, elderly patients are treated identically to younger patients, and most differences in burn management between patient groups are related to comorbid conditions and adversities that may arise. One unique exception to this is that massive burns are more commonly managed expectantly in older adults, and palliative care may be indicated.

Box 36.3 Parkland Formula:

Predicted volume (mL) = Weight in kg × TBSA 2nd and 3rd × **4 mL**

Modified Brooke Formula:

Predicted volume (mL) = Weight in kg × TBSA 2nd and 3rd × **2 mL**

Benicke's Formula:

Predicted volume (mL) = (50 × Weight in kg)
+ (300 × TBSA 2nd and 3rd)
+ (3500 × IHI) + (4000 × BAL)
− (3500 × Age ≥ 65 years) *

*First 24 hours; IHI (inhalation injury) present: yes = 1, no = 0; BAL (blood alcohol level), <0.1% = 0, ≥0.1 = 1.
TBSA, Total body surface area.

INITIAL RESUSCITATION

Improved fluid resuscitation over time is one of the factors associated with decreased mortality. Compared with younger patients, more fluid is required to resuscitate elderly patients with the same burn size to avoid hypovolemia.[44] This is likely attributable to decreased skin turgor, which reduces resistance to fluid accumulation or edema production. Burn depth, inhalation injury, and delayed resuscitation can influence fluid requirements.[45] In addition to the Parkland and modified Brooke formulas, Benicke et al. developed a multifactorial resuscitation formula with a compensating factor for advanced age (Box 36.3).[46] Early ventilatory support is more commonly required because of decreased lung reserve.

WOUND MANAGEMENT

Early removal of the burn wound and rapid closure with skin grafts are essential for survival.[35,42,43] Because of thinner skin, thermal injuries often create full-thickness wounds, and skin graft procurement may create significant donor site complications.[35] Thinner skin grafts are necessary, and healing time is prolonged.[36]

METABOLIC AND NUTRITIONAL SUPPORT

Although elderly patients do not generate the degree of hypermetabolism seen in younger patients, the catabolic response is comparable, necessitating a 1.5- to 2-g/kg/day protein intake.[46,47] In already malnourished patients, the goal of nutritional support must be not only maintenance but also replacement therapy, especially for protein and micronutrients.[25,48] Nutrient supplements are invariably required. Most supplements are protein hydrolysates because the gut is more capable of absorbing peptides and amino acids than whole proteins broken down from food.[21,49]

Anabolic agents are valuable adjuncts to optimal nutrition.[33,34,50,51] The effects of insulin and oxandrolone on postburn hypercatabolism have been studied in the pediatric population, and these anabolic agents may be used in older adults, given that endogenous anabolic hormones are decreased in this group after injury.[51–54]

Fram et al. demonstrated continuous insulin infusions, with tight euglycemic control, to restore insulin sensitivity, improve mitochondrial oxidative capacity, and reduce resting energy expenditure.[50] Lower-dose infusions of 9–10 U/h of insulin promote substantial muscle anabolism without the need for additional large doses of carbohydrate.[55] Intensive insulin therapy during acute care reduces morbidity, mortality, and complications caused by infection.[51,56] Testosterone restoration is effective in both male and female burn patients. However, the synthetic analog oxandrolone is preferable because it possesses only 5% of the virilizing androgenic effects of testosterone and is available in a peroral formulation. Oxandrolone restores lean body mass and improves wound healing in burned adults,[52] especially in emaciated subjects whose treatment has been delayed.[54,57] The effects of oxandrolone are independent of age.[53]

Treatment of acute pediatric burn patients with oral oxandrolone (0.1 mg/kg twice daily) enhances the efficiency of protein synthesis and increases anabolic gene expression in muscle. It also significantly increases lean body mass at 6, 9, and 12 months after burn and bone mineral content at 12 months after injury.[58] Recombinant human growth hormone has been successfully used in pediatric patients;[59,60] however, it has several adverse effects, such as hyperglycemia.[61] Its potential positive effects on the adult and elderly burn patient population are currently under investigation in prospective trials.

β-Adrenergic blockade with propranolol during the acute phase and long term attenuates the effects of the burn-induced hypermetabolic response. In severely burned subjects, titration of propranolol to reduce baseline heart rate by 15–20% improves muscle–protein balance and diminishes obligatory thermogenesis, tachycardia, cardiac work, resting energy expenditure, and fatty infiltration of the liver.[47,62,63] However, no study has directly focused on geriatric patients.

Pain, Sedation, and Comfort Care

Geriatric burn patients are often undertreated for pain because of the misconception that less pain occurs with age.[64] This can be detrimental because both pain and anxiety further increase the levels of catecholamines. Reduced clearance of many therapeutic agents occurs with aging, necessitating lower dosages (Table 36.1).[65] For this reason, pain assessment using reliable tools is essential to create an individualized treatment plan, which should also account for any comorbid conditions that may be present on admission. Untreated pain and incorrect sedation may result in posttraumatic stress disorder, major depression, and delirium.[66] In addition, although the burn injury primarily determines the extent of the metabolic response, metabolic rates are also increased by physical activity, background pain, procedure-related pain, and anxiety. Judicious narcotic support, appropriate sedation, and supportive psychotherapy are mandatory to minimize these effects.[67] Combination drug therapy is often required to achieve adequate analgesia. Different approaches ranging from patient-controlled analgesia to virtual reality have been found to ameliorate pain in burned patients. Intravenous

Table 36.1 Commonly Used Drugs Requiring Decreased Doses in Elderly Patients*

Drug	Comments
Barbiturates	Should be avoided; paradoxical pharmacologic response, often leading to restlessness, agitation, or psychosis caused by a decreased rate of elimination
Benzodiazepines	Increased sensitivity to pharmacologic effect; some benzodiazepines may be metabolized more slowly
Narcotic analgesics	Increased sensitivity to analgesic effects: possibly impaired clearance
Tricyclic antidepressants	Increased incidence of cardiac and hemodynamic adverse effects; urinary retention and other anticholinergic effects; decreased drug clearance

*Decreased dose due, in part, to decreased renal function in the elderly.

drug administration is preferable during the acute phase. A proactive geriatrics consultation team may also be beneficial in managing pain. Use of only comfort care measures needs to be considered for elderly patients with burns likely to be fatal.[68]

Perioperative Optimization

Aging produces many changes in the cardiovascular system that make hemodynamic stability more difficult to achieve and increase adverse outcomes. Coronary artery disease is prevalent, being estimated to exceed 80% in patients older than 80 years of age.[69] Elderly patients are at higher risk for congestive heart failure, and special considerations should be taken during acute and long-term treatments.[70] The revised cardiac risk index stratifies patients into risk groups and helps identify those likely to need additional cardiac evaluation.[71] Patients with minor perfusion abnormalities undergoing low-risk surgery may not require catheterization but should be considered for prophylactic β-blockers and aspirin before operation. High-risk subgroups of patients identified based on clinical risk factors and positive noninvasive tests should undergo cardiac catheterization. Patients with significant cardiac lesions should have definitive coronary revascularization via angioplasty before large TBSA burns are excised. The potential benefits of using β-adrenergic blocking agents during the perioperative period have been studied[72,73] because perioperative ischemic events are related to an exaggerated postoperative sympathetic response that leads to an increased heart rate.[72,74] β-Blockade has an added advantage in burn patients:[75] Severe thermal injury induces hypermetabolism that persists for up to 9–12 months,[63] and the resting metabolic rate in burn patients doubles for those injuries covering greater than 40% TBSA.[62] Catecholamines are key in the initiation of various cascades that stimulate postburn hypermetabolism.[76] Preventing initiation of these cascades by blocking the action of catecholamines at the receptor level using β-blockers such as propranolol attenuates this response and reduces supraphysiological thermogenesis,[62] tachycardia, cardiac work, and resting energy expenditure.[76]

The drawback of β-blockade in older adults is that the aging cardiovascular system is less responsive to β-receptor stimulation. This decrease, together with anesthetic agents, may lead to deleterious intraoperative hypotension in the presence of prophylactic β-blockade. Further investigations are necessary to determine the most appropriate therapeutic regimen for reducing perioperative ischemia, cardiac morbidity, and postburn hypermetabolic responses in older adults.

Pulmonary complications are more strongly linked to coexisting comorbidities than to chronological age.[77] Because of the prevalence of chronic obstructive pulmonary disease and asthma in older adults, physicians should be alert for these conditions during perioperative evaluation. With the appropriate diagnosis, aggressive pulmonary rehabilitation including exercise training, patient education, smoking cessation, and medication optimization is effective in elderly patients.[77] All of these aspects must be integrated into long-term patient management. Aggressive use of antibiotics, judicious use of bronchodilators, adequate hydration and postural drainage, and chest physiotherapy reduce the incidence of pneumonia, atelectasis, and other pulmonary complications.

Rehabilitation

Burn rehabilitation is a long multidisciplinary process that aims to preserve patients' functional ability and restore independence. Physical and occupational therapy should begin immediately after injury. Important components of rehabilitation include wound healing, scar prevention and correction, splinting, casting, traction, pressure therapy, pharmacologic therapy, exercise, and psychological support. Older adults should be aggressively managed during rehabilitation to avoid any further loss of function or strength, which are difficult to recover. Older patients are capable of recovering muscle strength with resistance exercise and should not be managed conservatively.[22] As with children, providing support and guidance for caretakers is essential because these individuals will be responsible for the patient's well-being upon discharge.[78,79]

Intentional Burns in Older Adults

Identifying physical abuse by burning in older adults is difficult because no pathognomonic signs exist. Although such abuse is relatively rare, professionals consistently underestimate the prevalence of elder abuse. The growth in the elderly population makes it necessary to raise awareness among health professionals and reevaluate the clinical approach and assessment for burn injuries inflicted intentionally or negligently.[80] Older adults often live alone, interacting predominantly with the caregivers who enact their abuse. These patients may keep their abuse a secret because of shame, guilt, or fear of reprisals.[81,82] Most forms of intentionally inflicted burns have a higher associated morbidity and mortality than equivalent accidental burns, in part because of comorbidity from other physical abuse, substance abuse, or psychological problems that contributed to or resulted from the inflicted burn. Elder mistreatment can

be associated with confidentiality difficulties because they may not want abuse reported. The priority of the examining physician is to treat life-threatening conditions. They should then promptly record symptoms and signs of abuse or neglect (including photographs). Deliberately inflicted burn injuries are best managed by a multidisciplinary team of health care, social service, and legal professionals.[80]

Conclusion

Despite the remarkable reduction in mortality in burned children over recent decades, we have not yet achieved the same results in elderly patients. This age group still constitutes a major challenge. Surgical decision making in these patients must take into account physiological age, preburn functional status, degree of impairment from comorbid conditions, and clear treatment goals. No patient should be denied an operation based on age alone because age-related declines in organ function are predictable for the population but not necessarily for the individual. More so, the burn surgeon's general mindset should be to treat geriatric patients as aggressively as younger patients. Currently, no "score" can improve decisions based on a thorough evaluation and discussion with the patient and family. Favorable outcomes in elderly burn patients should pertain more to relieving suffering and maintaining independence and quality of life rather than expanding lifespan. Clear, repeated communication between the burn team and patients or their surrogates is critical for guiding therapy and achieving acceptable outcomes.

37 Surgical Management of Complications of Burn Injury

OMAR NUNEZ LOPEZ, FREDRICK J. BOHANON, RAVI S. RADHAKRISHNAN, and DAI H. CHUNG

Introduction

Various surgical complications can occur in burn patients resulting from pathologic progression of the burn injury itself or from iatrogenic etiologies. Multiple organ system injuries can exist that require both a thorough assessment and expeditious management according to advanced trauma life support (ATLS) guidelines. Patients with large (>30% of the total body surface area [TBSA]) burns generally require a prolonged hospital stay with numerous debridement and skin grafting procedures that can be complicated by wound infection and subsequent graft failure.

Burn patients are at risk for potential surgical complications involving multiple organ systems, particularly the gastrointestinal (GI) tract. Such complications include stress gastritis and ulceration, acalculous cholecystitis, superior mesenteric artery (SMA) syndrome, and acute pancreatitis. In this patient population, the cause for occult systemic sepsis is frequently attributed to GI sources. Necrotizing enterocolitis (NEC) is a serious GI tract complication in burn patients, representing a phenomenon of transient ischemia–reperfusion injury to the gut. It can progress to full-thickness necrosis of involved segments, perforation, and rapid clinical decline.

Abdominal compartment syndrome (ACS) can occur during the acute phase of massive fluid resuscitation in severely burned patients. Based on determination of increased intra-abdominal pressures (designated as "compartment syndrome") and additional physiologic parameters, a decompressive laparotomy may be necessary to prevent further end-organ damage. A major burn significantly affects hemodynamics, and invasive monitoring may be necessary. As a consequence, catheter-related complications, such as distal limb ischemia and catheter-associated sepsis, can be seen with both arterial and venous vascular access. Prolonged intravascular manipulation secondary to the need for access predisposes to septic thrombophlebitis, central line-associated bloodstream infections (CLABSI), and poor outcomes.

Because of delays in diagnosis and treatment, there is a high risk of nonthermal complications in burn patients. As such, these secondary and sometimes fatal complications demand immediate recognition and treatment. This chapter reviews the frequently encountered, surgical, nonthermal complications in burn patients with respect to diagnosis and management.

Burns and Trauma

Although the overall incidence of combined burn and traumatic injury is low, the mortality is nearly twice that of burns without associated trauma.[1,2] A retrospective study examined upward of 24,000 patients with burn, trauma, or combined injuries and found the overall incidence of combined burn and trauma rate to be low (3.8%),[3] consistent with the National Trauma Data Bank and National Burn Repository data. There was no difference in length of hospital stay, injury severity scores, or mortality among burn or trauma patients alone. However, inhalational injury, length of stay, and mortality in patients suffering from combined injuries were significantly increased (Table 37.1). This increase in mortality was seen despite similar burn size, demonstrating the additive effects of trauma and burns in these patients.[3] In particular, approximately 24% of military burns are associated with concurrent traumatic injuries, compared to the 2–7% of burn/trauma injuries found in civilians in the same study.[4] In order of frequency, injured organ systems include musculoskeletal, head and neck, abdominal, thoracic, and genitourinary. Industrial accidents, attempts to escape house fires, explosions, and electrical burns with falls account for the majority of other victims. High-voltage electrical burns rarely occur at ground level and are often accompanied by falls resulting in spinal cord injuries, solid organ injury, intracerebral hemorrhage, and multiple fractures, including vertebral, rib, pelvic, and long bone fractures.

PRIMARY ASSESSMENT

The shocking appearance of the burn injury may unduly shift attention away from the other seemingly underwhelming injuries in patients with combined trauma, resulting in potential delays in diagnosis. The initial assessment of a trauma patient, including burn victims, should focus on airway, breathing, and circulation according to the ATLS guidelines. With the exception of respiratory compromise secondary to circumferential chest burns, the burn injury itself is usually not immediately life-threatening. Inhalational injury is common in burn patients. Some of the common signs of inhalational injury include singed nasal and facial hair, erythematous oropharynx, cough, stridor, and carbonaceous sputum. Asphyxia can be seen with carbon monoxide, for which pulse oximetry is an unreliable measure of oxygenation. Intubation or a surgical airway is

Table 37.1 Increased Morbidity and Mortality With Combined Burn and Trauma[3]

	Trauma (n = 22,284)	Burn (n = 1717)	B/T (n = 92)
Age	35.1 (±27.5)	31.0 (±23.2)	40.1 (±25.4)*
TBSA	N/A	17.5% (±19.7)	20.8% (±24.4)
ISS	5.5 (±10.3)	12 (±14)	23 (±16)*
LOS (days)	5.3* (±12.2)	13.7 (±16.5)	18 (±20.8)
INH	N/A	11.0%	44.5%*
Mortality	4.3%	9.8%	28.3%*

B/T, burn/trauma; TBSA, total body surface area; ISS, injury severity score; LOS, length of stay; INH, inhalation injury.
*$P < 0.05$ (Age, B/T vs. Burn; ISS, B/T vs. Burn and Trauma; LOS, B/T vs. Trauma; Mortality, B/T vs. Burn and Trauma)

warranted when significant respiratory distress exists. The inhalational injury can progress rapidly over hours such that an initial chest radiograph and arterial blood gas may be normal. Smoke inhalation induces a multitude of physiologic changes that result in increased vascular permeability and pulmonary edema, infiltration by leukocytes, and bronchorrhea.

Once the airway has been secured, attention should focus on the rest of the primary assessment. Third-degree circumferential chest burns can impair respiratory mechanics and require escharotomy to release the constrictive eschar. This should be performed in a sterile manner with incisions extending from the clavicle to the costal margin in the anterior axillary line bilaterally and may be joined by transverse incisions. The more common thoracic injuries, such as pneumothorax and hemothorax, should be managed as they would be in any other blunt or penetrating thoracic injury. However, because burns carry such a high risk of infection, thoracostomy tubes should be placed away from burned skin whenever possible to reduce the risk of infectious complications such as empyema. Finally, adequate circulation should be assessed. Pericardial tamponade resulting from a heavy impact to the anterior chest wall can be detected by focused assessment with sonography for trauma (FAST) examination and managed with pericardiocentesis or a pericardial window. Myocardial dysfunction may be encountered, especially with electrical injuries, and dysrhythmias should be managed accordingly. If central venous access is necessary, it should similarly be placed away from burned tissue when possible.

ASSOCIATED INJURIES

Burn victims frequently present with concomitant trauma injuries. Bone fractures are the most common associated injuries; in these cases, multidisciplinary management is mandatory. Fractures anatomically distant to the burned area can be treated with reduction and/or casting, as indicated. In addition, open fractures are preferably treated within the first 24 hours; surgical treatment options include irrigation, debridement of nonviable soft tissue, and internal fixation. If the injury occurs in—or the operative incision is made through—a burned area, the wound closure must be performed to the level of the fascia. Additional considerations in the treatment of fractures in burned patients include characteristics of the fracture (stability, displacement, and complexity), need of grafting of the burned area, wound care, and prompt initiation of physical therapy.

A complete physical evaluation is needed in all patients; the cervical spine should be stabilized until spinal injuries have been ruled out. When intracranial pressure (ICP) monitoring is indicated, placement of the ICP monitor is preferably done through a nonburned area of the scalp.

Severe burn injury may mask intra-abdominal injuries that may have devastating complications due to the delay in diagnosis. Furthermore, hemodynamic fluctuations secondary to intra-abdominal injuries may be overshadowed by the massive fluid shifts and inflammatory response following thermal injury. If an intra-abdominal injury is suspected, diagnosis and treatment modalities that are used in nonburned trauma patients should be utilized. Laparoscopy may be a useful approach for the delineation of intra-abdominal injuries but achieving adequate peritoneal insufflation may be difficult with the presence of significant abdominal eschar. If laparotomy is indicated, wound dehiscence is a known complication regardless of burn wound location. Retention sutures or alternative methods of abdominal wall closure should be considered when there is increased tension when closing the abdomen. Frequently, ACS may develop in the massively burned patient that may require emergent laparotomy and temporary wound closure.

Vascular injuries also present with a delay in diagnosis in the presence of large burned areas, anasarca, hypotension, and compartment syndromes. The assessment of vascular injuries includes the routine use of Doppler ultrasound and ankle-brachial index (ABI). Both of these modalities have their limitations in areas of significant burned or edematous skin. Computed tomography (CT) angiography is a highly sensitive and specific method useful to diagnose vascular injuries in burn patients.[5]

Gastrointestinal Tract Complications

Although the superficial effects of burn injuries are often striking, the systemic physiological response to these injuries may result in significant end-organ dysfunction and cannot be overemphasized. Burn injuries of greater than 30% TBSA produce a physiological response leading to systemic shock, hypermetabolism, and widespread immunosuppression.[6] The combination of intravascular fluid loss, vasoactive hormone release, catabolism, and immune dysfunction results in the development of nonthermal complications associated with burn injuries.

Physiological changes in blood flow have a dramatic effect on organ response to injury. This has been particularly well demonstrated in the GI tract, where a combination of diffuse capillary leak, hypovolemia, and the release of vasoconstrictive agents can cause a decrease in splanchnic blood flow.[7,8] Splanchnic hypoperfusion occurs early in the post-burn period despite adequate

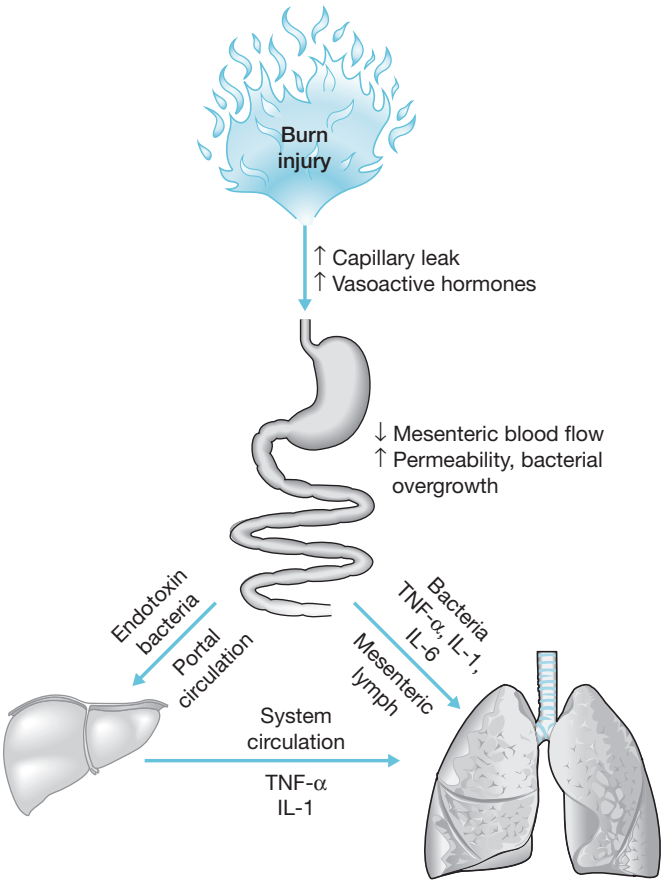

Fig. 37.1 Schematic representation of the role of the gastrointestinal tract in multiorgan sepsis after cutaneous burn injury. (Adapted from Gosain A, Gamelli RL. Role of the gastrointestinal tract in burn sepsis. *J Burn Care Rehabil* 2005;26: 85–91.)

cardiac output and fluid resuscitation, as demonstrated in 40% TBSA pig models that had an early reduction in superior mesenteric blood flow associated with intestinal mucosal hypoxia, acidosis, and increased bacterial translocation.[9–11]

A combination of hypoperfusion and hypermetabolic response can lead to breakdown of the gut mucosal barrier resulting in bacterial translocation from the gut, systemic inflammation, and ultimately, sepsis[12,13] (Fig. 37.1). Several studies have demonstrated the association between massive cutaneous burn injury and bacterial translocation.[10,14,15] Following massive burn injury, the GI tract mucosa sustains immediate atrophy, resulting in significant gut barrier dysfunction. The increase in intestinal apoptosis does not appear to be from mesenteric hypoperfusion alone, but is speculated to be related to proinflammatory mediators.[16] An in vivo study using a 30% TBSA rat burn model confirmed that there was increased bacterial translocation and permeability to macromolecules that peaked at 18 hours post injury, lending credence to the idea that disruption of intestinal barrier integrity in severe burns can lead to sepsis from bacterial translocation.[17] Thus, interventions aimed at preventing splanchnic hypoperfusion and hypermetabolism may circumvent complications associated with severe burns.

PARALYTIC ILEUS

Intestinal ileus is a commonly encountered condition following large burns. Multiple factors contribute to the development of ileus in burn patients, including electrolyte imbalances, narcotic use, prolonged immobilization, abdominal trauma, sepsis, and surgery. In addition, proinflammatory cytokines and proteins that are elevated as part of the postburn systemic response, such as interleukin (IL)-1α, IL-6, tumor necrosis factor (TNF)-α, p38 mitogen-activated protein kinase, and endothelins have been found to be linked to altered intestinal permeability.[15,18–21] Electrolyte disturbances, opioids use, prolonged immobilization, abdominal trauma, sepsis, and surgery are factors that can result in decreased GI motility in burn patients

Cramping abdominal pain, abdominal distension, and intolerance to enteral feedings are the most common symptoms. The cause of ileus should be thoroughly evaluated because it may represent an early indicator of systemic sepsis and can ultimately help direct care.[22] Physical examination must be performed to rule out fecal impaction and to identify signs of peritonitis associated with more serious complications such as acute colonic pseudo-obstruction, also known as Ogilvie's syndrome. The treatment of ileus involves correction of electrolyte derangements and adequate hydration; implementing these basic measures in burn patients can be difficult due to the pathophysiologic changes that occur after severe.[12,15]

OGILVIE'S SYNDROME

Ogilvie's syndrome, first described in 1948, is characterized by massive colonic dilation without a mechanical cause for obstruction.[23,24] This entity has been well described in burns, with a reported incidence of 0.3%.[25] Clinical presentation includes insidious and progressive abdominal distension. Some patients may report a history of diarrhea prior to the onset of distension. Nausea, vomiting, and bowel sounds are not reliable indicators of this condition. Mild abdominal pain can develop as distension increases.[23,26] Diagnosis and management of pseudo-obstruction require that mechanical bowel obstruction be absolutely excluded. Radiologic studies showing colonic air in all colonic segments, including the rectum, are warranted before considering pharmacologic therapy.[27,28]

The goal of the management is to decompress the colon in order to minimize the risk of colonic perforation and ischemia, which are associated with high mortality.[29] Close monitoring including serial physical examinations and plain abdominal radiographs every 12–24 hours to evaluate colonic diameter are recommended. Initial management is conservative in patients without significant abdominal pain, severe colonic distension (>12 cm), or signs of peritonitis. In patients with cecal diameter of greater than 12 cm or who have failed 24–48 hours of supportive management, intravenous neostigmine can be used. In patients who fail or who have contraindications to neostigmine, colonic decompression is indicated.[30] Acute colonic pseudo-obstruction secondary to opiates can benefit from methylnaltrexone prior to decompression.[31] Endoscopic decompression is the preferred method to decompress the colon; surgical decompression (e.g.,

surgical cecostomy) is performed if endoscopic decompression and pharmacologic therapy fail or if there is evidence of perforation or signs of peritonitis. Percutaneous cecostomy should be reserved for patients who are not surgical candidates.[32]

ABDOMINAL COMPARTMENT SYNDROME

ACS refers to the onset of new organ dysfunction caused by increased intra-abdominal pressure.[33,34] Intra-abdominal pressure measurements have allowed grading of ACS; however, for clinical purposes, ACS is defined as new organ dysfunction secondary to increased intra-abdominal pressure without a strict threshold.[35,36] Aggressive fluid resuscitation, severe burns (>30% TBSA), and sepsis increase the risk for ACS.[37–40] Secondary ACS is commonly related to the extent of volume resuscitation. For this reason, the amount of fluid being administered and the development of early signs of ACS should be closely monitored.[41,42] Mortality for patients who have progressed to ACS ranges from 40% to 100%.[36,43]

Nearly all patients have a tense and distended abdomen; however this clinical finding is a poor predictor of ACS.[44,45] Oliguria and increased ventilator requirements are common in patients with ACS. Tachycardia, hypotension, jugular venous distension, and peripheral edema can also be found. Imaging studies are not helpful to diagnose ACS; however expected findings include decreased lung volumes, atelectasis, or elevated hemidiaphragms in chest radiographs. Compression of the inferior vena cava, massive abdominal distension, renal compression or displacement, bowel wall thickening, and bilateral inguinal herniation can be demonstrated in CT of the abdomen.[46]

Management of ACS consists of supportive care and surgical abdominal decompression. However, in patients with abdominal burns, mechanical limitations due to burn eschars can be a significant contributing factor for increased intra-abdominal pressure; thus early escharotomy is advocated.[47,48] Supportive care includes measures that can decrease intra-abdominal pressure, such as evacuation of intraluminal contents (e.g., nasogastric and rectal drainage) and improvement of abdominal wall compliance (supine positioning without head elevation, adequate pain control and sedation, chemical paralysis).[39,49]

Surgical decompression is the definitive management of ACS; however a specific threshold for decompression has not been defined. Several factors can be considered to decide the need for this intervention, including progression of organ dysfunction after supportive measures, intra-abdominal pressure of greater than 25 mm Hg, or abdominal perfusion pressure (difference between the mean arterial pressure and the intra-abdominal pressure) of less than 50 mm Hg.[50,51] Decompression is achieved by making a midline incision through the linea alba to open the abdominal cavity. A temporary abdominal wall closure is often used to maintain an open abdomen.[52]

Complications Associated With Feeding Tubes

Adequate nutrition is one of the major determining factors of success in the treatment of severe burns. Exclusive oral feeding is often a nonviable option due to multiple factors frequently observed in burn patients (e.g., endotracheal intubation, feeding intolerance, compromised mental status, oral burns, concomitant oral and/or facial trauma, etc.). Furthermore, the oral route, in severe burns, is not the preferred route of alimentation because it can represent a limiting factor for the intake of the needed calories to treat severe catabolism.[53]

Nutritional therapy is preferentially delivered via the enteral route.[54] Parenteral nutrition increases the risk of complications such as intestinal atrophy, bacterial overgrowth and translocation, liver malfunction, and catheter-related infections.[53,55]

Nasogastric, nasojejunal, gastric, and jejunal feeding tubes can all deliver enteral nutrition. In the GI tract, malposition, coiling, or kinking of tubes can occur anywhere along the course of the tube, including in the pharynx, pyriform sinus, esophagus, stomach, and duodenum.[56] The presence of a nasogastric or nasoenteric tube impairs the normal function of the lower esophageal sphincter, making the patient more susceptible to reflux of gastric contents. which may lead to esophagitis, esophageal stricture, gastrointestinal bleeding, or pulmonary aspiration.[57] Placing feeding tubes past the pylorus has become standard practice to minimize the risk of aspiration and complications of enteral feeding in patients with impaired gastric emptying. However, a meta-analysis did not find significant differences in the incidence of pneumonia, caloric goal achieved, or mortality between gastric and post-pyloric tube feeding.[58] Nasogastric tubes can cause gastritis or bleeding due to chronic irritation or pressure necrosis due to suctioning of the gastrointestinal mucosa. Patients with bloody gastric drainage require further evaluation, and, whenever possible, the nasogastric tube should be removed.[59] If tubes are left in place for long periods of time, they can be associated with nasal alar necrosis. Frequent retaping of the tube to decrease pressure at any particular point or less traumatic methods of tube fixation can prevent this complication. Patients with prior esophageal or gastric surgery are at risk for gastrointestinal perforation, and infants, children, and patients with facial trauma are at risk for cribriform plate perforation and intracranial intubation.[60,61]

STRESS GASTRITIS

The incidence of acute gastroduodenal ulceration in burn patients, known as Curling's ulcer, has decreased dramatically with the introduction of aggressive fluid resuscitation, early enteral feeding, and the administration of proton pump inhibitors (PPIs). This condition is clinically recognized in most cases only by the onset of upper GI bleeding, and it was once associated with mortality rates of up to 70%. Fortunately, with the institution of the aforementioned interventions, the occurrence of clinically significant ulcers has decreased from 15% to 3%, as has mortality.[62]

Although the exact pathogenesis of Curling's remains unknown, the hypoperfusion, hypermetabolism, and immune dysregulation described earlier are all implicated in ulcer formation. Specifically, intravascular depletion leads to mucosal ischemia and disruption of the protective mucosal barrier. Compounded by the increased acid production, bile reflux, and direct mucosal injury due to the presence of intraluminal tubes, the end result is

gastroduodenal ulceration.[63] Recent studies have proposed an additional mechanism of stress ulcer formation secondary to the systemic production of reactive oxygen species (ROS) in response to stress. Studies have confirmed that the activation of ROS-producing pathways, such as p38 MAPK, results in gastroduodenal ulcer formation.[64]

An effective approach in the prevention of stress gastritis in burn patients is early enteral feeding. It has been proposed that this may be because of dilutional alkalinization or because enteral feeds provide the energy required for mucosal cell resiliency despite ischemia. Studies have shown that intraluminal glucose provides significant protection to ischemic cells of the small intestine and gastric mucosa.[62] Additionally, aggressive fluid resuscitation along with H_2-receptor antagonists or PPIs have proved effective against development of stress gastritis. However, once a stress ulcer is established, many of the same treatments just described are initiated. Aggressive medical therapy, typically involving a high-dose continuous PPI infusion, must be started in patients with massive burns who develop hemorrhage. The PPIs have been demonstrated to reduce instances of rebleeding and the need for subsequent surgery and/or endoscopic treatment.

Endoscopic control of bleeding is indicated as a first approach for patients with gastric bleeding. Specific surgical indications include massive bleeding (>2.5 L in adults, >50% blood volume in children per 24 hours), ongoing uncontrolled blood loss, and evidence of a perforated viscus. Operative repair of ulcers is rarely necessary, the simplest approach consists of a long anterior gastrotomy with oversewing of bleeding sources. In patients who are hemodynamically stable after ligation of actively bleeding ulcers, a vagotomy and pyloroplasty can be added.[65] Although Curling's ulcers are far less common than in the past, they remain a potential risk to all burn-injured patients.

ACALCULOUS CHOLECYSTITIS

Acute acalculous cholecystitis (AAC) is a rare complication of burn injury found in an estimated 0.4–3.5% of burned patients, but it may result in significant morbidity if not quickly recognized and appropriately treated.[66] Patients with extensive burns (>40% TBSA), multiple transfusions, sepsis, dependence on total parenteral nutrition (TPN), and a history of narcotics use are particularly susceptible to the development of AAC. Age, number of packed red blood cell transfusions, and duration of ventilatory support are independent predictive factors for the development of AAC in severely burned patients.[67] Proposed etiologies of AAC include bile stasis, hypoperfusion causing gallbladder ischemia, cystic duct obstruction, and sepsis.[68] Patients with heavy narcotic use for pain control or who are dependent on TPN tend to experience bile stasis. Hypoperfusion affects circulating vasoactive mediators and local tissue perfusion, leading to local ischemia of the gallbladder wall, inflammation, gangrene, and perforation.

AAC commonly presents with fever, right upper quadrant tenderness, leukocytosis, and elevated liver enzymes. AAC is a surgical emergency because patients may rapidly develop complications, including perforation or gangrenous cholecystitis. Mortality following perforation or gangrenous emphysema is reported to be as high as 65%, but early diagnosis and intervention may reduce the likelihood of severe complications significantly, as reflected by the reduction in mortality to 7%.[69]

Ultrasonography is usually the first diagnostic study performed when cholecystitis is suspected; gallbladder wall thickening (>3 mm), pericholecystic fluid, mucosal sloughing, gallbladder distension, emphysematous gallbladder, and frank perforation of the gallbladder with abscess formation are findings suggestive of AAC.[68] When the diagnosis is unclear despite ultrasonography, a hepato-iminodiacetic acid (HIDA) scan can confirm the diagnosis. The specificity of HIDA scan for AAC has been reported as high as 100%, with a sensitivity as low as 67%.[70] CT scanning can also be used to diagnose AAC. Findings suggestive of AAC include absence of gallstones or sludge, gallbladder wall thickening, subserosal halo sign (intramural lucency), pericholecystic fat infiltration, pericholecystic fluid, intramural gas, and gallbladder distension;[68] the accuracies of CT scanning and ultrasonography are similar.[71]

The treatment of AAC consists of initiation of antibiotics with Gram-negative and anaerobes coverage after collecting blood cultures, and either cholecystectomy or placement of a cholecystostomy tube. Prompt treatment is needed or gallbladder gangrene can develop and result in gallbladder perforation. Delayed treatment carries mortality rates as high as 75%.[72] Cholecystectomy is the definitive therapy for AAC, with drainage of associated abscesses often being required. Due to the significant inflammatory process, the laparoscopic approach is challenging, with a higher risk of bile duct and vascular injuries. However, it is appropriate to attempt a laparoscopic approach and convert to open if necessary. For extremely ill patients for whom surgical intervention is not an option, ultrasound-guided percutaneous cholecystostomy should be considered; success rates range from 56% to 100%. Patients treated with a cholecystostomy tube should improve rapidly, usually within 24 hours. Patients with AAC who fail to improve or worsen require cholecystectomy.[73-75]

PANCREATITIS

Acute pancreatitis is an underrecognized complication following thermal injury. Increased serum pancreatic enzymes have frequently been associated with burns, but the nonspecific symptoms, such as epigastric pain radiating to the back, are often overlooked. Reported rates of post-burn pancreatitis range from 0.05% to 40%.[76,77] Despite its rarity, pancreatitis is associated with increased mortality, as survival rates were reported to be only 69% compared to 87% in burn patients unaffected by pancreatitis. Management for acute pancreatitis in the burn patient is similar to the management in nonburn patients. Treatment includes supportive care, bowel rest, fluid resuscitation, and parenteral nutrition. Abdominal ultrasound should be performed to rule out gallstone disease. Occasionally, a more detailed workup with an abdominal CT scan is necessary to identify complications such as pseudocyst formation, pancreatic necrosis, or pancreatic abscess. Operative intervention is rarely indicated.

SUPERIOR MESENTERIC ARTERY SYNDROME

Superior mesenteric artery (SMA) syndrome, or Wilkie's syndrome, occurs when the third part of the duodenum is extrinsically compressed by the superior mesenteric vascular pedicle (Fig. 37.2). SMA syndrome is usually precipitated by rapid and substantial weight loss, leading to a loss of retroperitoneal fat. In burned patients, weight loss resulting from the hypermetabolic response is common. Symptoms include nausea, feeding intolerance, bilious vomiting, and abdominal pain aggravated by feeding and relieved by the knee-to-chest position. The diagnosis is established by an upper GI series demonstrating duodenal dilation, retention of barium within the duodenum, and extrinsic pressure on the third portion of the duodenum with a characteristic sharp cutoff.[78–80]

The management of SMA syndrome consists of nonoperative treatment with nutrition supplementation. Nasojejunal tubes are advocated as the most appropriate mode of feeding because the tube is placed past the obstruction point. In selected cases, TPN may be necessary to optimize the nutritional status of the patient.[79] Surgical procedures are rarely indicated, but, when necessary, the operative goal should be to bypass the point of obstruction caused by the superior mesenteric vascular pedicle. The operation of choice is duodenojejunostomy, in which a lateral duodenotomy is made and the proximal jejunum is then used to create a side-to-side anastomosis. A laparoscopic approach has been used with some success to relieve the duodenal obstruction in patients with SMA syndrome.[81,82] Gastrojejunostomy and the Strong procedure (division of the ligament of Treitz with mobilization of the duodenum) are alternative surgical options, but they have proved inferior to duodenojejunostomy because of failure to adequately relieve the obstruction, peptic ulceration, and blind loop syndrome.[83]

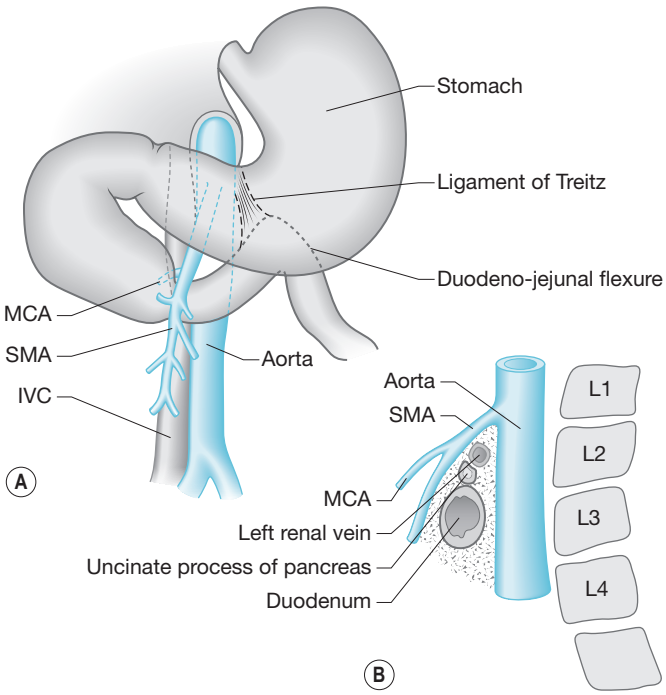

Fig. 37.2 Superior mesenteric artery syndrome. **(A,B)** Schematic illustrations of the mechanism of superior mesenteric artery syndrome, where superior mesenteric vessels extrinsically compress the third portion of the duodenum. Vascular compression of the duodenum, in: Fischer JE (ed.), *Mastery of Surgery*, 5th ed., Philadelphia; Lippincott Williams & Wilkins; 2007: 956.)

NECROTIZING ENTEROCOLITIS

Splanchnic hypoperfusion occurs as a result of hypovolemia and circulating vasoactive mediators. The degree of intestinal insult ranges from mucosal atrophy to full-thickness necrosis and perforation, and is a product of the severity and duration of ischemia combined with reperfusion by resuscitative efforts. Moreover, the presence of virulent bacteria and fungi in the immunocompromised state contributes to intestinal complications and can lead to sepsis. In a study of 2114 patients with burn injury, only 10 (0.5%) patients demonstrated clinically apparent ischemic necrotic bowel disease, and they had more severe burns.[84] Although only 2–5% of patients are clinically diagnosed with this condition, autopsy findings identified pathologic changes consistent with ischemia in 50% of burn patients who died as a result of their injuries.[85] Unfortunately, the mortality rate of patients experiencing ischemic enterocolitis is reported to be extremely high, in the range of 60–69%.[86]

Patients with ischemic bowel demonstrate feeding intolerance, abdominal distension, and abdominal pain. Dilated loops of bowel and pneumatosis intestinalis can be observed in abdominal radiographs (Fig. 37.3A). Because the overall incidence is quite low, early recognition and intervention requires a high index of suspicion. Burn patients with sepsis or an inability to tolerate tube feeds should be started on broad-spectrum antibiotics. Failure to respond to medical treatment mandates surgical intervention, in which frankly necrotic intestinal segments should be resected (Fig. 37.3B). However, questionable areas of necrosis, particularly when they involve extensive lengths, should be re-examined at a second-look operation within 24–48 hours. Thus, the primary goal is to eliminate nonviable bowel while preserving as much intestine as possible to avoid the additional risk of short gut syndrome.

Intestinal ischemia may result in transmural mucosal damage, which predisposes already immunocompromised patients to bacterial translocation and systemic sepsis. Nearly 75% of burn patients with bowel ischemia at autopsy had concomitant sepsis documented at the time of their death, which emphasizes the high incidence of sepsis and mortality associated with intestinal ischemic complications.[87]

CLOSTRIDIUM DIFFICILE INFECTION

Massively burned patients are at high risk for pseudomembranous colitis because they are frequently treated with multiple antibiotics for documented systemic infections and for prophylaxis during burn wound excision and grafting. *Clostridium difficile* overgrowth can result in pseudomembranous colitis, with the potential to progress to fulminant toxic colitis and bowel perforation. In a report of 180

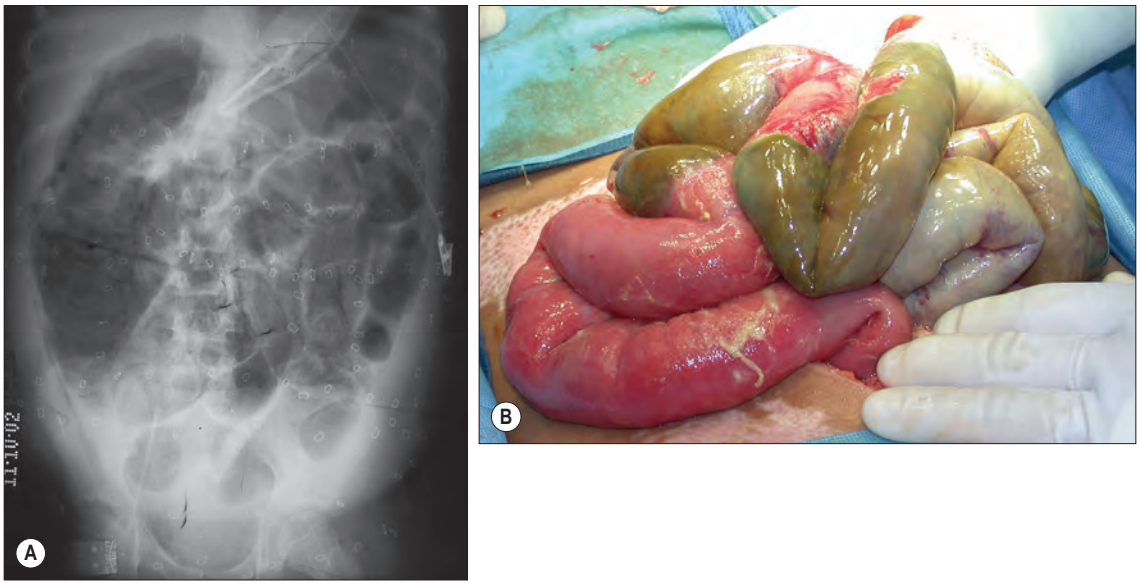

Fig. 37.3 Necrotizing enterocolitis. **(A)** Representative radiograph demonstrating multiple, dilated, persistently "fixed" bowel loops, an ominous sign for full-thickness necrosis of involved segments of bowel. **(B)** At operation, multiple necrotic bowel loops were found.

thermally injured patients, the overall incidence of *C. difficile* infection (CDI) was ~8% with a mean burned TBSA of 42%.[88] Toxic megacolon is a potential complication and places patients at higher risk for colonic perforation.[89] Thus, symptoms of colitis, such as leukocytosis, abdominal pain, distension, and grossly bloody diarrhea, must be promptly recognized. Stool samples are tested for *C. difficile* antigen. All unnecessary systemic antibiotic therapy should be discontinued, and appropriate CDI treatment should be initiated. Guidelines for the treatment of CDI are rapidly evolving. Currently treatment options for the first episode of CDI include oral or IV metronidazole, oral or rectal vancomycin, and fidaxomicin; choice of drug, route of administration, and dosing depend on the severity of the infection, the presence of complications, and other patient-related factors (e.g., drug allergies, pregnancy, prior colonic surgery).[90,91]

Surgical intervention may be required for patients with complicated or fulminant CDI; in addition, surgical intervention must be considered in patients with progressive abdominal distension, peritonitis, shock, signs of sepsis, altered mental status, leukocytosis and lactic acidosis, or failure to improve after 5 days of medical therapy. Subtotal or total abdominal colectomy with end ileostomy has been advocated as the operation of choice.[92,93] An alternative surgical approach is to create a loop ileostomy with intraoperative colonic lavage using warmed polyethylene glycol 3350/balanced electrolyte solution (Go-Lytely) followed by postoperative vancomycin colonic flushes via the ileostomy in an antegrade fashion, with a reported mortality of 19% versus 50% for patients undergoing colectomy. This operation can be performed laparoscopically with a high rate (80%) of reversal of ileostomy for GI tract continuity restoration.[92,94]

Therapeutic options for recurrent infections include fecal microbiota transplant (FMT) and fidaxomicin in addition to the above-mentioned antibiotics; similarly, choice of drug, route, and dosing will depend on the severity and number of recurrences.[90] Novel treatment strategies in development include the use of new antibiotics (ridinilazole, surotomycin, cadazolid), luminal antibodies (oral administration of whey protein concentrate prepared from hyperimmune bovine colostrum against *C. difficile* toxins), intravenous immunoglobulins, vaccines, and nontoxigenic *C. difficile* strains.[95–98]

Vascular Complications

SUPPURATIVE THROMBOPHLEBITIS

Suppurative thrombophlebitis is characterized by venous thrombosis associated with inflammation and bacteremia. Not all of these infections occur in association with venous thrombosis, and specific risk factors for suppurative thrombophlebitis include both burn injury and prolonged intravenous catheterization. The diagnosis may be made based on culture results together with evidence of thrombosis. The classic physical examination findings of edema, erythema, pain, and a palpable cord may not all be present. Burned patients frequently have positive blood cultures and clinical sepsis without an obvious source, and, in the setting of suppurative thrombophlebitis, the most commonly cultured organisms from infected veins reflect those cultured from the burn wound.

The incidence of suppurative thrombophlebitis complications in burn patients has been estimated to be as high as 7%, with significant risk in patients with greater than 20% TBSA burns, and it is associated with significant mortality.[99] The principles of treatment include removing the source of infection, administration of intravenous antibiotics, and/or anticoagulation.[100] Surgical treatment consists of surgical cut-down and evacuation of vein contents. If pus or clot is found, the vein segment should be excised to a normal-appearing vein (usually up to the first uninvolved tributary). If exploration is negative at one site, then

sequential exploration of other sites is necessary until the source of infection is identified. Prompt surgical intervention is necessary to prevent hematogenous dissemination and septic emboli that can result in endocarditis and osteomyelitis. The wound should be loosely packed and allowed to heal either by secondary intention or by delayed closure upon resolution of the infection.[101]

To minimize the incidence of catheter-related complications, the current standard of practice for central venous access at most institutions involves aseptic care at the catheter insertion site along with regularly scheduled catheter site dressing changes.

COMPLICATIONS RELATED TO CENTRAL VENOUS ACCESS

Adequate venous access is imperative in the acute postburn period for aggressive fluid resuscitation. Although large-bore peripheral intravenous catheters are the preferred route for resuscitating trauma patients, placement can be extremely difficult in those with major burns involving the extremities. Therefore, central venous catheters have become standard practice in major burns. Particular attention should be given to the use of various available cannulation sites, depending on the size of the patient, as well as taking into consideration the clinical condition of the burn wounds. The rate of catheter-related bloodstream infections in burn patients is estimated to be 20 per 1000 catheter days.[102] Therefore, compulsory site care is required. Because it is more difficult to relocate lines in severely burned than in nonburned patients, guidewire exchange is acceptable unless there is clinical evidence of infection, such as erythema, drainage from the site, or bacteremia.

Central venous line placement is associated with potentially serious complications. In order to reduce the risk of bleeding complications, many burn centers rely on fluoroscopic or ultrasound guidance during the insertion of central venous catheters.

Bleeding complications associated with central venous access vary in location and can be local, mediastinal, intrathoracic, or pericardial. Local hemorrhage typically occurs in patients with a coagulopathy and can be controlled with local pressure. Hemorrhage into the thoracic space can occur at the time of catheter insertion, but it can also be seen when the catheter erodes through the vein wall. The most common situation leading to venous wall perforation occurs during the insertion of the percutaneous introducer sheath over a guidewire. As the sheath is introduced, it can fail to negotiate the path of the vein and traumatize the vein wall. Consequently, blood may accumulate into the mediastinum, pleural space, or pericardium.

If the injury is small, it should resolve on its own. However, in cases of a larger venous tear, rapid bleeding into the thoracic cavity can occur, and emergency thoracotomy may be necessary. Bleeding or infusion of fluid into the pericardial space can rapidly compromise cardiac function and result in hemodynamic collapse. Pericardial tamponade typically presents with hypotension, muffled heart sounds, and distended neck veins (Beck's triad). However all components of the classic triad of symptoms are rarely present, and a physician must have a high index of suspicion in order to recognize this condition early. Echocardiography can confirm the clinical suspicion, and pericardiocentesis or pericardial window is therapeutic.[103]

DISTAL LIMB ISCHEMIA

Arterial monitoring is frequently required in patients with major burns. Although radial and femoral arterial catheters are routinely placed without significant complications, they can be associated with problems such as hematoma, thrombosis, and pain. Occasionally the common femoral artery is considered for access, given its larger caliber. Because the femoral artery is the major blood supply to the lower extremity, this site should be approached with caution for fear that thrombosis could lead to distal limb ischemia.[104] Especially in pediatric burn patients, the femoral artery is small, and the catheter within the vessel can result in near complete occlusion of blood flow to the distal limb. However reported complication rates after catheterization of the femoral artery in burn patients are low (1.9%) while providing a more accurate measure of hemodynamic parameters (Table 37.2).[105] Nonetheless, complications can be devastating, ranging from transient distal limb ischemia to amputation. Management of distal limb ischemia starts with removal of the catheter along with systemic heparinization. If there is no full recovery after 24 hours, surgical intervention is warranted. Should conservative management fail, exploration of the femoral artery with thrombectomy, fasciotomy, and completion arteriography is recommended. Although rare, amputation may be required if flow is not re-established and tissue salvage is not possible.

Thoracic Complications

PNEUMOTHORAX

Several factors increase the risk of pneumothorax in burn patients; these factors can be related to the traumatic injury itself (barotrauma associated with explosions or blast injuries, concomitant rib fractures, etc.) or associated with the treatment of burns (barotrauma secondary to positive pressure mechanical ventilation, iatrogenic injuries during placement of central venous catheters, etc.). Additionally pneumothorax can occur following electrical injury; the exact mechanisms responsible for pneumothoraces in electrical injuries are debatable, and a blast-like injury due to a high-voltage electric arc is one of the proposed explanations.[106,107]

Pneumothoraces are classified into small or large based on the separation from the pleural surface (lung edge) to the chest wall. A pneumothorax is considered small if the distance is less than 3 cm.[108] Typically, stable patients with a small pneumothorax (<3 cm) are managed conservatively with observation and oxygen supplementation. Conversely, patients who are symptomatic and/or have a large pneumothorax (>3 cm) require thoracostomy. However, several operations and the possible need for reintubation are common scenarios in the hospital stay of severely burned patients. Thus, conservative management of pneumothorax, regardless of size, is not recommended. The placement of a small-caliber (8–14F) pigtail tube is advocated; it is a

less invasive procedure compared to a standard chest tube. Pigtail catheters cause less pain and muscle spasms, with a potential to decrease atelectasis and risk of pneumonia. Although the use of large-bore chest tubes (24–28F) is advocated for patients who need mechanical ventilation,[108] current practice trends and recent studies support the use of pigtail catheters in burn patients.[109–111]

EMPYEMA

Parapneumonic effusions, or empyemas, are pleural effusions located in anatomical contiguity to bacterial pneumonia.[112] Most of the empyemas are small and resolve after antibiotic therapy. However, complicated empyemas, characterized by bacterial invasion of the pleural space, may occur. Burn patients are particularly susceptible to the development of empyema owing to high bacterial colonization and impaired immune defenses.

Common clinical features include cough, fever, pleuritic chest pain, dyspnea, and sputum production. In general, the presenting symptoms, other than pleuritic pain and duration of fever, are not helpful in determining which patients have pneumonia versus pneumonia with empyema. Patients with empyema may report a longer course, with several days of fever and malaise rather than hours. The presence of empyema is first suggested by a chest radiograph showing a pleural-based opacity that has an abnormal contour or does not flow freely on lateral decubitus views. When these features are noted, additional imaging with ultrasound allows for identification of loculations and helps to rule out the presence of a solid mass. Optimal evaluation of an empyema or loculated effusion requires a chest CT scan with intravenous contrast. The use of contrast enhances the pleural surface and assists in delineating pleural fluid loculations.[113]

Management of empyema includes appropriate antibiotic therapy and a drainage procedure (tube thoracostomy, video-assisted thoracoscopic surgery [VATS], open decortication or open thoracotomy). Choice of procedure will be influenced by cavity size, loculations, and pleural thickness.[114] Goals of treatment consist of sterilization of the empyema cavity, complete pleural fluid drainage, and obliteration of the empyema cavity by lung expansion. The intrapleural administration of fibrinolytic agents is debatable; however a recent double-blind randomized crossover trial reported that intrapleural instillation of alteplase was associated with lower treatment failure compared to placebo.[115] In the pediatric population, randomized controlled trials have demonstrated that VATS has no therapeutic or recovery advantages over fibrinolysis. Conversely, VATS is associated with increased costs and longer parenteral antibiotic administration. With the implementation of a standardized protocol, only 16% of these patients are expected to require VATS after fibrinolysis.[116–118] These results have promoted the adoption of fibrinolysis as the first therapeutic option for the treatment of empyema in children.

Urologic Complications

Urologic complications following thermal injury are rare. Direct injury to the external genitalia only comprises 1.7% of cases but has increased morbidity, with elevated risk of infections. More importantly, it is an independent predictor of mortality.[119] Furthermore, these injuries should prompt the burn care team to carefully assess the events leading up to the injury. One study found that child abuse was the cause in 46% of cases involving males and 48% of cases involving females.[120] Surgical repair of urologic complications is rarely reported. Electrical injury resulting in bladder rupture, urinary fistula, and erectile dysfunction have been reported in small studies and case reports.[121–123] The presence of these injuries should be managed by a

multidisciplinary approach with consultation with pediatric surgery and urology specialists.

Conclusion

When presented with patients with multiple organ injuries, the protocols for ATLS should be initiated first, followed by a systematic approach to the management of any and all other injuries. Complications requiring operative management in the setting of a burn injury are common and can compound an already overwhelming physiological response. When there is an exaggerated systemic inflammatory response, associated complications are often clinically masked, promoting delays in diagnosis that result in worsened outcomes. Surgical issues and complications in this patient population are often unavoidable, and clinicians must be thorough in the evaluation of patients with a significant burn injury.

38 Electrical Injuries

EILEEN BERNAL and BRETT D. ARNOLDO

Introduction

The harnessing of electricity may be the technical advance with the greatest impact on human life and culture in recorded history. The tools of modern life are increasingly powered by electricity, and life without it would be unrecognizable. There is, however, a price to be paid for this advancement. Electrical burn injuries are estimated to make up several thousand admissions to burn centers each year in the United States. The American Burn Association (ABA) 2016 Burn Incidence Fact Sheet, which is composed of registry statistics compiled by ongoing national health care and fire casualty surveys and the National Burn Repository, estimated 40,000 burn admissions of which 4% had a reported electrical etiology.[1] These injuries are the most devastating of all thermal injuries on a size-for-size basis and are the most frequent cause of amputations on the burn service.[2] These injuries are distributed in a bimodal fashion in regards to age. Work-related injuries are seen most commonly in adults. Together, electricians, power company linemen, and crane operators are especially at risk. Exposure to electricity made up 3% of all work-related deaths in 2013–2014 according to the United States Department of Labor; Bureau of Labor Statistics.[3] There is a 2:1 male-to-female ratio in childhood, but more than 90% of electrical injuries in adults are in men.[4-8] Children are more commonly injured in accidents in and around the home. Children younger than 6 years are more likely to encounter low-voltage outlets or electric cords. Older children have an increased incidence of high-voltage injuries by comparison because of their increased mobility and adventurousness.[9–11]

Electrical burn injuries have several unique acute manifestations that differ from other thermal injuries and require expertise in management. Decisions must be made early regarding cardiac monitoring and emergent or urgent exploration and decompression for compartment syndrome, as well as a more complex fluid management strategy to avoid the complications of acute kidney injury associated with myoglobinuria. These patients may need access to other specialty services such as plastic surgery consultation for possible early flap coverage to protect potentially viable tissue. In addition, physical medicine and rehabilitation services, with experience caring for patients with electrical injuries, are simply not available in nonburn centers. These injuries benefit from the multidisciplinary team approach and vast experience typically seen at ABA-verified burn centers.

Pathophysiology

Electrical current passing through tissue can cause injury by multiple distinct mechanisms. These include the direct action of electrical forces on proteins, cell membranes, and other biomolecular structures, as well as tissue injury mediated by the generation of heat.[12,13] The severity of injury is multifactorial and determined by voltage, current (amperage), type of current (alternating or direct), path of current flow, duration of contact, resistance at the point of contact, and individual susceptibility. These burns are somewhat arbitrarily classified as low (<1000 V) and high voltage (≥1000 V). Although the low-voltage injuries are generally more localized to the area of the contact point, the high-voltage injuries may be associated with both extension into deep tissue as well as a spreading out phenomenon to surrounding structures. So, although a low-voltage injury may penetrate deeper structures, the zone of injury is more limited. In contrast, high-voltage injuries, somewhat resembling crush injuries, tend to demonstrate a "tip of the iceberg" phenomenon, extending into deep structures (muscle or bone) as well as spreading out proximally and distally beneath the contact point.[14] The clinical implications of this will be discussed later, but from the surgeon's point of view, these injuries are potentially more urgent and occasionally emergent, but low-voltage injuries are not.

Domestic wiring in the United States operates on alternating current (AC) at 120 V. Therefore, nearly all burns occurring indoors are of the low-voltage type. Coworkers typically witness high-voltage injuries occurring indoors because these are more common in industrial or factory settings.

Unlike voltage, the actual amount of current is unknown. Current flow is related to the voltage by Ohm's law where:

$$\text{Current (I)} = \text{Voltage (E)}/\text{Resistance (R)}$$

Animal experiments have demonstrated that resistance varies continuously with time, initially dropping slowly then much more rapidly until arcing occurs at the contact sites. Resistance then rises to infinity and current flow ceases.[15] Temperature measurements taken simultaneously showed that the rate of temperature rise parallels changes in amperage. Interestingly, tissue temperature, a critical factor in the magnitude of tissue injury, does not increase distal to the contact points. Clinically, it is common to see relatively normal and intact digits in association with devastating tissue damage at the wrist and forearm that

ultimately results in amputation at the forearm level. Early and detailed discussion between the surgeon and patient and family can avoid confusion if the patient progresses to amputation.

In North America, the majority of all electricity used and the burn injuries it causes are the result of 60 cycle-per-second commercial AC, which reverses polarity 120 times per second. Exceptions where direct current (DC) is used for power are seen in industrial settings, as well as computers, light-emitting diodes (LEDs), solar cells, and electric vehicles. A series of events in American history, known as the War of the Currents, explains the dominance of AC over DC. Contributions from notables such as Thomas Edison, Nikola Tesla, and George Westinghouse led to concerns over commercial competition, electrical safety, and debates associated with the introduction of the electric chair. The degree of sordid detail surrounding these events can make for interesting tangential information during resident and medical student teaching sessions.[16,17]

Given the nature of AC and its rapid reversal of polarity and the relative inability to reconstruct the history with accuracy, the terms *entrance* and *exit* wounds are inaccurate and should be used with caution if at all. The term *contact point* is more appropriate. A thorough search for contact points should occur in all patients with electrical injuries because they may be few or many, obvious or well hidden (e.g., in the hair line).

The path of current, although often imprecise, can make a significant difference in outcome. Current potentially traversing the conduction system of the heart or a pathway including the central nervous system can alert the clinician to potential complications. AC causes tetanic muscle contractions, which may either throw the victim away from the source or draw him or her into a continued contact known as the "no-let-go" phenomenon. This occurs because both forearm flexors and extensors are stimulated by the current flow, but the flexors overpower the extensors, making the person unable to let go voluntarily. Given that humans most often explore their environment by grasping rather than tapping with the back of the hand, contact is usually prolonged. Altered levels of consciousness reported in about half of high-voltage victims also contributes to prolonged periods of contact.[18] Resistance, measured in ohms, at the point of contact varies from approximately 100,000 ohms for heavily calloused hands or feet during very dry winter weather to less than 2500 ohms when skin is damp.[11]

The classification of electrical injuries from a clinical point of view comes in four varieties: (1) the true electrical injury caused by the flow of current, (2) an arc injury resulting from the electric arc generated as the current passes from the source to an object, (3) flame injury caused by the ignition of clothing or surroundings, and (4) lightning strikes.

Electricity arcs at temperatures up to 4000°C and causes a flash-type injury without actual current flow through the body.[19] This is most commonly seen in electricians working with metal objects in close proximity to an electrical source. The victim may be thrown by the force and sustain trauma, including ruptured eardrums and any other variety of blunt force injuries. These injuries that occur without actual current flow may be classified like any other flame injury. However, the potential problem that arises is in the difficulty in ascertaining whether there was actual flow of current. As a result, most of these patients will be treated as having true electrical injuries.

The mechanism of electrical injury appears to be a multifactorial combination of thermal and nonthermal causes. Electricity flowing through tissue generates heat. Electrical current via ohmic conduction leads to Joule heating that can cause severe burn injury to the victim.[13] The burn injury is the result of damaging supraphysiological temperatures, which affect all proteins and cell membranes with Joule's law defining the amount of power (heat) delivered to an object:

$$\text{Power (J [Joules])} = \text{I}^2\ \text{(Current)} \times \text{R (Resistance)}$$

In increasing magnitude, tissue resistance is lowest from nerves, blood vessels, muscle, skin, and bone. Theoretically, current flow would be distributed in proportion to resistance, with tissues having the highest resistance generating the most heat. However, in animal models, the body tends to act as a single uniform resistance rather than a collection of different resistances. In other words, the body acts as a volume conductor, with the severity of injury being inversely proportional to the cross-sectional area of the involved body part.[15] Clinically, this is observed in particularly severe injuries at the level of the wrist and ankle. Deep tissue does appear to retain heat such that periosseous tissue, especially between two bones, will often have a more severe injury pattern than more superficial tissue. Clinically, this may be seen during exploration of the forearm wherein the superficial flexors are clearly involved and injured but the deeper pronator quadratus muscle appears to have a more severe injury. The associated macro- and microvascular injury appears to occur at the time of injury and is irreversible.[20] This vascular injury has been studied in a rabbit model in which optical microscopy demonstrated severe injury to blood vessels. Necrosis of vascular walls and thrombosis with destruction of arterial endothelium, pyknosis of vascular smooth muscle, and fibrinous exudates accompanying the thrombotic changes were noted. Progressive muscle necrosis over the first 72 hours after injury was also observed and thought attributable to vascular injury.[21] The study period followed the injury pattern for only 72 hours, but experienced clinicians can attest to a longer period of progression that may extend more than a week. These findings as well as clinical experience argue in favor of serial debridement and a conservative approach to definitive grafting. The pathophysiology, although not completely understood, also includes electroporation and electrochemical interactions in addition to thermal interactions.[22–24] These affect all tissue components, but the cell's plasma membrane appears to be the most important structure in determining the rate and quantity of tissue injury accumulation.[13] Electroporation is the formation of aqueous pores in lipid bilayers exposed to a supraphysiologic electrical field. The formation of these pores allows calcium influx into the cytoplasm and triggers a subsequent cascade leading to apoptosis. Particularly interesting, owing to characteristics of electric fields, it has been shown that cells of long length (skeletal muscle and nerve) are more vulnerable to electroporation.[13] Further experimental work

by Block et al.[23] in a Sprague-Dawley rat model confirmed that nonthermal effects alone could induce cellular necrosis. *Electroconformational denaturation of transmembrane proteins* refers to the changes in polarity of amino acids in response to exposure to electrical fields. Experimentally, voltage-gated channel proteins were found to change their conductance and ion specificity after exposure to a powerful pulsed field.[25]

Acute Care

Electrically burn-injured patients present some unique challenges in the acute setting. There are essentially three acute management concerns differentiating these patients from patients who were thermally injured without flow of electric current. In addition to the application of the basic principles of Advanced Trauma Life Support (ATLS), the three issues that need to be addressed in the "golden hour" are (1) which patients require electrocardiographic monitoring and for how long; (2) which patients are at risk for compartment syndrome and may need emergency surgical intervention (sometimes directly from the emergency department [ED]); and (3) how fluid resuscitation should proceed in the light of the preponderance of deep tissue injury that may not be appreciated on physical examination, particularly in the presence of pigmented urine.

Electrocardiographic Monitoring

All studies reviewed in a recent ABA guidelines paper confirmed that cardiac abnormalities, including dysrhythmias and myocardial damage, occur after both low- and high-voltage injuries, thus reinforcing the need for electrocardiography (ECG) as part of the initial evaluation in all patients.[26] The most frequent reason for death after electrical injury is cardiac.[27] Nonspecific ST changes are the most common ECG abnormality, and atrial fibrillation the most common dysrhythmia,[28,29] but ventricular fibrillation is the most common case of death at the scene of injury.[30]

Direct myocardial injury may also result. This injury behaves more similar to a traumatic myocardial contusion than a true myocardial infarction, not having the hemodynamic or recurrence consequences of atherosclerotic myocardial infarctions. Housinger et al. have shown that creatine kinase (CK) and MB creatine kinase (MB-CK) levels are poor indicators of myocardial injury in the absence of ECG findings of myocardial damage, especially in the presence of significant skeletal muscle injury.[31–33] In contrast, Saracoglu et al. have shown that elevated levels of both are related to an increased mortality rate.[34] Myocardial damage and dysrhythmias are manifested very soon after injury.[35] Although cardiac troponins are the preferred biomarkers for detecting myocardial injury in most clinical settings, this has not been adequately studied in the setting of electrical injuries. A recent study using serum troponin levels and serial echocardiography in 20 patients surviving high-voltage injury concluded that this was not a useful diagnostic test for predicting impaired left ventricular contractility.[36] Orak et al. have found an additional biomarker, pro-B-type natriuretic peptide (pro-BNP), to be elevated in high-voltage electrical injury with use as a marker for both morbidity and mortality.[27] However, the interpretation of cardiac biomarkers is problematic and needs to be correlated with other clinical findings. All patients should be monitored during transport and in the ED. Rather than a policy of more prolonged cardiac monitoring for all patients, a selective policy makes most efficient use of expensive medical resources, without patient risk.[2,35]

Indications for cardiac monitoring include (1) loss of consciousness, (2) ECG abnormality or evidence of ischemia, (3) documented dysrhythmia either before or after admission to the ED, (4) cardiopulmonary resuscitation (CPR) in the field, and (5) patients with other standard indications.[30] Therefore, asymptomatic and stable patients who have normal initial ECG findings and are without any risk factors do not need inpatient cardiac monitoring.[37]

No published studies have directly studied the appropriate duration of telemetry monitoring, but most series indicate 24–48 hours.[38–40] Our institutional bias is to monitor for approximately 24 hours after injury in patients with an indication. Low-voltage injuries not meeting the criteria for cardiac monitoring and no other indication for admission can be safely discharged from the ED. This is not applicable to high-voltage injuries, although retrospective evidence indicates that dysrhythmias will occur early, if at all, in these patients.[35]

Myoglobinuria

The presence of pigmented (darker than light pink) urine in a patient with an electrical burn indicates significant muscle damage with potentially ongoing ischemia. Myoglobinuria and hemoglobinuria secondary to rhabdomyolysis present a risk of acute renal failure and must be cleared promptly.[41,42] Whereas low levels are of little clinical concern, grossly visible urinary pigmentation requires a rapid response to minimize tubular obstruction. Titrating resuscitation fluid (Ringer's lactate) to maintain urine output double the goal rate of the standard burn patient, or approximately 100 mL/h in an adult, is the goal of therapy. The required urinary output is generally very high for several hours after injury followed by a significant reduction in urine requirements, as venous return from the injured part to the central circulation is thrombosed. Therapy continues until the urine appears clear. Other therapeutic options include the prevention of oliguria using loop diuretics, alkalinization of the urine with either a bolus or continuous infusion of sodium bicarbonate, normalization of serum electrolytes, and decompression of compartment syndromes.[43] Alkalinization and osmotic diuresis are not supported by level I evidence, but many burn centers have successfully adopted their use in various forms. Failure to clear pigment from the urine is generally an indication of significant muscle necrosis or ongoing ischemia. This should prompt a thorough evaluation of the likely current path and underlying muscle damage because failure of therapy can often be taken as an indication for operative intervention for decompression versus debridement or amputation.

Compartment Syndrome and Initial Operative Intervention

Patients with low-voltage electrical injuries are at low risk of compartment syndrome. The authors have not had to decompress any patients with low-voltage injuries for compartment syndrome in their combined burn experience. In contrast, high-voltage injuries require vigilance in regards to clinical decision making. Treatment may include ED to operative suite urgency, underscoring the need for these to be seen in centers with 24-hour surgical capability.

Multiple explanations for the pathophysiology of acute compartment syndrome exist, but in all cases, the final common pathway is cellular anoxia.[44] Damaged muscle and swelling in the investing fascia of the extremity may cause increased pressure compromising blood flow such that metabolic demand exceeds delivery. Venous outflow is jeopardized, leading to a decreased arteriovenous pressure gradient that ultimately can cause arteriolar collapse.[45,46] Loss of pulses is one of the last signs in true compartment syndrome, which is different from the early loss of pulses seen in a circumferentially burned extremity requiring escharotomy. Compartment pressure measurement is generally considered an adjunct in electrical injuries and is often an extra step that may not add to what is generally an obvious diagnosis. These injuries are rarely subtle. In the past, a very aggressive approach to fasciotomy was recommended, but significant morbidity may accompany this approach. Amputation rates in the early literature were generally reported in the range of 35% to 40%.[47–51] Mann et al. argued for a conservative course of management calling for fasciotomy in the patient with the usual clinical signs of compartment syndrome—progressive nerve dysfunction or failure of resuscitation.[52] The ABA guidelines paper indications for surgical decompression were in agreement with this management strategy.[26] In a review of the National Burn Repository, Pannucci et al. found early fasciotomy to be a marker for increased disease severity. Among patients who underwent early fasciotomy after electrical injury, 7.5% developed deep vein thrombosis, and 49% required amputation during their initial hospitalization.[53] Elevated CK levels have been correlated to the extent of muscle damage with some authors advocating early decompression and aggressive surgical management in patients with markedly elevated CK levels.[17] In the experience of the authors, high-voltage electrical injuries requiring decompression have significant clinical findings, making adjuncts such as CK levels and compartment pressures moot. They add little to the diagnostic evaluation other than for educational purposes in a training environment. Again, these injuries are generally dramatic. This tends to alleviate consternation regarding the decision to perform urgent exploration or fasciotomy; vigilance, however, must be maintained for the first 24 to 48 hours.

Fasciotomies are best performed in the operating room under general anesthesia.[54] Lower leg fasciotomy is a common procedure and should be within the skill set of all general surgeons. The upper extremity fasciotomy is less common and yet another reason to refer patients with these injuries to a specialized burn center. We favor a lazy-S incision with the caveat that formal forearm fasciotomy from elbow to wrist may not be needed given that the most

Fig. 38.1 High-voltage injury with neurologic deficit on examination.

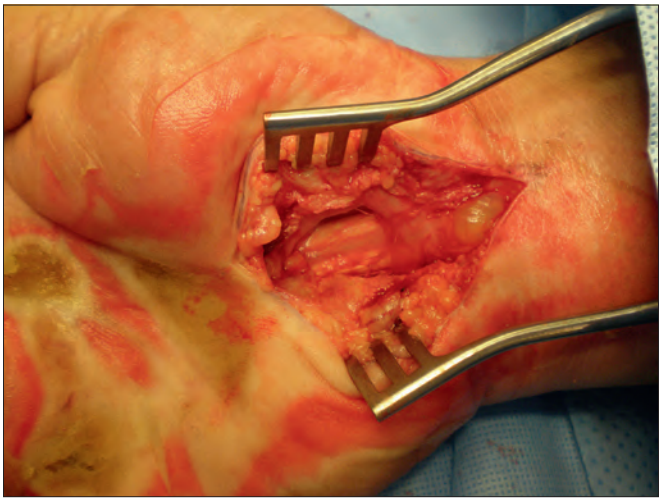

Fig. 38.2 Carpal tunnel release.

significant injury is often at the wrist with variable degree of spread. Beginning the skin incision distally and extending it as indicated is a reasonable approach. On occasion, all that may be required is a carpal tunnel release with a short proximal extension (Figs. 38.1 and 38.2).

Coverage of the wound may include wet to moist mafenide acetate 5% solution or a biologic such as porcine heterograft. The initial operation is followed by a second look in 24 to 48 hours, and depending on the degree of injury, serial debridement may follow. Fasciotomy wound closure is often not possible and skin grafting for wound coverage is common. Rarely will any amputation be indicated as the first operative procedure, and a more conservative approach is usually indicated. The clearly mummified, contracted extremity is one exception, however.

Further Surgical and Wound Considerations

For high-voltage injuries that do not require urgent surgical intervention, initial wound care and observation are

appropriate. Patients with small surface area low-voltage injuries that do not meet criteria for cardiac monitoring and do not have excessive pain control needs can either be discharged or observed depending on local capabilities such as ease of follow up or distance traveled to the burn center. Local wound care can be performed with 11.1% mafenide acetate cream (Sulfamylon) on thick contact points, given the excellent penetration and spectrum of coverage. Other involved areas may be treated by any number of topical agents, including silver sulfadiazine, bacitracin, or one of the silver-containing dressings. Surgical excision is begun 2 to 3 days postburn, either as a second-look operation after fasciotomy or as a first procedure in patients not requiring an urgent procedure. Obviously, necrotic tissue is removed, and tissue of questionable viability retained for reevaluation every several days until all nonviable tissue is ultimately removed. A very conservative course of tissue removal and wound closure with a combination of skin grafts or flaps for soft tissue coverage gives the best functional result. The addition of the vacuum-assisted closure (VAC) device has greatly simplified the management of these wounds. Applying a VAC device over a wound that has questionable tissue remaining loses nothing. If there is a suspicion of infection, the VAC device can simply be removed; otherwise, it can be exchanged at scheduled intervals at the bedside or in the operating room. For extremity injuries, particularly the hand, early involvement of a plastic surgeon with experience in burn reconstruction can provide an important contribution to long-term function. However, surgical options such as local or regional flaps may be unavailable because of the large zone of injury, and a free flap may not be tolerated by a sick patient given the prolonged operative time required. In these cases, a distant pedicle flap may be appropriate.[55] These may include older techniques such as the Crane principle as described by Barrilo et al. or the use of random abdominal wall flap, groin flap, tensor fascia lata flap, or a cross-arm flap.

Multiple diagnostic modalities have been investigated in an attempt to speed up the process of identifying the extent of deep tissue necrosis. These include xenon-133 and technetium pyrophosphate scans as well as gadolinium-enhanced magnetic resonance imaging.[56–60] Albeit very sensitive and specific, diagnostic scans add little to direct clinical evaluation and are ultimately expensive and unnecessary. An ongoing program of physical therapy and functional splinting is begun the day of admission if practical and continued throughout the hospital stay. Serial neurologic examinations are performed and documented. Regional anesthesia is avoided to minimize medical legal complications if late neurologic dysfunction arises.

Problem Areas

Contact points on areas such as the scalp and torso add complexity to management. Scalp burns that spare the galea are managed by excision and grafting directly onto the galea. Wounds that penetrate or expose the outer table of the skull or deeper require a different approach. Exposure of nonviable calvarium has historically been approached by providing a viable wound bed after debridement of dead bone with an osteotome or a dental burr. Drilling multiple holes deep enough to cause bleeding from viable cancellous bone is a method to encourage granulation tissue, which eventually can be skin grafted. This is a prolonged process, and methods such as the use of wound VAC or Integra may accelerate the process. The best and most expedient option may be a rotational scalp flap over the burned area followed by a split-thickness skin graft to cover the adjacent defect[61] (Figs. 38.3–38.5). Larger scalp defects are approached with free flaps anastomosed to appropriate vessels outside the zone of injury.[62]

Fig. 38.3 Rotational flap planning.

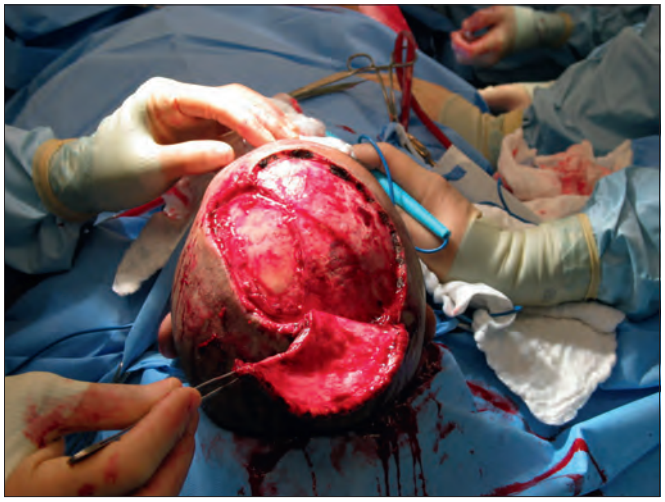

Fig. 38.4 Rotational flap creation.

Although significant electrical burn to the torso is seen less commonly than extremity wounds in both the high- and low-voltage categories, they can present special problems. Chest wall injuries may be particularly difficult to close, and early consultation with plastic surgery services may be helpful. Costal chondritis can be a long-term complication of these wounds. Visceral injuries are reportedly very rare and range from 0.4% to 1.7%.[63,64] The colon and small intestine are the most frequently affected, but gallbladder, liver, pancreas, stomach, and urinary bladder injuries have been described.[65] Vigilance for these potential

Fig. 38.5 Rotational flap with skin grafted defect.

injuries is required because they can occur in the absence of obvious contact points, and mortality rates are significant.[66,67] The relatively insensitive finding of feeding intolerance or a changing abdominal examination may be the only findings. Computed tomography (CT) may make the diagnosis and mandates laparotomy.

Lightning Injury

Lightning is the second leading cause of weather-related death in much of the world, but underreporting likely influences the data.[68–71] Approximately 100,000 thunderstorms occur in the United States each year, with lightning killing more people than any other weather phenomenon—about 80 fatalities per year—with Florida and Texas having the most deaths.[72–74] Although lightning strikes involve millions of volts of electricity, the spectrum of burn injury is extremely varied, from minimal cutaneous burns to significant burns equal in depth to commercial high-voltage electricity. Major cutaneous injury is rare unless a nearby object is turned incandescent, causing a flash and flame type of injury, as when a bag of golf clubs on the victim's back is struck. The pathognomonic sign of a lightning strike is a dendritic, arborescent or fernlike branching erythematous pattern on the skin. These Lichtenburg figures (also known as keraunographic markings) consist of extravasation of blood in the subcutaneous tissue that appears within an hour of injury and fades rapidly, much like a wheal-and-flare reaction.[75,76] Full-thickness isolated burns on the tips of the toes have also been reported as characteristic. Both findings are useful in determining the cause of injury in a patient found down under uncertain circumstances.[77]

Lightning may cause both respiratory and cardiac standstill, for which CPR is especially effective when promptly initiated,[78] although approximately 10% of lightning strikes prove to be fatal.[79] Patients may respond to resuscitation even when they appear dead and even when the interval between injury and resuscitation is prolonged. It is important to realize that dilated or nonreactive pupils are not necessarily a reliable sign of brain death in the early postinjury period, nor is Glasgow Coma Scale score a predictor of outcome.[80–82] The ears should be carefully examined because injuries are frequent, ranging from ruptured tympanic membranes (most common) to middle and inner ear destruction.[83] Electrical current injuries predominantly cause pure sensorineural hearing loss and may significantly increase a patient's lifetime risk of vertigo.[84] Associated ophthalmic injuries are varied; can be bilateral; and include the formation of thermal keratopathy, anterior uveitis, subcapsular cataract, vitreous hemorrhage, retinal detachment, central retinal artery and vein occlusion, cystoid macular edema, macular hole, and optic neuropathy.[81,85,86]

Neurologic complications are relatively common and include unconsciousness, seizures, paresthesias, and paralysis, which may develop over several days after injury. The term *keraunoparalysis* (Charcot's or temporary paralysis) has been used to describe the latter symptom complex, is associated with vasomotor disorders, and is characterized by complete tetraplegia and loss of sensory awareness of the trunk and all four extremities.[87] Fortunately, these are usually transient. Surgically treatable lesions, including epidural, subdural, and intracerebral hematomas, may occur, mandating a high index of suspicion for altered levels of consciousness.[74] The prognosis of many lightning-caused neurologic injuries is generally better than for other types of traumatic causes, although subtle neurologic changes may persist, suggesting a very conservative, watchful waiting and supportive approach with serial neurological examinations after an initial CT scan to rule out correctable causes. A study by Muehlberger et al. with follow-up to 12.3 years after injury showed that none of their 10 patients had long-term neurologic or psychological deficits.[88] However, posttraumatic stress disorder is common, occurring in about 30% of patients after lightning injury.[89]

Low-Voltage Injuries

Low-voltage (<1000 V) AC injury is usually localized to the points of contact. With prolonged contact, tissue damage may extend into deep tissues with little lateral extension, as seen in high-voltage (≥1000 V) wounds. These wounds are treated by excision to viable tissue and appropriate coverage based on wound depth and location.

Burns of the oral cavity are the most common type of serious electrical burn in young children.[90] Most of these injuries are the result of an unattended small child (commonly <4 years of age) chewing on an electrical cord. Injuries involving only the oral commissure are almost never excised because the extent of injury is difficult to predict. Simple wound care is performed as an outpatient procedure.[91,92] The most serious complication is bleeding from the labial artery, occurring 10–14 days after injury. Families are instructed to compress the labial artery digitally if bleeding occurs and to return to the ED. After healing, treatment varies according to the severity of injury. Gentle stretching and the use of oral splints give good cosmetic and functional results in most patients, with reconstructive surgery being reserved for the remainder. Severe microstomia is corrected by mucosal advancement flaps. Burns of the midportion of the mouth heal poorly and may require a more aggressive surgical approach.[93,94]

Complications

The primary early complications of electrical injury include renal, septic, cardiac, neurologic, and ocular manifestations. Neurologic deficits may be present on admission or develop days to weeks after injury.

Cataract formation is the most frequent ocular complication of electrical injury, although ocular manifestations may affect all portions of the eye.[95,96] The exact pathophysiology is unknown, but ocular changes may affect as many as 5–20% of patients with true electrical burns. Saffle et al. reported on seven patients with 13 cataracts, noting a high rate of bilateral involvement and little association with voltage or location of contact points, although often thought of as being more frequently associated with contact points of the head, neck, and upper trunk.[97] Of this series, 77% eventually progressed to surgical therapy, the results of which were uniformly good. Lag time before appearance may be as short as 3 weeks and as long as 11 years after injury.[98]

Neurologic complications are protean in their diversity and may present either early or late (as late as up to two years after injury). Neuromuscular defects including paresis, paralysis, Guillain-Barre syndrome, transverse myelitis, or amyotrophic lateral sclerosis can be caused by electrical injury.[99] Several studies put the incidence of post-electrical injury sequelae into perspective. Grube et al. reported on 64 patients with high-voltage burns, 67% of whom developed immediate central or peripheral neurologic symptoms.[18] One third had peripheral neuropathies, and one third of those were persistent. Furthermore, 12% had delayed onset of peripheral neuropathy, with 50% resolving. They reported no late-onset central neuropathies. Singerman et al. reported neurologic and psychological complication rates of 81.6% and 71%, respectively.[100] The most common neurologic symptoms were numbness (42%), weakness (32%), memory problems (32%), paresthesias (24%), and chronic pain (24%). The most common psychological symptoms were anxiety (50%), nightmares (45%), insomnia (37%), and flashbacks to the event (37%). Interestingly, the low-voltage injuries resulted in more long-term sequelae than high-voltage injuries. Further studies from the same center demonstrated only a 30% return to work after low-voltage electrical injuries.[101] In a study by Chudasama et al., the patients with high-voltage injuries had longer and more complex hospital stays and more frequent complications than patients with low-voltage injuries.[102] Despite this, the low-voltage group experienced similar rates of neuropsychiatric sequelae, limited return to work, and delays in return to work. Ko et al. reported on 13 patients with delayed onset of spinal cord injuries, postulating on a vascular cause of the deficits.[103] The most common peripheral defect is a peripheral neuropathy, with weakness being the most common clinical finding.[104] In general, resolution of early-onset lesions is much better than for late onset, spasticity is more frequent than flaccidity, and function is affected more than sensation.

Sympathetic overactivity, with changes in bowel habits and urinary and sexual function, is the primary autonomic complex complication. Although the exact mechanism of nerve injury has not been explained, both direct injury by electrical current or a vascular cause receive the most attention. To date, imaging studies, including angiography and magnetic resonance imaging, have not been helpful in either predicting or evaluating the extent of deficit. Very often, the patient's neuropsychological status is abnormal. In a study comparing electrical burn patients with non-burned electricians, Pliskin et al. showed significantly higher cognitive, physical, and emotional complaints not related to injury or litigation status.[105] A full neurologic examination must be performed on admission, documenting the initial presentation. Early involvement of an experienced, interested physiatrist is important in assessing long-term needs and participating in the creation of a therapy plan.

Heterotopic ossification occurring at the cut ends of amputation sites is unique to electrical burn patients. This occurs in about 80% of patients with long bone amputations but not in patients with disarticulations or small bone amputations. Helm et al. found ossification severe enough to require surgical revision of the bone end in 28%.[106] This is easily accomplished by opening the incision and using a bone rongeur to remove the soft heterotopic bone and reclosing the residual limb.

Although electrical burns comprise only about 4% of all burn injuries, they consume enormous amounts of resources, requiring a carefully planned team approach for optimal care.

39 Cold-Induced Injury: Frostbite

AMALIA COCHRAN and STEPHEN E. MORRIS

Videos available at www.expertconsult.inkling.com

History of Frostbite

Frostbite is a traumatic injury caused by the failure of normal protective mechanisms against the environment, resulting in freezing of tissue. Cold-induced injury remains surprisingly frequent in the United States owing to increasing interest in outdoor winter recreational activities as well as the common presence of homeless and socioeconomically disadvantaged individuals in large urban centers.[1,2]

The incidence of and circumstances surrounding frostbite have been documented in numerous military histories.[3] Hannibal lost nearly half of his army of 46,000 soldiers during a 2-week crossing of the Alps due to frostbite injury. During the Revolutionary War, Dr. James Thatcher recorded that Washington lost 10% of his army to cold-related casualties during the winter of 1778. Baron Dominique Jean Larrey produced the first systematic medical observations of frostbite while serving as Surgeon General of Napoleon's forces during the ill-fated invasion of Moscow in the Fall of 1812 and the subsequent retreat in a harsh Russian winter.[4] Because of the epidemic nature of frostbite in this campaign, Larrey was able to create seminal descriptions of frostbite and to identify the debilitating effects of daily refreezing that occurred with bonfire thawing and subsequent marching in frigid conditions; in addition, many soldiers burned their insensate frostbitten feet while attempting to rewarm them over bonfires. Larrey became convinced that the optimal therapeutic management consisted of friction massage with snow or ice, resulting in slow rewarming.[4] These recommendations were maintained as the standard of care for frostbite in military medicine for more than 100 years.

In the winter of 1941–1942, German troops sustained an estimated 250,000 frostbite injuries in the attempt to take Moscow, constituting the largest reported number of related frostbite injuries in history.[5] During World War II both German and Russian troops moved to a philosophy of rapid rewarming based on work conducted at the Kirov Institute in the 1930s.[5,6] Following World War II existing Russian and German works were translated into English and became the basis for rapid rewarming as the predominant Western paradigm. In 1960, Mills published the first major clinical experience with rapid rewarming and included a philosophy of total care for frostbite with his report.[7] Meryman subsequently edited a seminal text elucidating the scientific bases for frostbite injury.[8] Both military and civilian cold-induced injury data continued to accrue over the subsequent three decades in the absence of any significant clinical advances in the care of frostbite.[9–16] Frostbite continues to present a tremendous clinical challenge, with the greatest clinical advance coming only in the past decade with the use of thrombolytic therapy in early management.[17–19]

Pathophysiology and Classification of Frostbite

The injury associated with frostbite results from two broad mechanistic categories: the first is that of direct cellular damage and death due to the cold insult, and the second is the delayed process mediated by progressive tissue ischemia.[20–23] The immediate effects of frostbite are evidenced by formation of extracellular ice crystals that cause direct injury to the cell membrane, resulting in cellular dehydration due to a change in the osmotic gradient.[24] Rapid cooling results in intracellular freezing, causing more severe cellular damage and cell death, whereas a slower rate of cooling produces extracellular ice crystals. This slower process results in a transmembrane osmotic shift that draws water from within the cell and produces intracellular dehydration. This dehydration causes changes in protein and lipid conformation as well as changes in biochemical processes that are deleterious to intracellular homeostasis.[25–29] As the temperature continues to fall, intracellular crystals develop, with a loss of the linear relationship of temperature to metabolism, decreased DNA synthesis, and histamine response with skin flushing and development of a fluid-filled wheal.[13,30–33]

Microvascular pathophysiology may be even more important than the direct cold injury to the cell, a concept suggested by studies showing the survival of full-thickness skin subjected to freezing and thawing that progressed to necrosis when left in situ but survived when transplanted to a normal, uninjured recipient site.[23] Zacarian identified a number of processes that may play a role in the microcirculatory changes of frostbite. Transient vasoconstriction of both arterioles and venules with subsequent resumption of capillary blood flow appears to occur, and microemboli result from this course.[34] With thawing, the capillaries demonstrate restoration of blood flow that diminishes within minutes. Complete cessation of blood flow is often seen within 20 minutes of rewarming frozen tissue. Similar changes have been seen with random skin flap models after reperfusion, suggesting reactive oxygen species as mediators of injury.[35] Within 72 hours, significant deendothelialization and deposition of fibrin in the capillary bed occurs. Examination of the endothelial ultrastructure demonstrates swelling, fluid extravasation, endothelial cell dilation, and significant projection of the cell into the vascular lumen prior to cell lysis.[36] There is regional variation in the extent of injury, with low-flow venules being most

profoundly affected, resulting in the hypothesis that stasis also plays a role in this pathophysiologic process.[32]

The pathobiochemistry of frostbite has been closely compared to the inflammatory response in the burn wound.[37] Inflammatory mediators such as eicosanoids in burn blister fluid coupled with bradykinin and histamine release in the region of injury draw parallels with findings in cold-induced injury.[38–44] This has prompted investigators to hypothesize a frostbite soft tissue model similar to that of Jackson's for burns, including zones of necrosis and stasis.[45] Similar to their burn blister analysis, Robson and Heggers examined the fluid in frostbite blisters and found high levels of prostaglandin F_2 and thromboxane B_2.[37] These agents or their precursors have been implicated in vasoconstriction and leukocyte adherence. In addition, when refreezing follows thawing, the cellular damage caused by ice crystals and the subsequent inflammatory response are exaggerated.[46,47]

Clinical Findings and Classification of Frostbite Injury

In many situations, the patient is unaware that frostbite is occurring. The presence of hypothermia and the frequent use of mind-altering substances by frostbite patients may contribute to this problem. Typical distribution of injury is acral, with injuries to ears, nose, cheeks, and penis also being fairly common.[9,14,48] The patient may note insensitivity and clumsiness of the affected part. This complex of symptoms rapidly reverses upon rewarming. Severe pain occurs during and immediately after the rewarming process, is often described as throbbing in character, and typically requires parenteral opioids for relief.[49]

Because of the nature of freezing injury, classification has traditionally been based on physical examination findings that occur after rewarming. The most common presentation of *frostnip* is numbness and pallor of exposed skin. Frostnip does not include injury to the underlying dermis or soft tissues, so rewarming results in near-complete resolution of symptoms and physical findings. In contrast, true frostbite involves some degree of dermal and soft-tissue injury. Clinical appearance evolves over a period of time after rewarming, although the initial appearance may be deceptive because hyperemia is present in both frostbite and frostnip.[9,50] The development of skin blebs may require hours to days from the time of injury. After 12–24 hours, the character of the blebs usually becomes apparent and an assessment of the severity of involvement can allow for management planning for the injury.

Traditional classification of frostbite is similar to that of burn injury. First-degree injury is superficial, with hyperemia in the absence of vesicles or blebs. There may initially be an area of pallor with surrounding erythema that evolves into general edema and erythema without long-term sequelae. Second-degree injury has associated light-colored blisters and subsequent epidermal sloughing. This may correlate with partial dermal involvement but has a generally favorable prognosis. Third-degree frostbite typically has hemorrhagic blisters that evolve into thick, black eschar over 1–2 weeks. Fourth-degree injury involves bone, tendon, or muscle and uniformly results in tissue loss. Precision in depth of injury cannot be expected from visual inspection,

Fig. 39.1 Superficial frostbite injury with clear vesicles.

Fig. 39.2 Deep frostbite injury with hemorrhagic vesicles.

and some favor a more general classification of superficial (first- and second-degree injury, see Fig. 39.1) or deep (third- and fourth-degree, see Fig. 39.2) frostbite injury;[51,52] clinically, these can be delineated by clear vesicles, present with superficial injury or hemorrhagic blisters indicative of structural damage to the subdermal tissues.[52,53] Cauchy most recently proposed an alternative classification system based on risk of amputation that includes the extent of the lesion immediately after rewarming, findings from bone scan on day 2, and the presence of blisters on day 2.[54] Although this system has not come into widespread use, the relationship of objective findings to prognosis may prove helpful for future therapeutic trials in the management of frostbite.

Initial Management of Freezing Cold Injury

Prevention is obviously the ideal means of treatment for frostbite. Alcohol and drug intoxication heighten the risk for frostbite, most notably in urban populations and the mentally ill.[55,56] Although the cases of frostbite that occur in intoxicated, mentally ill, and homeless individuals are truly preventable only through broader social interventions, simple techniques exist for those who sustain frostbite secondary to involvement in cold-weather wilderness activities. Frostbite prevention measures in planned cold-weather wilderness activity include, but are not limited to, wearing appropriate clothing, which may include layers and wicking fabrics; keeping that clothing dry; responding appropriately to changing environmental conditions; and performing "cold checks" of at-risk or suspect areas.[57]

If frostbite is identified in the field, the greatest management priority is to not incur further injury. Jewelry should be removed if present in the affected area; rubbing the area with ice or snow is now known to incur further damage to fragile, injured tissue.[4,49,51,58,59] Injured areas should be mechanically protected from trauma because they are typically insensate and are at high risk for further injury.[49,51,58,60] The key decision that must be made in the field is whether thawing should be pursued prior to transfer to definitive care for the frostbite injury.[61] Based on the work of Mills at the Arctic Aeromedical Laboratory demonstrating the deleterious effects of thawing and refreezing on clinical outcomes from frostbite, rewarming in the field should not be pursued unless the ability to maintain the affected tissue in a thawed state is certain.[7,58,62] Systemic cold injury in the form of hypothermia often accompanies local frostbite injury, thus mandating that patients be carefully evaluated to verify that they are normothermic prior to initiating definitive frostbite management. Hypothermia causes peripheral vasoconstriction and diminished blood flow, processes that are exacerbated by the local cold injury. Most importantly, hypothermia can be life-threatening, as opposed to the digit or limb threat posed by frostbite.[63,64] Moderate to severe hypothermia, defined as a core temperature of less than 32°C, must be addressed prior to initiation of frostbite treatment.[48,50,57,62]

The traditional recommendations for rapid rewarming favor a water bath temperature of 40–42°C.[49,53,58,62] The State of Alaska guidelines recently changed the water bath recommendation to a temperature of 37–39°C because this does not substantially increase the time to rewarming but causes less pain for the patient.[51,57] The water bath for thawing should be maintained in this range with the water circulating around the involved tissue. The duration of rewarming is approximately 30 min, although clinical findings to determine the length of time for rewarming include the return of sensation and presence of flushing at the most distal aspect of the involved tissue.[51,61] Administration of narcotics is appropriate at the time of definitive rewarming because of the pain associated with the thawing process.[49] In addition, because these are tetanus-prone wounds, the patient's tetanus immunization should be verified and updated as appropriate. Finally, systemic antibiotics are recommended by some authors in patients with marked edema because of loss of the protective properties of the skin against skin flora when significant edema is present.[47,53,57,61,65–67]

Post-Thaw Evaluation and Management

Following rewarming, local care of the involved tissue is the first priority. Unroofing of blisters remains a matter of controversy.[67] Alteration in local chemokines through the presence of blister fluid, including high levels of $PGF_{2\alpha}$ and TXB_2 and diminished levels of PGE_2, result in vasoconstriction of the involved area, increased leukocyte adherence, and increased platelet aggregation, all of which cause progressive dermal ischemia.[13,37,41,44] However, concern also exists about removal of hemorrhagic blisters because of the damage to subdermal structures associated with these blisters, indicating that debridement may extend the soft-tissue damage in these areas.[52,53] A more practical justification for debridement of blisters is that it improves the visualization of underlying tissue, allowing the clinician to better assess the status of the wounds.[66]

Aloe vera has properties that counter the arachidonic acid cascade and therefore benefit the local care of frostbitten areas. Heggers demonstrated that the use of systemic NSAIDs and local aloe vera to address the inflammatory chemokines, coupled with systemic penicillin as prophylaxis against Gram-positive infection, resulted in demonstrably less tissue loss, a lower amputation rate, and shorter hospital stay versus patients managed with traditional topical antimicrobials.[13] Topical aloe vera alone was credited with clinically significant tissue salvage in these patients, resulting in preferential management with aloe vera rather than topical antimicrobials such as silver sulfadiazine or sulfamylon.[13,57,61,67] Topical wound care also should address mechanical protection of the affected areas, with careful padding, splinting, and elevation and/or compression to manage edema formation.[51,53,61,67]

NONSURGICAL THERAPIES

Pharmacologic management of the frostbite patient also includes systemic blockade of the arachidonic acid pathway to ameliorate the inflammatory response to the local cold injury. Historically aspirin was used and did demonstrate tissue survival improvement of greater than 20% in a rabbit ear model.[13] However aspirin blocks all arachidonate metabolites, including those that are beneficial for wound healing. Therefore, more recent recommendations center on the use of ibuprofen and specific blockade of TXA_2.[1,61,65,68]

Pentoxifylline, a phosphodiesterase inhibitor that is primarily used in claudication, has been shown to synergistically improve tissue viability in conjunction with topical aloe vera.[69] Pentoxifylline improves red blood cell flexibility, which may limit microvascular sludging and thereby diminish thrombus formation in small vessels. In addition, pentoxifylline may reduce blood viscosity, again contributing to improved tissue survival.[70] When pentoxifylline is used for post-thaw pharmacologic management, the current recommendation, based on a study of pedal frostbite, is 400 mg

Fig. 39.3 **(A)** Angiogram of foot with deep frostbite prior to tissue plasminogen activator (t-PA). **(B)** Angiogram of foot with deep frostbite following 19 hours of t-PA.

t.i.d. for 2–6 weeks following injury.[70] Iloprost, a prostacyclin analog that also serves as a vasodilator, has interesting features that may be of benefit, although all data on its use are preliminary.[57,71] Although studies of pentoxifylline and iloprost are ongoing in Europe, current data are inadequate to recommend their use.

Thrombolytics have demonstrated the most notable clinical advance in the management of frostbite in the past 50 or more years. The first demonstration of possible utility for thrombolytics in frostbite management was an animal model using IV urokinase.[72] In 1992, a preliminary account indicated that thrombolytics were potentially better than slow rewarming for reducing amputation following frostbite injury.[73] Subsequent publications have shown improved digit salvage with the use of tissue plasminogen activator (t-PA) (see Fig. 39.3).[17,19,74–77] Unfortunately, t-PA only appears to be efficacious within 24 hours of thaw, meaning that this may not be an option for patients who are injured in extremely remote environments. Additionally, although digit salvage has been improved with thrombolytics, the long-term functional results of this salvage remain unclear, particularly the impact on neuropathic complications of freezing cold injury.

Surgical and chemical sympathectomy has largely fallen out of favor owing to clinical results that are mixed at best. Sympathectomy has not shown any improvement in tissue preservation in frostbite and may ultimately result in more proximal injury demarcation.[78,79] The two best-documented benefits of sympathectomy relate to long-term function, with improved cold tolerance and amelioration of the neuropathic pain and paresthesias that often present one of the greatest clinical challenges following freezing cold injury.[78,80] Therefore, the best use of sympathectomy may be in the longer-term management of otherwise disabling complications of frostbite.

Studies of hyperbaric oxygen (HBO) are limited but have some of the most promising functional results of an adjunctive therapy for frostbite. An early documented use of HBO for therapy in frostbite involved four Alpine mountaineers, all of whom presented 10 or more days following injury and all of whom demonstrated good tissue preservation with HBO.[81] Several subsequent case reports have demonstrated improved nutritive blood flow and/or complete maintenance of frostbitten areas following HBO therapy, even with delayed presentations.[82–85] The utility in delayed presentation combined with the potential for improved functional outcomes make HBO an extremely attractive therapy in frostbite. Multicenter trials of HBO would provide substantial progress toward understanding the role for this therapy in frostbite management.

IMAGING AND SURGICAL MANAGEMENT

Both scintigraphy and magnetic resonance imaging/angiography (MRI/MRA) have been recommended as diagnostic aids to improve the process of surgical management of frostbite. More than 20 years ago, Mehta identified three different patterns in triple-phase bone scanning that were useful indicators of outcome within 48 hours of injury.[86] Specifically, he found that perfusion and blood pooling

phases demonstrated at-risk tissue, and the bone phase showed deep tissue and bone infarction. Several studies have demonstrated excellent correlation between scintigraphic findings and surgical outcomes, although some authors claim that bone scan findings best correlate with surgical findings at 7–10 days following injury.[66,87,88] Confidence in scintigraphic findings by some practitioners has been adequate for them to derive a protocol using the findings to direct early surgery.[54,89] The use of MRI/ MRA initially seemed promising, allowing direct visualization of occluded vessels and possible better delineation of viable tissue than ^{99}Tc scanning.[90] However a subsequent study demonstrated that MRI was no better than bone scanning to identify anatomic sites for amputation and that the limited soft tissue present in digits hampered the utility of MRI.[65]

Because of a historical bias based on data showing that early surgery was potentially associated with worse outcomes, the adoption of scintigraphy with early operative intervention has been limited.[79] However, Greenwald developed a protocol with early scintigraphy followed by operative intervention at 7–10 days following injury.[89] Cauchy makes a plausible argument for intervention at 10–15 days post injury with a bone scan based on a shorter waiting time for the patient, lower infection risk, and earlier progression to rehabilitation; of note, Cauchy advocates repeat scanning at 7–10 days post injury if the injury is not clearly delineated on early (<48 hours) bone scan.[66] Nevertheless the prevalent clinical practice remains to time surgery anywhere from 4 weeks to 3 months following injury, once tissues have clearly demarcated to an experienced clinical eye.[49,67]

Conclusion

Frostbite has a long clinical history and remains a modern clinical challenge. Although the pathophysiology of freezing cold injury is well delineated, few advances from the traditional "frostbite in January, amputation in July" management approach have occurred. Thrombolytic therapy has shown benefit in digital salvage but requires early use and has unclear long-term functional outcomes. HBO has shown promise in terms of salvage and functional outcomes but so far has only been evaluated in case series. Vasodilation with pentoxifylline or iloprost merits ongoing study as a potential therapy for frostbite. Scintigraphy may provide a means to expedite the surgical management of frostbitten digits and extremities, but again has only been studied in limited settings. Large-scale multicenter evaluation of these varied evaluation and management techniques is required to demonstrate whether any of these practices will ultimately improve tissue salvage and functional outcomes.

40 Chemical Burns

FELICIA N. WILLIAMS and JONG O. LEE

Introduction

Chemical burns represent a small percentage of burn injuries yet up to one third of burn-related deaths.[1] Many common household and industrial compounds have the potential to induce severe chemical burns. The American Association of Poison Control Centers' National Poison Data System 2014 annual report demonstrated 199,291 cases of exposure to cosmetic or personal care products; 198,018 household cleaning substances; 83,005 pesticides; 31,903 hydrocarbons; and 38,975 unspecified chemicals.[2] Exposure to specific chemicals, including acids, alkalines, peroxides, bleaches, and phenols, in 2014 totaled 38,594, which was up from the 38,552 cases of exposures in 2013.[3] The unfortunate reality concerning the ease of access to toxic products is evident in the presence of a rising number of pediatric exposures to chemical injuries. Most chemical burns involving children are secondary to common household products. Domestic chemical burn injuries are often due to poor labeling and storage, as well as secondary to intentional assault and suicide attempts. The most commonly affected areas of the body are the face, eyes, and arms and legs. As a result, the length of hospital stay and duration of healing tend to be greater with chemical burns. The majority of these deaths are related to the ingestion of chemical substances.[4] This chapter provides general principles for the treatment of chemical injuries.

Pathophysiology

All burn wounds, whether caused by chemical or thermal sources, have in common the denaturation of key structural and functional proteins. The structure of biological proteins involves not only a specific amino acid sequence but also a three-dimensional structure depending on weak forces, such as hydrogen bonding or van der Waals' forces. These three-dimensional structures impart biological activity to the proteins and are easily disrupted by outside influences, specifically chemical and thermal energy sources. Weak bonds are impaired by heat energy sources degrading and denaturing proteins. Moreover, any variations in pH or dissolution of surrounding lipids may neutralize a protein and disrupt its function. Direct chemical effects on a reactive group in a protein will similarly render it inactive.

The severity of a chemical burn injury is determined by several factors:[5]

- Concentration of chemical in contact or ingested
- Quantity of chemical agent
- Manner and duration of contact (skin or ingestion)
- Extent of penetration
- Mechanism of action of the chemical
- Physical state of agent (liquid, solid, gas).

There are six mechanisms of action for chemical agents in biological systems, classified by how they denature and damage proteins:[5,6]

1. *Reduction*: Reducing agents act by binding free electrons in tissue proteins, causing denaturation. In general, they do so by reducing the amide link. Examples include hydrochloric acid, nitric acid, alkyl mercuric compounds, ferrous iron, and sulfite compounds.[5,7]
2. *Oxidation*: Oxidizing agents are oxidized on contact with tissue proteins. These agents cause destruction by inserting oxygen, sulfur, or halogen atoms to structural and functional proteins. Byproducts are often toxic and continue to react with the surrounding tissue. Examples of oxidizing agents are sodium hypochlorite, potassium permanganate, chromic acid, and peroxide.[5]
3. *Corrosive agents*: Corrosive substances denature tissue proteins on contact and form eschar and a shallow ulcer. Examples of corrosive agents include phenols, cresols, white phosphorus, dichromate salts, sodium metals, lyes, sulfuric acid, and hydrochloric acid.
4. *Protoplasmic poisons*: These agents produce their effects by binding or inhibiting calcium or other organic ions necessary for tissue viability and function. These agents form esters with proteins and/or chelate calcium or other ions. Examples of protoplasmic poisons include "alkaloidal" acids; acetic acid; formic acid; and metabolic competitors and inhibitors such as oxalic acid, hydrofluoric acid, and hydrazoic acid.
5. *Vesicants*: Vesicant agents produce ischemia with necrosis at the site of contact. There is associated tissue cytokine release and blister formation. Examples include cantharides, dimethyl sulfoxide (DMSO), mustard gas (sulfur and nitrogen), and Lewisite.
6. *Desiccants*: These substances cause damage by dehydrating tissues and exothermic reactions, causing the release of heat into the tissue. Examples include sulfuric acid, muriatic acid, calcium sulfate, and silica gel.

Chemical burns are often described as acidic or alkali.[8] Acids act as proton donors in the biological system, and strong acids have a pH less than 2. Alkali, or basic, materials capable of producing injury typically have a pH greater than 11.5.[8] In general, alkaline materials cause more injury than acidic compounds. Whereas acids cause coagulation necrosis with precipitation of protein, the reaction to alkali is "liquefaction" necrosis, allowing the alkali to penetrate deeper into the injured tissue.[9] The presence of hydroxyl ions within these tissues increases their solubility, allowing alkaline proteinases to form when the alkalis dissolve the proteins of the tissues.[1] Organic solutions tend to dissolve

the lipid membrane of cell walls and cause disruption of cellular architecture as their mechanism of action. Inorganic solutions tend more to remain on the exterior of cells but may act as transporters to carry the above-mentioned agents that denature proteins or form salts with proteins themselves.[5]

General Principles of Management

The most important aspects of first aid for patients with chemical burns involve removal of the offending agent from contact with the patient—stop the burn. This requires removal of all potentially contaminated clothing and copious irrigation. Irrigation of chemical burns requires protection of healthcare providers to prevent additional injuries and additional patients. In addition, the wounds should not be irrigated by placing the patient into a tub, thereby containing the chemical and spreading the injurious material. Irrigation should be a large-volume shower or decontamination station and drained out of an appropriate drain. Immediate copious irrigation has been shown to reduce the extent and depth of injury, especially to eyes.[10] No measure of adequacy of lavage has been developed, but monitoring the pH from the effluent can provide quantifiable information as to adequacy of lavage. Thirty minutes to 2 hours of lavage is often necessary.

Safety data sheets (SDS) are mandated to be available for all chemicals present in the workplace. These can be valuable resources for potential systemic toxicity and adverse effects of an agent. Further assistance is available from regional poison control centers for household chemicals or unidentified agents.

The use of neutralizing agents is generally contraindicated. Neutralizing agents cause exothermic reactions, producing a thermal component along with a chemical injury. When the chemical agent is known and an appropriate antidote to support the physiologic changes incited by the original agent is known, some benefit to its use has been documented but has not been found to be superior to water for irrigation.[11–13] An example is calcium gluconate for hydrofluoric acid burns (discussed later in the chapter).

Treatment paradigms remain unchanged for burn and trauma patients with strict adherence to Advanced Trauma Life Support (ATLS)and Advanced Burn Life Support (ABLS) guidelines. After airway patency is assured, adequate air movement and hemodynamics should be maintained. Conventional thermal burn formulas are used for resuscitation at maintaining end-organ perfusion. Monitoring of urine output remains paramount to assessment of adequacy of end-organ perfusion and hence resuscitation. Systemic disturbances of pH are potential complications and must be monitored until acid–base disorder and electrolyte abnormalities are corrected.

The typical large-volume lavage required to adequately dilute chemical exposures puts the patient at potential risk for hypothermia, both from evaporative cooling losses and from the use of unwarmed lavage fluid. Principles of wound care for chemical burns are typically the same as for thermal burns. Early excision and grafting of obviously nonviable tissue is advocated, particularly in light of the observation that chemical burns tend to be deeper than they initially appear. As a result, they tend to heal more slowly.

Specific Agents

ACIDS

Acetic Acid

Acetic acid, also known as ethanoic acid, ethylic acid, and methane carboxylic acid, is a mild chelating agent. Solutions diluted to less than 40% concentrations, such as table vinegar and hair-wave neutralizing products, are usually harmless, but if used inappropriately, they may cause injuries. Chemical exposures may cause symptoms of upper and lower airway irritation, including cough, tachypnea, wheezing, nose and throat irritation, and pharyngeal and pulmonary edema. Other symptoms found are tooth erosion, conjunctivitis, headache, nausea, vomiting, impaired vision, abdominal pain, eye pain, and whitish discoloration of the skin.[5] In such cases, initial treatment involves irrigation.[14]

Carbolic Acid (Phenol)

Carbolic acid is a hydrocarbon derived from coal tar, which acts to cause damage secondary to its ability to induce denaturation and necrosis.[15,16] The most common adverse effects are dermatitis, abnormal pigmentation, and burns to the skin.[17] Concentrated amounts of phenol are caustic; therefore, prolonged skin contact causes partial- or full-thickness burns. These burns tend to become extensive before detection, secondary to the local anesthetic properties of phenol. Ingestion of as little as 1000 mg may be fatal. Systemic effects include ventricular arrhythmias,[18] pulmonary edema, stridor, and tachypnea. Locally, conjunctivitis, corneal edema or necrosis, and skin necrosis result.[16]

Acute poisonings are potentially fatal; hence, prompt action is necessary with copious irrigation. Polyethylene glycol (PEG; molecular weight 300 or 400 Da) has been shown to be of potential benefit, but large-volume lavage should not be delayed while PEG application is begun. Reports in the literature indicate that intravenous (IV) sodium bicarbonate may be of use to prevent some of the systemic effects of phenol.[19–26]

Chromic Acid

This acid causes nonpainful but corrosive ulcers upon contact with the skin.[27] Ulceration of the nasal septum and bronchospasm can occur with inhalation. This agent causes protein coagulation. Peak blood levels are thought to be achieved within 5 hours of exposure. Symptoms may occur with just 1% total body surface area (TBSA) burn, but a 10% burn or greater is often fatal owing to its systemic effects. Irrigation is the primary treatment for exposure, but in an industrial setting, washing with a dilute solution of sodium hyposulfite or water followed by rinsing in a buffered phosphate solution may be a more specific antidote. Dimercaprol may be used at 4 mg/kg intramuscularly every 4 hours for 2 days followed by 2–4 mg/kg/day for 7 days in total to treat the systemic effects. Dialysis in the first 24

Fig. 40.1 Epichlorohydrin acid burn 3 days after admission.

Fig. 40.2 Hydrochloric acid burn to the hand before blister removal.

Fig. 40.3 Hydrochloric acid burn to the hand after blister removal.

hours is a reasonable means to remove circulating chromium and to address existing electrolyte imbalances. Exchange transfusion may be necessary. Various ointments containing products such as 10% calcium ethylenediaminetetraacetic acid (EDTA) or ascorbic acid are available for small superficial burns.[28,29] There have been case reports supporting the early excision of chromic acid burn to assist in preventing systemic toxicity.[28,30]

Epichlorohydrin Acid

Epichlorohydrin is a rare, corrosive carcinogen that is colorless and exudes a garlic-like odor. It is used in the production of glues, plastic, glycerols, and resins, as well as in paper reinforcement and water purification. It can also be converted into a binder used in the production of explosives. These burns may demonstrate a rapid progression to a full-thickness wound within hours. Management commences with copious irrigation and hemodynamic monitoring (Fig. 40.1).

Formic Acid

Formic acid is a strong inorganic acid used by glue makers and tanning workers. After contact, it creates an eschar, which does not prevent systemic absorption. After it is absorbed, metabolic acidosis, intravascular hemolysis with hemoglobinuria, renal failure, pulmonary complications, and abdominal pain with necrotizing pancreatitis usually occur.[31] All patients injured by formic acid should be hospitalized because of this multitude of potential systemic effects. Formic acid is the acid most commonly used in assaults, especially in developing countries, because of its easy availability.[32]

Hydrochloric Acid, Muriatic Acid, and Sulfuric Acid

Hydrochloric acid is one of the most commonly treated chemical burns. Hydrochloric acid and sulfuric acid are proton donors, which cause the pH in local tissues to drop to zero as hydrogen ions disassociate.[33] Coagulation necrosis and tissue ulceration occur, leading to consolidation of connective tissue and thrombosis of intramural vessels, ulceration, fibrosis, and hemolysis.[7] Many household cleaners contain dilute hydrochloric acid (3–6%) and sulfuric acid and its desiccant precursor (sulfur trioxide) in concentrations up to 80–99%. Muriatic acid is the commercial grade of concentrated hydrochloric acid. When in contact with the skin, it denatures proteins into their chloride salts. Copious irrigation and early excision are the treatments of choice. Hydrochloric acid fumes can cause inhalation injury with acute pulmonary edema (Figs. 40.2 and 40.3). Other symptoms found to occur are white or grayish discoloration of the skin and exposed mucosa. Patients may have eye, mouth, throat, and abdominal pain and injuries. They may experience hematemesis, vomiting, dizziness, headache, dyspnea, cough, tachypnea, pneumonia, laryngospasm, and ultimately respiratory failure.[5]

Hydrofluoric Acid

Hydrofluoric acid is a corrosive that is commonly used in industrial applications and computer processing. It is used as a cleaning agent in the petroleum industry, in the production of high-octane fuel, glass etching, germicides, dyes, tanning, and fireproofing material, as well as in rust removal. Hydrofluoric acid is particularly lethal owing to its properties both as an acid and as a metabolic poison. The acid component causes coagulation necrosis and cellular death. Fluoride ions then gain a portal of entry that chelates positively charged ions such as calcium and magnesium, resulting in hypocalcemia and hypomagnesemia.[34] This causes an efflux of intracellular calcium with resultant cell death. The fluoride ion remains active until it is completely neutralized by the bivalent cations. This may exceed the body's ability to mobilize calcium and magnesium rapidly enough, causing muscle contraction and cellular dysfunction. Fluoride ion also acts as a metabolic poison by inhibiting Na-K ATPase, allowing efflux of potassium.[35] Excess potassium subsequently causes shifts at nerve endings and is thought to be the cause of the extreme pain associated with hydrofluoric acid burns.[36–38] Patients may present with self-limiting symptoms such as nausea, vomiting, fever, whitish tissue with surrounding erythema, immediate profound abdominal, mouth and throat pain, skin edema, ulcers and necrosis or stridor, laryngeal edema, wheezing, tachypnea, tetany, and potentially fatal cardiac arrhythmias.[5]

Hydrofluoric acid burns are classified based on the concentration of the exposure.[39] Concentrations greater than 50% cause immediate tissue destruction and pain. Concentrations of 20–50% result in a burn becoming apparent within several hours of exposure. Injuries from concentrations less than 20% may take up to 24 hours to become apparent.

Death from hydrofluoric acid exposure is usually secondary to systemic toxicity. Systemic symptoms are secondary to acidosis, hypocalcemia, hypomagnesemia, and hyperkalemia, which can lead to ventricular fibrillation. Thus, electrolytes and cardiac rhythm should be monitored closely.[40] When cardiac dysrhythmias develop, it is difficult to restore a normal rhythm.[41] Compounding the problem of hypocalcemia, the fluoride ion may act as a metabolic poison in the myocardium to promote the irritability. The typical electrocardiographic change seen is Q–T interval prolongation. The fluoride ions can be removed by hemodialysis or cation exchange resins.[42]

Treatments for hydrofluoric acid exposure are designed to neutralize the fluoride ion and prevent systemic toxicity. Primarily, the wound should be copiously irrigated for 30 minutes. If the concentration of exposure is less than 20% or the duration of exposure is minimal, this may serve as the extent of treatment. For more serious exposures, topical, subcutaneous, or intraarterial mixtures of calcium gluconate can be used as a first option. The topical gel is a mixture of 3.5 g of 2.5% calcium gluconate and 5 oz of water-soluble lubricant. It should be applied to the wound four to six times each day for 3 to 4 days.[43] The mixture's penetration into the dermis is limited by its calcium component. This is improved with the use of DMSO, which has its own associated toxicity. Calcium gluconate injections into the area of the wound (0.5 mL/cm^2 of 10% calcium gluconate subcutaneously or intradermally) have also been used, with good results.[44] Intraarterial injections into the radial artery (10 mL of 10% calcium gluconate and 40 mL of 5% dextrose in water infused over 2–4 hours) can be used for management of burns to the hand, but in severe cases, palmar fasciotomy may be needed.[45,46] This injection should be performed within 6 hours of exposure to prevent tissue necrosis and minimize pain. It should continue until the patient is symptom free.

Nitric Acid

This is a strong oxidizing agent that can combine with organic proteins to produce organonitrates, which act as metabolic poisons. It is used in fertilizer management, casting iron and steel, and engraving. Upon skin contact, a yellow-brown stain develops on the skin and mucosa, with an eschar. Demarcation tends to occur slowly, causing difficulty in discerning burn depth. Initial treatment involves irrigation and the use of topical treatment.[47] In addition, patients may present with whitish tinge of the teeth, eye pain, oropharyngeal pain, or abdominal pain. Patients may have dyspnea, hematemesis, dizziness, cough, tachypnea, and even develop pneumonia and laryngospasm.[5]

Oxalic Acid

This is a potent metabolic poison that combines with calcium to limit its bioavailability, thereby limiting muscle contraction.[48] It is used industrially to remove rust and in bleaching products. Treatment consists of water irrigation and IV calcium, with continuous cardiopulmonary monitoring, as well as measurements of serum electrolytes and renal function.[48]

Phosphoric Acid

Phosphorus is an incendiary agent found in hand grenades, artillery shells, fireworks, and fertilizers.[18,49] White phosphorus ignites in the presence of air and burns until the entire agent is oxidized or the oxygen source is removed. The wounds are irrigated with water, and easily identifiable pieces of phosphorus are removed. Ultraviolet light can be used to identify embedded particles through phosphorescence. In addition, a solution of 0.5% copper sulfate can be applied, which will impede oxidation and turn the particles black to aid in their identification and removal. Hypocalcemia, hyperphosphatemia, and cardiac arrhythmias have been reported with phosphorus burns.[18,49] Patients may present with eye and respiratory tract irritation, blepharospasm, endophthalmitis, a sensation of a foreign body in the eye, lacrimation, photophobia, cornea perforation, and even ultimately blindness.[5]

ALKALIS

Strong alkalis have a pH of 12 or greater. Wounds caused by alkalis initially appear superficial but may often become full thickness in 2–3 days. This chemical creates a soluble protein by binding with lipids and proteins, thus allowing passage of hydroxyl ions into the tissue. Eventually, a soft, brownish, gelatinous eschar is created. Alkalis are very corrosive in nature and penetrate deeply. Examples of strong alkalis (lyes) include barium, sodium, ammonium, calcium, lithium, and potassium hydroxides. They are present in

Fig. 40.4 Sodium hydroxide burn to the face and tongue.

Fig. 40.5 Crude oil burn to the face.

many household cleaning solutions and have historically been ingested in suicide attempts, causing death secondary to airway occlusion.[17] Management of these burns necessitates immediate and copious irrigation.

Dry residues of alkali (e.g., lime) must be brushed away and then copious irrigation is undertaken. Attempts to neutralize alkali are not recommended. Alkaline injury to the eye is particularly devastating. These compounds rapidly penetrate the cornea, causing scarring and opacification, with associated perforation.[17]

CEMENT

Cement acts both as a desiccant and an alkali. Cement is calcium oxide, which becomes calcium hydroxide upon exposure to water. It usually contains lime, sand, and other metal oxides. The dry powder is very hygroscopic and will cause desiccation injury if not hydrated or washed away. Injury results from the action of the hydroxyl ion.[50]

METALS

Occupational injuries often occur to workers using molten metal, such as elemental metals, sodium, lithium, potassium, magnesium, aluminum, or calcium. After exposure, the use of water is contraindicated because it may result in an explosive exothermic reaction. Class D fire extinguishers or sand are ideal for management, but mineral oil is also an option (Fig. 40.4).

HYDROCARBONS

Hydrocarbons are corrosive agents, often contained within plants, animal fats, and fuel oils. Prolonged contact with petroleum distillates results in dissolution of lipid cell membranes, leading to cell death.[51] These burns tend to be superficial. Systemic toxicity usually involves respiratory depression. Heat loss from rapid evaporation of gasoline can cause the development of frostbite and dehydration. Early decontamination is most efficiently achieved with soap and water.

HYPOCHLORITE SOLUTIONS

These are potent oxidizers delivered in alkaline solution used as bleaches and household cleaners. Exposure to 30 mL of 15% solution is potentially fatal. Systemic manifestations of toxicity include vomiting, confusion, dyspnea, airway edema, cyanosis, cardiovascular collapse, and coma.[49] Treatment consists of copious irrigation.

ALKYL MERCURIC COMPOUNDS

Skin reaction with these substances releases free mercury, which can be found in blister fluid. With time, mercury is absorbed, leading subsequently to systemic effects. After blisters are debrided, repeat washing to lavage the blister fluid is necessary.

TAR

Tar, crude oil, and asphalt are various names for mineral products created from long-chain petroleum and coal or fossil hydrocarbons. This compound should be removed from the skin immediately. After it has cooled, the tar produces liquefaction injury and should be debrided from the skin, especially if obvious burn, blister, or tissue loss is apparent. Antibiotic ointments and household items such as baby oil, mineral oil, mayonnaise, and butter have been found to aid in its removal (Fig. 40.5).[52]

VESICANT CHEMICAL WARFARE AGENTS (MUSTARD, LEWISITE, NITROGEN)

These agents affect all epithelial tissues, including the skin, eyes, and respiratory epithelium. Symptoms described after exposure to mustard gas include burning eyes, a burning throat, and a feeling of suffocation.[43,46] This is followed by erythema of the skin within 4 hours and blister development within 12 to 48 hours. Severe pruritus develops, particularly in moist areas such as the axilla and perineum. When the blisters rupture, they leave painful, shallow ulcers. Exposure to larger quantities of these agents

produces coagulative necrosis of the skin, with either no blistering or "doughnut blisters" surrounding a central necrotic zone.[43,44,46]

Lewisite (2-chlorovinyl-dichloroarsine) is the best known arsine. It is more powerful than the mustards, and the symptoms occur sooner.

Phosgene oxime is another common agent in chemical warfare. It is the most widely used halogenated oxime and has the immediate effect of stinging, likened to contact with a stinging needle.[46] Affected areas quickly become swollen with blister formation, and eschars develop over the ensuing week. Wound healing is slow, typically over 2 months. Eye involvement is extremely painful and can result in permanent blindness. Inhalation leads to hypersecretion and pulmonary edema.

Clothing must be removed from the victim and large-volume lavage of the skin is undertaken. Eyes are irrigated with water or "balanced salt solution." Blisters are debrided and dressed with topical antimicrobials. Dimercaprol is a chelating agent that is an antidote for lewisite poisoning. There is no specific antidote for nitrogen mustard, but sodium thiosulfate and *N*-acetylcysteine may be helpful to reduce the effects if administered early.[46] The blister fluid from nitrogen mustard injuries does not contain active agent and is hence harmless.[47] Agranulocytosis or aplastic anemia can result from exposure to these agents.[24] In the appropriate setting, bone marrow transplantation may be considered.

Conclusion

Many chemical compounds can cause burn injury. The principal idea behind the treatment of chemical burns is early, copious irrigation. Wound care is the same as for thermal burns. Chemical burns tend to be deeper than they initially appear, often requiring skin grafting for management.

41 Radiation Injuries and Vesicant Burns

GABRIEL HUNDESHAGEN and STEPHEN M. MILNER

Radiation Injury: Introduction

In the aftermath of 9/11 and more recent acts of unrelenting terrorism, such as the mass killings in Paris, Brussels, and Orlando, the possibility of the use of nuclear weapons or crude nuclear devices in attacks on nuclear facilities and use of chemical agents cannot be ignored. Given the devastating medical consequences that would follow the use of such weapons, the training of medical personnel will be a crucial factor in the effective management of such casualties if the unthinkable ever occurs.

Only 4 months after Roentgen reported the discovery of X-rays, Dr. John Daniel observed that irradiation of his colleague's skull caused hair loss. Since this finding was reported in 1896, many biomedical effects of radiation have been described.[1] Knowledge of nuclear physics was rapidly amassed in the early part of the 20th century, leading eventually to the Manhattan project and the development of the atomic bomb. The use of this weapon over Japanese cities Hiroshima and Nagasaki in 1945 with at least 129,000 direct casualties and an extended amount of long-term sequelae stands as the most gruesome demonstration of the impact and threat that nuclear weapons hold. The past 50 years has also seen widespread deployment of energy-generating nuclear reactors and the expanding use of radioactive isotopes in industry, science, and health care.[2] In 2011, a tsunami following an earthquake near the Fukushima 1 power plant in Japan led to severe equipment failures and three nuclear meltdowns and the release of radioactive material with contaminative consequences.[3] This incidence was preceded by other major industrial accidents of note at Three Mile Island in Pennsylvania, Chernobyl in the Ukraine, and Goiania, Brazil, all of which have resulted in potential or real radiation injuries to hundreds of people. According to the latest National Council on Radiation Protection & Measurements report on radiation exposure to United States citizens, the most significant increase in ionizing radiation exposure, over the past 20 years, has been through medical imaging.[4]

Exposure to ionizing radiation can follow one of three patterns:

1. Small-scale accidents, or cumulative exposures, as might occur in a laboratory or from an X-ray device in a hospital setting
2. Large industrial accidents (such as those mentioned above), stretching the need for treatment beyond available resources
3. Detonation of a nuclear device in a military conflict in which resources are totally overwhelmed or unavailable and associated multiple and combined injuries also exist.

Terminology

Damage to biological tissue by ionizing radiation is mediated by energy transference. This can be the result of exposure to electromagnetic radiation (e.g., X-rays and gamma rays) or particulate radiation (e.g., alpha and beta particles or neutrons). The severity of tissue damage is determined by the energy deposited per unit track length, known as linear energy transfer (LET). Electromagnetic radiation passes through tissue almost unimpeded by the skin and is called low LET because little energy is left behind. In contrast, neutron exposure has high LET, resulting in significant energy absorption within the first few centimeters of the body. Alpha and low-energy beta particles do not penetrate the skin and represent a hazard only when internalized by inhalation, ingestion, or absorption through a wound.

The biological effect of ionizing radiation is measured by the radiation absorbed dose (rad). The newer SI unit of absorbed dose is the gray (1 Gy = 100 rad). Not all radiation is equally effective in causing biological damage, although it may cause the same energy deposition in tissue. For example, 1 Gy of neutron radiation will not have the same effect as 1 Gy of gamma or X-radiation. For this reason, a unit of dose equivalence was derived that allows radiations with different LET values to be compared. One such unit is the rem (acronym of roentgen equivalent man). The dose in rem is equal to the dose in rads multiplied by a quality factor (QF).[5] The QF takes into account the LET and has a different value for different radiations; for X-rays, it is 1.0, and for neutrons, it is 10. The international unit, now more widely in use, is the sievert (Sv). One sievert equals 100 rem; 1 rem equals 10 mSv. This allows radiations with different LET values to be compared because 1 Sv of neutron radiation has the same biological effect as 1 Sv of low LET gamma or X-radiation.

Incidence

The source of the most abundant type of biologically relevant electromagnetic radiation is the sun. Ultraviolet (UV) light with a wavelength of 315–400 nm (UVA), 280 to 315 nm (UVB), and 10–280 nm (UVC) would normally be absorbed by 98% in the atmosphere's so-called ozone layer, which extends at about 20 miles above sea level.[6] However, mostly because of human-made pollution and the resulting increase in local permeability of this protective layer, UV radiation can reach the surface of the skin and unfold its hazardous effects. Although not technically ionizing, UV light can severely irritate dermal structures in terms of first- and second-degree burns. Simultaneously,

the formation of pyrimidine dimers in the DNA of dermal cells can be induced, which in the long term can result in malignancies.[6,7]

A significant radiation accident is one in which an individual exceeds at least one of the following criteria:[8]

- Whole-body doses equal to or exceeding 25 rem (0.25 Sv)
- Skin doses equal to or exceeding 600 rem (6 Sv)
- Absorbed dose equal to or greater than 75 rem (0.75 Sv) to other tissues or organs from an external source
- Internal contamination equal to or exceeding one-half the maximum permissible body burden (MPBB) as defined by the International Commission on Radiological Protection (this number is different for each radionuclide)
- Medical misadministration provided it results in a dose or burden equal to or greater than the criteria listed above.

Radiation accidents within the United States should be reported to the federally funded Radiation Emergency Assistance Center/Training Site (REAC/TS), where a Radiation Accident Registry System is maintained. It is operated by Oak Ridge Institute for Science and Education (ORISE) at Oak Ridge, Tennessee, and can be contacted by calling 865-576-1005 (website: http://orise.orau.gov/reacts). An emergency response team of physicians, nurses, health physicists, and support personnel provides consultative assistance on a 24-hour basis and has the capability of providing medical advice or treatment whenever a radiation accident occurs. If an accident involving radiation occurs outside the United States and local resources fall short in providing immediate advice, the REAC/TS hotline can be consulted internationally as well. The International Atomic Energy Agency (IAEA) provides a detailed publication concerning the immediate actions that should be taken in the event of large-scale radiation accidents, which can be found at http://www-ns.iaea.org/tech-areas/emergency/iec/frg/default.asp.

The number of accidents, the number of persons involved, and the number of fatalities, in the United States and worldwide are shown in Table 41.1. There have been a total of 128 fatalities recorded by the Registry worldwide (Dainiak N, personal communication and unpublished data, 2010).[8] The majority of the radiation deaths occurred as a result of the Chernobyl accident in 1986 (>40). The classification of radiation accident by device for the period 1944 until 2016 is shown in Table 41.2.

Table 41.2 Major Radiation Accidents Worldwide (1944–2016): Classification by Device

Type	Accidents (*n*)
Radiation devices	347
Sealed sources	222
X-ray devices	87

The majority of radiation accidents involve radioactive sources used for industrial radiography. The next most frequent accidents are radioisotope accidents involving unsealed radioactive materials, such as tritium, fission products, radium, and free isotopes used for diagnosis and therapy. Uncommon criticality accidents occur when enough fissionable material, such as enriched uranium, is brought together to produce a neutron flux so high that the material undergoes a nuclear reaction.

The most devastating radiation injuries and fatalities yet seen, however, resulted from detonation of nuclear weapons at Hiroshima and Nagasaki during World War II. Since 1945, nuclear weapon technology has developed enormously, and current strategic thermonuclear warheads dwarf the weapons used in Japan.[9] The majority of radiation exposure occurred within the first minute of the explosion. There were no deaths attributed to the products left behind by the atomic explosions. As detailed by Kucan in 2004, the majority of radioactive fallout from these weapons was dispersed into the atmosphere because both were detonated several thousand feet in the air.[10]

Perhaps a more likely weapon of terrorism will involve the use of a radiological dispersal device (RDD). The term "dirty bomb" generally refers to a conventional explosive packaged with radioactive material that is scattered over a wide area when detonated. It is believed that these devices would probably elicit more harm by public fear and panic than by serious injury.[11]

In clinical practice, there are concerns that relatively low levels of radiation delivered over a long period of time might induce cancer or exert genetic or teratogenetic effects.

Table 41.3 The Effectiveness of Shielding Devices

Device	Transmission (%)
Lead apron	<10
Thyroid shield	<10
Leaded glasses	<10
Unleaded glasses	50
Human body	1
Human body wearing lead apron	0.1
Portable lead shields	<1

Although most of the literature that explores this issue refers to case studies, it confirms that exposure at a younger age increases the risk of cancer. Even more important, this risk is not reduced with time.[12] Exposure to radiation through computed tomography imaging is now commonplace, and healthcare personnel should not disregard the cumulative effects of these examinations, which can approximate levels seen in atomic bomb survivors (30 mSv).[13] Because distance and radiation intensity obey the inverse square law, radiation dose can be limited most effectively by increasing the distance from the source of radiation. Although the efficacy of shielding devices will be determined by the type and thickness of the material and the energy and type of radiation, Table 41.3 illustrates the effectiveness of these devices when used at diagnostic X-ray energies.

Cumulative doses of radiation can be recorded on radiation badges containing photographic emulsion. The personnel dosimeter is relatively cheap and accurate but has limitations. The smallest exposure that can be measured is 10 millirem; film badges can be exposed by heat, giving false readings, and they are analyzed only at monthly intervals.

Pathophysiology

The detonation of a nuclear device over a population center will produce an extremely hot, luminous fireball, which emits intense thermal radiation capable of causing burns and starting fires at considerable distance. This is accompanied by a destructive blast wave moving away from the fireball at supersonic speed and the emission of irradiation, mainly gamma rays and neutrons.[14] The result of a combination of thermal and radiation injuries can have a synergistic effect on the outcome. Several animal experiments have demonstrated a significant increase in mortality rate when a standard burn wound model is irradiated, over and above that expected from either injury alone.[15]

THERMAL EFFECTS

Exact information about the cause of fatalities in a nuclear blast is not available, but from the nuclear attack on Japan, it has been estimated that 50% of deaths were due to burns, and some 20% to 30% were flash burns.[16] The clinical picture may range from an erythema of exposed areas to a charring of the superficial layers of the skin. Secondary flame burns may be present after the ignition of the victim's clothing or environment. The physicians at Hiroshima and Nagasaki observed that the "flame" burn wound seemed to heal at first. However, between 1 and 2 weeks later, a serious relapse occurred. Wound infection set in; there was disorder in granulation tissue formation; and a gray, greasy coating would form on the wounds. Thrombocytopenia resulted in spontaneous bleeding both into the wound and elsewhere. Histologically, the normal collection of leukocytes delineating a necrotic area was found to be absent because of agranulocytosis, and gross bacterial invasion was evident; both of these changes obviously affected the prognosis of these otherwise relatively small injuries.[17]

RADIATION EFFECT

The transference of radiation energy can damage critical parts of the cell directly or indirectly by formation of free radicals. The primary targets are cellular and nuclear membranes as well as DNA.[18]

The morbidity of radiation depends on its dose, the dose rate, and the sensitivity of the cell exposed. Cells are most sensitive when undergoing mitosis so that those that divide rapidly such as bone marrow, skin, and the gastrointestinal (GI) tract are more susceptible to radiation damage. Radiation to an organ such as brain or liver, which has parenchymal cells with a slow turnover rate, results in damage to the more sensitive connective tissue and microcirculation.

The overall effect on the organism depends on the extent of the body surface involved, duration of exposure, and homogeneity of the radiation field. It is convenient to consider radiation injuries as localized or whole body (acute radiation syndrome).

Long-term effects of radiation exposure include the formation of cancer and wound-healing deficits. These have been studied in various venues including exposure to tanning beds, which have been linked to an increase in melanoma in young women of up to 75%. These changes are thought to be due to a defect in the p53 tumor suppressor pathway. Children are particularly at risk for radiation-induced injuries because they have a proportionally larger amount of replicating cells and will live long enough to see the effects of radiation, which can have upwards of a 30-year latency period.[19]

LOCALIZED INJURY

In a localized injury, a relatively small part of the body is affected without significant systemic effects.[20] The skin and subcutaneous tissue alone may be involved after exposure to low-energy radiation. Exposure to high-energy radiation may injure deeper structures.

Radiation damage depends on the dose of exposure and several progressive features are observed in skin: Erythema is equivalent to a first-degree thermal burn and occurs in two stages. Mild erythema appears within minutes or hours after the initial exposure and subsides in 2–3 days. The second onset of erythema occurs 2–3 weeks after exposure and is accompanied by dry desquamation of the epidermal keratinocytes. Epilation (loss of hair) may occur as soon as 7 days after injury. It is usually temporary with doses less than 5 Gy but may be permanent with higher doses.

Moist desquamation is equivalent to a second-degree thermal burn and develops after a latent period of about 3 weeks with a dose of 12–20 Gy. The latency period may be shorter with higher doses. Blisters form, which are susceptible to infection if not treated.

Full-thickness skin ulceration and necrosis are caused by doses in excess of about 25 Gy. Onset varies from a few weeks to a few months after exposure. Blood vessels become telangiectatic, and deeper vessels occlude. Obliterating endarteritis results in fibrosis, atrophy, and necrosis. Skin cancers may be evident after months or years.

One of the most closely studied local effects of radiation injury involves the treatment of breast cancer. It is well known that radiation therapy improves postmastectomy outcomes in women with multiple nodal involvement. This outcome comes at a cost as significantly increased rates of tissue contracture, hyperpigmentation, and asymmetry after all types of reconstruction paired with radiation.[20]

THE ACUTE RADIATION SYNDROME

The physiological effects of whole-body radiation are described as the acute radiation syndrome (ARS). The clinical course usually begins within hours of exposure. Prodromal symptoms include nausea, vomiting, diarrhea, fatigue, fever, and headache. There then follows a latent period, the duration of which is related to the dose. Hematopoietic and GI complications ensue. ARS can be subdivided into three overlapping subsyndromes, which are related to the dose exposure.

Hematopoietic Syndrome

This may occur after an exposure of 1–4 Gy. The bone marrow is the most sensitive, and pancytopenia develops. Opportunistic infections result from the granulocytopenia and spontaneous bleeding from thrombocytopenia. Hemorrhage and infection can cause death.

Gastrointestinal Syndrome

This requires a larger dose exposure usually in the range of 10–12 Gy. Severe nausea and vomiting associated with bowel cramps and watery diarrhea occur within hours of irradiation. There is a shorter latent period of 5–7 days, which reflects the turnover time of the gut epithelium (3–5 days). The epithelial damage results in loss of transport capability, bacterial translocation with septicemia, bowel ischemia, and bloody diarrhea. Large fluid imbalances can result in hypovolemia, acute renal failure, and anemia from both bleeding and the loss of erythropoiesis. Critical exposure will lead to rapid deterioration with unrelenting bloody diarrhea, fever, refractive hypovolemic shock, sepsis, and death.[21,22]

Neurovascular Syndrome

An exposure to a dose of 15–30 Gy or greater can cause an immediate total collapse of the vascular system superimposed on the aforementioned syndromes. This may be caused by the massive release of mediator substances, nitric oxide abnormalities, or destruction of endothelium.[21] This syndrome can progress rapidly with variable neurologic symptoms, respiratory distress, cardiovascular collapse, and death.

Table 41.4 Survival Rates With Major Resources Available

Burn alone	<70% TBSA	50% survival
Burn alone	>70% TBSA	Probably fatal
Burn plus radiation	<30% TBSA	May survive
Burn plus radiation	>30% TBSA	Probably fatal

TBSA, Total body surface area.

TRIAGE

Triage is the initial classification of casualties into priority groups for treatment and is essential in the management of large numbers of casualties. All first responders should take into account their own safety and remember that exposure to radiation is reduced by distance and shielding. Therefore, a perimeter should be established beyond which those without shielding should remain until the donning of personal protection equipment is complete. In most circumstances, ionizing radiation is not immediately life threatening, and after life-saving measures have been carried out and the patient stabilized, assessment of radiation exposure can proceed.[23]

If large-scale casualties are encountered, triage may, of necessity, seem to be draconian. Patients who are unlikely to survive should not be allowed to overwhelm available resources, so that adequate treatment reaches those most likely to survive. In conventional warfare with limited medical resources, 50% of soldiers with thermal injuries of up to 70% total body surface area (TBSA) are expected to survive (Table 41.4).

This survival rate should be bettered in a smaller civilian accident. Thus, patients with burns alone over 70% TBSA should receive expectant treatment, and those with burns under 20% can have their treatment delayed. If there has been a significant exposure to radiation as well as a thermal injury, individuals with over 30% TBSA burns are unlikely to survive without the use of major resources.[24]

Treatment

The treatment of any burn requires massive support from a dedicated team. This will be available for small accidents. With larger accidents or a nuclear attack, the number of victims could swamp the services; treatment facilities may be destroyed; normal supply channels would be drastically reduced, if present at all; production, distribution, and transportation of supplies may be greatly impaired; and local care workers may also be the victims.[2]

FIRST AID

The victims must be evacuated from the source of radiation to limit exposure. Normal resuscitation procedures must be followed. Contaminated clothing must be removed, and the skin wounds must be decontaminated by copious but gentle irrigation with water or saline. The goal of decontamination is to dilute and neutralize particles without spreading

them to unexposed areas. Thus, patients should not be immersed in tubs. Irrigation should be continued until a dosimeter such as a Geiger–Müller counter indicates a steady state or minimum radiation count has been reached.

Intact skin may also be irrigated with a soft brush or surgical sponge, preferably under a stream of warm tap water. If this is inadequate, a second scrubbing with mild soap or detergent (with a pH of 7) for 3–4 minutes is recommended. This is followed by application of povidone-iodine solution or hexachlorophene soap, which is then rinsed again for 2–3 minutes and dried. If the patient is known to have had exposure to less than 100 rem (1 Sv/Gy), he or she can be followed as an outpatient. Exposures greater than 100 rem (1 Sv/Gy) require full evaluation in the hospital. Patients with exposures greater than 200 rem (2 Sv/Gy) or who have symptoms of ARS should preferably be sent to specialist centers with facilities to treat bone marrow failure.[25]

ASSESSMENT

The assessment of thermal injury has been covered in preceding chapters. Exposure to radiation can be estimated clinically by noting the onset of symptoms of ARS, supported by biological parameters. A complete blood count, including platelets and differential count, should be performed immediately and repeated at 12–24 hours if indicated by a change in the absolute lymphocyte count. If the patient sustains a fall in lymphocyte count of 50% or a count less than 1×10^9/L in a time period of 48 hours postexposure, a moderate dose of radiation has been encountered.[26] Levels of serum amylase and diamine oxidase (produced by intestinal villi) may be useful biological dosimeters of the future. Amylase levels are only reliable when the salivary glands have been exposed, and diamine oxidase has not yet been fully assessed in humans. Lymphocyte chromosomal analysis allows for accurate measurement even at low levels of exposure. However, this test is impractical with large numbers of casualties.[27]

GENERAL CARE OF IRRADIATED PATIENTS

A history should be obtained from the patient or others. Factors such as age, concurrent medical problems, smoke inhalation, and multiple trauma will affect the prognosis. A full physical examination is carried out to exclude other injuries. Those exposed to lethal doses of radiation will exhibit early signs of radiation sickness and should be triaged accordingly.

All patients should be administered adequate analgesia. Opiates or opioids are the drugs of choice and must be titrated to effect and administered by the intravenous (IV) route. Early nausea and vomiting will be distressing and must be treated with available antiemetic drugs. Ondansetron may prove successful because it is used against similar symptoms encountered in radiotherapy and chemotherapy and can also be used in children.

Patients with thermal burns in excess of 40% TBSA or with associated inhalation or major trauma should be treated expectantly in the mass casualty situation. They should be made comfortable and given adequate analgesia, sedatives, or both if available and thought appropriate.

Table 41.5 Oral Resuscitation Formulas

Formula	Na	Cl	K^+	Buffer	Use
WHO ORS (1975)	90	80	20	30	Diarrhea

HLS, Hypertonic lactated saline; *ORS,* oral resuscitation solution; *WHO,* World Health Organization.

Adapted from Kramer GC, Michell MW, Oliveira H, et al. Oral and enteral resuscitation of burn shock the historical record and implications for mass casualty care. *Eplasty* 2010;10:e56, with permission from ePlasty.

Resuscitation should be the same as that for an uncomplicated thermal injury. Any resuscitation formula can be used, but it must be closely monitored and adjusted as necessary to maintain an adequate urine output. Fluid losses from diarrhea and vomiting may be excessive and need to be replaced.

Oral Resuscitation

Intravenous fluids may be limited, and the victims may be advised to take oral fluids consisting of balanced salt solutions and maintain a large urine output. Studies in humans and animal models have shown that intestinal absorption remains intact in burn patients. Kramer et al. reviewed the use of oral resuscitation therapy in burn care and found 12 reports, most of which show equal outcomes to IV infusions. This solution should be readily available, cheap, easy to transport, and palatable (Table 41.5).[28,29] A study published by one of the authors shows a reduction in IV fluid requirements by 58% on average when Parkland formula-driven protocols are supplemented with oral resuscitation (Fig. 41.1).[30]

CARE OF BURN WOUNDS

After the patient has been cleaned, decontaminated, and debrided, the extent of any thermal burn and its depth can be ascertained more accurately.

Mild erythema may require little treatment; however, it is important to avoid further irritation of the skin by exposure to abrasive decontamination, irritating solutions, and sunlight. With a slightly higher radiation dose causing dry desquamation, a bland lotion and loose clothing to alleviate itching may be all that is required.

Deeper burns with moist desquamation are treated like conventional thermal injuries. Burns are best treated closed because of the high risk of sepsis in immunosuppressed patients whose wounds are susceptible to dehydration and colonization and invasion of organisms. Early tangential excision and split-skin grafting promotes early wound closure, decreases burn wound colonization and sepsis, and

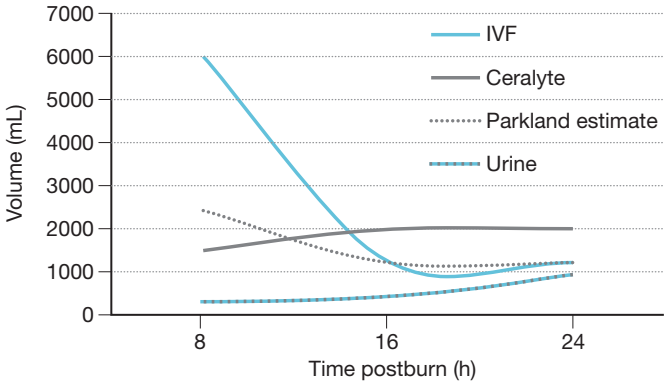

Fig. 41.1 The addition of oral resuscitation reduces overall intravenous fluid (IVF) requirements.

leads to shortened hospital stays.[31,32] Information regarding the grafting of radiation burns is not yet available but is probably best delayed. Dubos et al. performed early excision and grafting of burns in irradiated monkeys, showing that healing occurred fully by the end of the second week, although histologically, there was a slight delay in the healing process.[33] Blood loss in excess of 300 mL/% TBSA excised presents an increased anesthetic hazard and should be monitored closely. In irradiated tissue that is severely injured, definitive management often involves radical local resection and reconstruction with well-vascularized nonirradiated tissue, usually from a distant site. Research suggests injections of human mesenchymal stem cells may have a role in the treatment of local radiation-induced tissue injury.[34]

TREATMENT OF COMPLICATIONS

Hematologic

Blood and platelets are administered to maintain an adequate hemoglobin concentration and a platelet level of 20×10^9/L. If surgery is contemplated, this level should be raised to 75×10^9/L. All blood products should be irradiated to avoid graft-versus-host disease.

Bone marrow transplantation is the treatment of choice after total-body irradiation. It should be performed between 3 and 5 days postexposure as the immunosuppression is at its peak.

The proliferation and differentiation of residual hematopoietic stem and progenitor cells can be stimulated. Administration of antiapoptotic cytokine combinations such as stem cell factor, Flt-3 ligand, thrombopoietin, and interleukin-3 may assist recovery, if administered early.[35] Moreover, hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF) have been recommended based on improved survival rates in irradiated primates and reduced neutropenia in humans after accidental irradiation.[36,37]

Infection

The immunosuppression associated with irradiation makes the victim susceptible to exogenous and endogenous pathogens. Exogenous infection can be limited by adequate aseptic technique and nursing the patient in a sterile environment. Monitoring the patient adequately will allow the early diagnosis of sepsis and its treatment. The antibiotic chosen should reflect the current pattern of susceptibility and nosocomial infections in the particular unit at the time. Combination therapy will be required with profound neutropenia. Broad-spectrum antibiotics such as imipenem, ceftazidime, and ciprofloxacin can be considered. If Gram-positive infection is suspected, vancomycin or teicoplanin should be administered. In case of an inadequate response, an antifungal agent must be added.

SUMMARY

Treatment of radiation injury, whether or not it is combined with other injuries, requires specialized knowledge and resources. The combination of radiation injury with associated injuries appears to have a synergistic effect on outcome. Significant increases in mortality rates occur because of immunosuppression secondary to radiation exposure in patients already vulnerable to infections. For localized radiation injury, it is often difficult to assess the level of severity quickly and with accuracy because of the delay between exposure and appearances of lesions and because of hidden lesions in underlying tissues. Medical treatment deals with inflammation, moist desquamation, and chronic pain; the most favorable time for surgical intervention is difficult to specify. Full intensive care support is needed for whole-body irradiation causing ARS and is available only if small numbers are involved. Oral replacement therapy may be a feasible alternative to IV resuscitation of burns and could potentially save many lives in mass casualty situations. Those who survive and show signs of regeneration of tissues will warrant late surgical intervention. Aplastic anemia, immunosuppression, hemorrhage, and sepsis will be major problems for survivors. The improving therapy of bone marrow transplantation is the treatment of choice. Large numbers of casualties will necessitate expectant treatment only. In the event of a radiation mass casualty, resources will be limited, and treatment may depend on oral routes of resuscitation to maintain intravascular volume. Evacuation of survivors will take days, and a natural selection will take place.

Vesicant Burns

INTRODUCTION

Vesicant agents are characterized by their ability to produce cutaneous blisters resembling "burns." In the 1980s, the conflict between Iraq and Iran displayed the most open and widespread use of chemical weapons on a battlefield in recent decades. Although sulfur mustard is the most important vesicant militarily, the vesicant category includes other agents, such as lewisite and phosgene oxime. These compounds affect not only the skin but also all epithelial tissue with which they come into contact, particularly the eyes and respiratory tract. Although most physicians are unlikely to encounter casualties of chemical weapons, the proliferation of these agents has increased the risk to both military

Fig. 41.2 Photograph of a child injured in the attack on Sardasht in 1987. (From Ghanei M, Aslani J, Khateri S, Hamedanizadeh K. Public health status of the civil population of Sardasht 15 years following large-scale wartime exposure to sulfur mustard. *J Burns Surg Wound Care* 2003;2(1):7-18, with permission from ePlasty, formerly *Journal of Burns and Wounds*.)

and civilian populations. They are likely to require expertise found in burn centers; for this reason, an account of the management of these injuries is included in this text.[38]

Chemical warfare was first introduced on a large scale during World War I, 100 years ago, when sulfur mustard (bis[2-chloroethyl]sulfide) and other agents were used extensively with devastating consequences in trench combat. The International Chemical Weapons Convention, an arms control treaty to ban and destroy chemical weaponry, was signed and ratified by 192 countries, entering into force in 1997, although the worldwide stockpile has not been deactivated and dismantled. The low technology required to manufacture the agents, easy stockpiling, and difficulty in detection cause vesicant agents to pose a continued major threat to civilians and military personnel.

MECHANISMS OF ACTION

The mechanism of action of mustard has eluded identification; however, most of the toxic effects are believed to be related to alkylation of DNA and critical target molecules. The DNA cross-links, which prevent replication and repair of DNA, ultimately lead to cell death. The dermal–epidermal separation, which causes the skin lesions, is believed to be due to release of proteases and other enzymes. Breakage of anchoring filaments connecting the basal cell layer to the basement membrane results in a blister with the basement membrane on its dermal side.[39]

CLINICAL FEATURES

Early symptoms ascribed to mustard gas include ocular photophobia and a feeling of suffocation associated with hoarseness and rhinorrhea with a burning throat.[40] After 4 hours, erythema is seen; in 12 to 48 hours, blistering appears accompanied by severe pruritus, which has a predilection for moist areas such as the axilla and perineum. The blisters tend to rupture, discharging an amber serous fluid and leaving painful shallow ulcers. Greater exposure produces coagulative necrosis of skin, with either no blistering or "doughnut blisters" surrounding a central necrotic zone.[39] This will be accompanied by severe conjunctivitis, corneal erosion, and necrotizing bronchitis. A secondary respiratory infection may develop over the next few days, coupled with associated bone marrow suppression, which may be fatal. Higher doses can lead to severe stem cell suppression, pancytopenia, and involvement of the GI tract with effects ranging from nausea and vomiting to severe hemorrhagic diarrhea. Excitation of the central nervous system, resulting in convulsions, has been reported.[41]

Lewisite (2-chlorovinyl-dichlorarsine) is the best known arsine. It is more powerful than the mustards, and symptoms occur sooner. Eye irritation is produced immediately, and sneezing, salivation, and lacrimation occur sooner. Nonlethal chronic exposure may lead to arsenical poisoning.

Exposure to phosgene oxime, the most common halogenated oxime, has the immediate effect of stinging, comparable to contact with a stinging nettle.[42] Within 1 minute, the affected area becomes swollen, and solid lesions resembling urticaria are seen. An eschar will form after 1 week, but healing is often delayed beyond 2 months. Contamination of the eyes is extremely painful and may result in permanent blindness. Inhalation causes irritation and coughing, hypersecretion, and pulmonary edema.[42]

Ghanei et al. reviewed 355 survivors and 108 deaths from exposure to sulfur mustard during an attack on Sardasht, Iran, in July of 1987. Their data revealed that mortality from exposure to this agent occurs in two waves. Initial deaths happened in the first 2–3 days after contact and were due mostly to respiratory involvement. The second wave of deaths occurred 1–3 weeks after contact and were attributed to respiratory distress syndrome or infection (pneumonia, septic shock, or wound infections). The authors suggest that patients should be kept in the intensive care unit (ICU) setting for the initial 4 weeks after contact and that antibiotic therapy be continued for at least the first 2 weeks of treatment.[43] Fig. 41.2 demonstrates numerous vesicles and a crusting rash after exposure to a sulfur mustard agent.

ACUTE TREATMENT FOR EXPOSURE TO A VESICANT AGENT

Butyl rubber gloves, boots, and a respirator are effective forms of prophylaxis. The first priority in treatment is to eliminate contact with the agent and initiate decontamination. During this procedure, attendants should also be suitably protected and contaminated clothing sealed in special containers to minimize self-endangerment. After clothing is removed, the skin is gently washed with soap and water.[44] At the initial encounter, eyes should be irrigated with copious quantities of water and the patient referred for ophthalmologic expertise.

Symptomatic relief is pivotal. Systemic analgesics can be started immediately and itching treated with sedatives (benzodiazepines or phenothiazines) and antipruritic agents. Dimercaprol (British antilewisite), a chelating agent, is a specific antidote for lewisite poisoning. It is of note that it is incompatible with silver sulfadiazine. It is available as an

ointment for skin lesions, as drops for eye applications (5–10% in oil), and in an intramuscular preparation for systemic toxicity. Other readily available chelating agents are:

- DMSA—mesodimercaptosuccinic acid
- DMPS—2,3-dimercapto-1 propanesulfonic acid sodium
- DMPA—N-(2,3-dimercaptopropyl) phthalamidic acid.

These have a high therapeutic index, are water soluble, and are effective orally. There is no specific antidote to mustard poisoning, and no pretreatments or treatments exist that provide practical or effective protection against mustard toxicity.[39,45]

Patients experiencing cutaneous injuries, erythema covering more than 5% TBSA in noncritical areas (face, hands, perineum) require hospitalization. The systemic fluid derangement is less severe than that seen with thermal burns; however, patients should be carefully monitored. Fluid requirements in Iranian casualties during the Iran–Iraq war appeared to have been relatively independent of affected TBSA.

Blisters should be deroofed and dressed with topical antimicrobials. The mustard blister fluid is harmless.[46] Favorable outcomes have now been demonstrated in a pig model by use of various debriding techniques and resurfacing with split-thickness skin grafts. Such methods have included laser, dermabrasion, sharp surgical excision, and enzymatic debridement.[38,47,48]

Respiratory injury requires symptomatic treatment according to its severity. Inhalation of high-dose steroids is controversial at present. Severe exposure will lead to agranulocytosis or aplastic anemia.[49] The pancytopenia seen after 7 days with the Iranian casualties did not appear to be helped by transfusion of relevant blood products. Bone marrow transplantation may prove useful, although of little practical value with large numbers of casualties. The effect of bone marrow stimulants such as oxymetholone and lithium carbonate is unknown but may be considered. Fluid replacement may be carried out dynamically with adequate cardiovascular monitoring. The maximum fluid loss occurs during blister formation and not necessarily in the first 24 hours.

LONG-TERM EFFECTS OF ACUTE EXPOSURE

Individuals who sustain mustard injury may experience difficulties after the initial effects of the injury have subsided. Destruction of melanocytes leave hypopigmented areas; otherwise, hyperpigmentation tends to predominate. Acute and severe exposure can also lead to chronic skin ulceration, scar formation, and the development of skin cancer.[39]

Recurrent or persistent corneal ulceration can occur after latent periods of 10–25 years. Chronic conjunctivitis and corneal clouding may accompany this delayed keratopathy.[50]

Clinical follow-ups on 200 Iranian soldiers who sustained injuries from mustard during the Iran–Iraq War indicate that about one third had experienced varied respiratory ailments, such as chronic bronchitis, asthma, recurrent pneumonia, bronchiectasis, and even tracheobronchial stenosis, more than 2 years after exposure. Some 12% of all British soldiers exposed to mustard in World War I were awarded disability compensation for respiratory disorders believed to have been caused by mustard exposures during combat.[51]

SUMMARY

The vesicant agents are perhaps poorly named because they have the ability to affect all epithelial surfaces, particularly the eyes and respiratory surfaces, and not just the skin. The most important vesicant is sulfur mustard, which acts as an alkylating agent, causing a series of clinical reactions ranging from vesicles to severe skin necrosis. Systemic effects are seen with high doses, and the combination of depressed bone marrow activity and respiratory involvement often proves fatal. There is no effective antidote, and treatment depends on prevention of contact and local therapy to achieve wound healing, which tends to be slow. There is no risk to the caregiver from the blister fluid, which contains no active agent. Treatment may require respiratory care in an ICU setting for upwards of 4 weeks, as well as several weeks of IV antibiotic therapy.

42 Exfoliative Diseases of the Integument and Soft Tissue Necrotizing Infections

SHAWN P. FAGAN, JOSHUA CARSON, CARLOS JIMENEZ, JIAKE CHAI, MARCUS SPIES, MAUREEN HOLLYOAK, MICHAEL J. MULLER, CLEON W. GOODWIN, and DAVID N. HERNDON

Introduction

Acute, severe, exfoliative and necrotizing diseases of skin and underlying structures may cause significant morbidity and mortality in the afflicted patient. The problems associated with these diseases, such as wound infection, sepsis, inadequate nutrition, and pain, are similar to those seen in patients with major burns. Thus burn centers, with their multidisciplinary teams, have been advocated to provide the treatment and management for this unique, critically ill patient population. This chapter describes the pathophysiological processes of severe exfoliative skin disorders, their diagnosis, and the specialized treatment offered by burn centers.

Severe Exfoliative Disorders

This classification of exfoliative diseases of the skin and mucous membranes historically consisted of three specific maladies, distinguished by the amount of skin involvement: erythema multiforme major (EM), Stevens–Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). For the terms of this chapter, we are maintaining that approach. However, some recent classifications list EM as its own distinct disease entity separate from SJS and TEN and most commonly associated with the herpes simplex.[1] This new designation does not affect the classifications of SJS and TEN: Each are still determined by the extent of total body surface (TBSA) affected by the disease process. SJS is considered to affect <10% total body surface area (TBSA), whereas TEN covers >30% TSBA, leaving a zone of overlap between 10% and 30% TBSA, which is referred to as SJS/TEN.[1,2] The most common characteristics of these disease entities are defined in Table 42.1.[3,4]

Toxic Epidermal Necrolysis

EPIDEMIOLOGY

TEN represents the severe extreme of the spectrum of necrolytic disorders. A rare disease, the incidence of TEN in this country is estimated at 0.4–1.9 cases per million persons per year and that of SJS has been reported to be only slightly higher at 1–7 cases per million persons per year.[5–10] This incidence is similar to 1.89 cases of TEN per million persons per year reported for Europe in 1996, but higher than reported for Asia.[11,12] The overall rarity of this disease process has been, and continues to be, a barrier to research. However, over the past several decades, the concentration of physician experience with TEN into a limited set of regional burn centers has facilitated an increasing quantity and quality of active research.

These exfoliative disorders occur in all age groups; however the incidence is increased in the elderly and females.[3,13–17] In addition, TEN has been linked to certain infectious disease processes. The annual incidence of TEN in the human immunovirus (HIV)-infected population is 1000-fold higher than in the general public.[18] Whether this increase is due to their immunocompromised state or to the increased prescription of high-risk drugs, particularly sulfonamides, is debated.[19,20] However cases with no drug history or preceding illness have been reported. An additional infectious disease process associated with SJS/TEN is *Mycoplasma* pneumonia. Finally idiopathic cases not related to drugs account for 3–4% of TEN.[6,7]

Prognosis, Morbidity, Mortality

On the surface, these exfoliative disorders may mimic the symptoms of a partial-thickness thermal injury, specifically in relation to the involvement of the skin. However these diseases also affect all epithelial surfaces, thus increasing the risk and incidences of infections, other complications, and death. Patients suffering from particularly complicated cases of SJS may benefit from the expertise of a burn center, although these patients are generally referred on an as-needed basis. In contrast, those diagnosed with TEN carry a specific set of severe and complicated medical needs that are clearly best addressed in the context of a specialized burn center.

Mortality of TEN ranges from 25% to 80%, with morbidity being reported as high as 65%.[21] However reports are variable and usually based only on small patient populations.[17,22,23] Death may occur early in the course of the disease, with sepsis being the most frequent cause. *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the predominant organisms involved.[17] Pulmonary embolism and gastrointestinal hemorrhage are other causes of death.

Mortality is increased significantly in those patients at the extremes of age and in relation to the percentage of

Table 42.1 Characteristics of Erythema Multiforme, Stevens–Johnson Syndrome, and Toxic Epidermal Necrolysis

	Erythema Multiforme	Stevens–Johnson Syndrome	Toxic Epidermal Necrolysis
Prodrome	Absent	High fever, malaise	High fever, malaise
Acute phase	4–8 days	4–8 days Sensation of skin burning or tenderness	Sudden onset, 1–2 days Sensation of skin burning or tenderness
Skin lesions	Symmetrical, primarily located on the extremities, some target lesions without blisters	Variable distribution, individual vesicles on an erythematous base <10% TBSA Nikolsky's positive	Diffuse generalized epidermal detachment, absence of target lesions, large confluent plaques >30% TBSA Nikolsky's positive
Mucosal involvement	Limited to one surface, usually oral	Severe, two or more surfaces involved	Severe, two or more surfaces involved
Histopathology	Dermoepidermal separation, mononuclear perivascular cell infiltrate, small areas of epidermal detachment associated with target lesions	Dermoepidermal separation, more intense dermal infiltrate, areas of epidermal detachment	Epidermal necrosis, dermoepidermal separation, minimal dermal inflammatory infiltrate, large areas of epidermal detachment
Recovery	1–4 weeks	1–6 weeks	1–6 weeks
Mortality	0%	0–38%	25–80%

Table 42.2 SCORTEN Scores and Mortality

SCORTEN (Sum of Scores)	Predicted Mortality
0–1	3.2%
2	12.1%
3	35.8%
4	58.3%
>5	90%

denuded skin and serum urea nitrogen levels.[17,22,24] Bastuji-Garin et al. in 2000 created the Score of Toxic Epidermal Necrolysis (SCORTEN), a scoring system to predict mortality in the adult population presenting with TEN. The scoring system uses seven independent risk factors to predict mortality by allotting 1 point for each variable:[25]

a. Age older than 40
b. Heart rate greater than 120 beats per minute
c. Comorbid malignancy
d. Epidermal detachment of greater than 10% of body surface area (BSA) on day 1
e. Blood urea nitrogen of greater than 28 mg/dL
f. Glucose of greater than 252 mg/dL
g. Bicarbonate less than 20 mEq/L.

The scoring system should be performed on day 1 and day 3 postadmission to maximize its predictive value. Mortality from TEN increases from 3.2% for a score of 0–1 to 90% for a score greater than 5 (Table 42.2).

While originally developed for adults, the scoring system has been validated in the pediatric population, but overall has been challenged for its lack of incorporating no more than one morbidity (malignancy) in its calculation.[26,27] While other investigators have developed formulas based on logistic regression analysis, the SCORTEN system is the most widely utilized.

SJS is associated with a mortality rate of 0–38%.[14,28] EM rarely causes death.[29]

ETIOLOGY

Keratinocyte apoptosis and secondary epidermal necrosis represent the pathopneumonic cellular process of TEN. The origins of the cellular process remain an active area of research, with an intricate meshwork of overlapping risk factors and processes starting to emerge as the picture sharpens. What has become clear is that the TEN disease process results from a complicated interaction of multiple processes and risk factors: genetic predisposition, environmental triggers, immunologic reaction, inflammatory mediators, and cellular apoptotic machinery.

Triggers and Risk Factors

TEN appears to be driven by immunological reactions to foreign antigens, often referred to as "triggers." Medications are by far the most commonly identified trigger, implicated in 77–94% cases of TEN. Antimicrobials, anticonvulsants analgesics, and nonsteroidal antiinflammatory agents of the oxicam type have been implicated.[6,16] Naturally the particular profile of TEN instigators will vary from population to population depending on the epidemiology of medication exposures in any given population.

Attempts to identify drugs suspected of having caused exfoliative necrolysis by skin test and laboratory tests seldom have been successful.[17] While some assays are trialed in research settings, there are currently no fully vetted, reliable methods available for identifying the inciting trigger in a patient with TEN. Historically the medication-specific trigger for any given case of TEN was ultimately a matter of speculation. However Sassolas et al. in 2010 developed an algorithm of drug causality for epidermal necrolysis termed ALDEN. The algorithm assigns a score of 1 to 10 for each drug based on six parameters.[32] The score is then categorized as very probable (>6), probable (4–5), possible (2–3),

unlikely (0–1), and very unlikely (<0) (Table 42.3).[32] The results of this algorithm were compared to a case-controlled analysis of the European Study of Severe Cutaneous Adverse Reactions (EuroSCAR) and found to have good accordance.[32,33] The use of ALDEN in the clinical setting may greatly improve the ability for clinicians and researchers to link medication-specific triggers and TEN.[32]

While advances have been made in correlating medications as the causative agent of TEN, the role of nonmedication triggers in the etiology of TEN remains murky. Upper respiratory tract infections, pharyngitis, otitis media, or viral illness are frequently reported as preceding or coinciding with the development of TEN in some patients.[13–15,34–36] *Mycoplasma pneumoniae* and herpes viruses (cytomegalovirus, Epstein–Barr virus, herpes simplex, and varicella zoster) have been implicated in the cause of EM and SJS, but not TEN.[14,37,38] Quantifying the association between TEN and antecedent viral syndromes is complicated by the rarity of TEN and the similarities between prodromal symptoms and other more common disorders. This leads to patients presenting with relatively prominent prodromal symptoms who are typically misdiagnosed as having a simple viral syndrome. Because of the delay between early prodromal symptoms and the more specific TEN rash, it is often impossible to determine in retrospect whether the pertinent symptoms were actually prodromal or if the patient had an antecedent viral infection. Furthermore, these prodromal symptoms are often treated with medications before the TEN diagnosis is considered. As such, medications used to treat prodromal symptoms are frequently misinterpreted as TEN triggers.

Table 42.3 Algorithm of Drug Causality for Epidermal Necrolysis (ALDEN)

Criterion	Values	Rules to Apply	
Delay from initial drug component intake to onset of reaction (index day)	Suggestive +3 Compatible +2 Likely +1 Unlikely −1 Excluded −3	From 5 to 28 days From 29 to 56 days From 1 to 4 days >56 Days Drug started on or after the index day In case of previous reaction to the same drug, only changes for: Suggestive: +3: from 1 to 4 days Likely: +1: from 5 to 56 days	−3 to 3
Drug present in the body on index day	Define 0 Doubtful −1 Excluded −3	Drug continued up to index day or stopped at a time point less than five times the elimination half-life[a] before the index day Drug stopped at a time point prior to the index day by more than five times the elimination half-life[a] but liver or kidney function alterations or suspected drug interactions[b] are present Drug stopped at a time point prior to the index day by more than five times the elimination half-life[a], without liver or kidney function alterations or suspected drug interactions[b]	−3 to 0
Prechallenge/ rechallenge	Positive specific for disease and drug: 4 Positive specific for disease and drug: 2 Positive unspecific: 1 Not done/unknown: 0 Negative −2	SJS/TEN after use of same drug SJS/TEN after use of similar[c] drug or other reaction with same drug Other reaction after use of similar[c] drug No known previous exposure to this drug Exposure to this drug without any reaction (before or after reaction)	−2 to 4
Dechallenge	Neutral 0 Negative −2	Drug stopped (or unknown) Drug continued without harm	−2 or 0
Type of drug (notoriety)	Strongly associated 3 Associated 2 Suspected 1 Unknown 0 Not suspected −1	Drug of the "high-risk" list according to previous case–control studies[30–32] Drug with definite but lower risk according to previous case–control studiesd Several previous reports, ambiguous epidemiology results (drug "under surveillance") All other drugs including newly released ones No evidence of association from previous epidemiology stud with sufficient number of exposed controls[c] **Intermediate score = total of all previous criteria**	−1 to 3 **−11 to 10**
Other cause	Possible −1	Rank all drugs from highest to lowest intermediate score If at least one has an intermediate score >3, subtract 1 point from the score of each of the other drugs taken by the patient (another cause is more likely)	−1
Final score			**−12 to 10**

<0, Very unlikely; 0–1, unlikely; 2–3, possible; 4–5, probable; ≥6, very probable.
ATC, anatomical therapeutic chemical; SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.
[a]Drug (or active metabolite) elimination half-life from serum and/or tissues (according to pharmacology textbooks, tentative list available in complementary table), taking into account kidney function for drugs predominantly cleared by kidney and liver function for those with high hepatic clearance.
[b]Suspected interaction was considered when more than five drugs were present in a patient's body at the same time.
[c]Similar drug = same ATC code up to the fourth level (chemical subgroups), see Methods.

Genetics

Genetics clearly plays an important role in the pathophysiology of TEN, with multiple alleles identified as potent risk factors. Interestingly, the genetic risk factors identified thus far all appear to be trigger-specific. That is, a particular allele may place a person at risk for developing TEN in response to one drug, but not increase that same person's risk for developing TEN in response to a different medication.[39] The majority of those alleles identified thus far appear to increase risk through two separate mechanisms: drug–antigen metabolism and antigen presentation. As early as 1986, Shear et al. identified a pattern of "slow" sulfonamide metabolism in patients with a history of severe cutaneous sulfonamide reactions. Insights and technologies developed through the maturation of the field have allowed pharmacogeneticists to trace such associations with polymorphisms in genes encoding for components of the cytochrome P450 machinery. Investigators studying TEN patients' genotypes have assembled a sizable catalog of cytochrome P450C variants that convey an increased risk for developing TEN, with each polymorphism associated with a specific trigger agent.[40–46] The largest family of genes with a documented association with TEN include polymorphisms at a number of HLA loci that have been associated with drug-specific risks for TEN. These polymorphisms presumably alter the morphology of the HLA molecules on antigen-presenting cells, making them more or less inclined to "recognize" a particular antigen. The "antigen" may be the medication molecule, a drug metabolite, a byproduct of drug metabolism, or a hapten created by the binding of the drug, metabolite, or byproduct to another peptide.[47]

The clinical application of these genetic markers is complicated by the fact that their predictive value varies widely when applied to populations of different ethnic makeups. An example of this strong association between HLA, drug sensitivity, and ethnic background was discovered by Chung et al.[48] They demonstrated a strong association between HLA-B*1502, SJS, and carbamazepine in Han Chinese. This unique relationship was later observed in a Thai population, but was absent in the Japanese and European populations.[49–52] In fact, RegiSCAR, a large European study, suggested that HLA-B*1502 is not a marker for carbamazepine, sulfamethoxazole, lamotrigine, or NSAID oxicam-type-induced SJS or TEN.[52,53]

Although the HLA-B*1502 and carbamazepine association demonstrated significant ethnic variance, this is not the observation for all HLA–medication interactions. A second strong relationship among HLA, drug sensitivity, and SJS/TEN was observed for allopurinol and HLA-B*5801.[54] While the strength of the relationship continued to vary between ethnicities, the correlation persisted in Han Chinese, Japanese, Thai, and Europeans, unlike for HLA-B*1502 and carbamazepine.

In summary, for many of these markers, prevalence patterns make the marker too rare to function as a screening tool outside the context of specific ethnicities. Beyond issues of prevalence, some markers are associated with a TEN reaction in one population, but not in another: a phenomenon that likely traces to interactions between the "maker" allele and other genetic variables.

Immunopathology

Multiple lines of evidence point to T cells as critical effectors of the TEN process. T cells are the predominant cell type found in the blister fluid and exudate of patients with acute TEN.[55]

Suppression or cytotoxic T-cell infiltrates are observed in the epidermis in TEN.[56,57] The observation of blebbing of the keratinocyte plasma membrane in TEN is considered a reliable morphological finding of cytotoxic T-lymphocyte cytolysis.[57] Serum and exudate levels of markers of T-cell activation have been shown to correlate with disease activity and resolution.[58–61]

TEN is perhaps best understood as an immunologically mediated burn. For the most part, TEN resembles a classic type IV (delayed) hypersensitivity disorder. The delay between exposure and reaction, the critical role of T cells, and the accelerated reaction reported in cases of re-exposure to an initial trigger all favor this characterization.[39,62] While some have pointed to immunofluorescence microscopy findings of IgM and C3 deposited along the dermoepidermal junction and dermal vessels in cases of postherpetic SJS and EM as evidence of an associated type II hypersensitivity reaction, others attribute this to simple nonspecific exudation.[36,63–65] The exact antigen that activates the T-cell receptor varies depending on the specific trigger agent: the recognized moiety could be a molecule within the medication, a byproduct of agent metabolism, or a complex formed between an endogenous peptide and either of the preceding. Keratinocyte apoptosis is central to the pathogenesis of TEN. This event is thought to be mediated by ligand/receptor interaction of the tumor necrosis factor (TNF) superfamily (as TNF-α/TNF receptor or FasL/Fas interaction).[66,67] Through a series of experiments, Viard et al. observed, in vitro, that TEN patients expressed lytically active Fas ligand and that the action of this ligand could be blocked by both a monoclonal antibody and human immunoglobins.[68] In SJS, keratinocyte DNA fragmentation has been found in about 90% of cases associated with dermal perforin-positive lymphocytes.[39,69]

CLINICAL PRESENTATION

A prodromal phase of TEN is frequently identifiable in retrospect and usually characterized by some combination of low-grade fever, malaise, cough, conjunctivitis, and dysuria. These symptoms typically precede any cutaneous manifestation by 1–21 days, but usually last for 2–3 days.[1,14] This prodrome precedes the development of a frank rash, although patches of tender erythema and inflamed mucosal membranes are sometimes present. Skin involvement usually begins with subtle patches of tender erythema and localized morbilliform eruptions or discrete erythematous or purpuric macules. Later vesicles and large bullae emerge from areas of erythema, either en masse or via coalescence of initial morbilliform eruptions. On light digital pressure, the epidermis desquamates in sheets: Nikolsky's sign is positive (Fig. 42.1). The TEN rash is extremely painful, even when bullae are still intact. Generally, a lag period of 1–3 weeks is observed from initiation of drug until skin eruption, but this may be shorter, particularly in cases of re-exposure in a previously sensitized individual.[1,2,17]

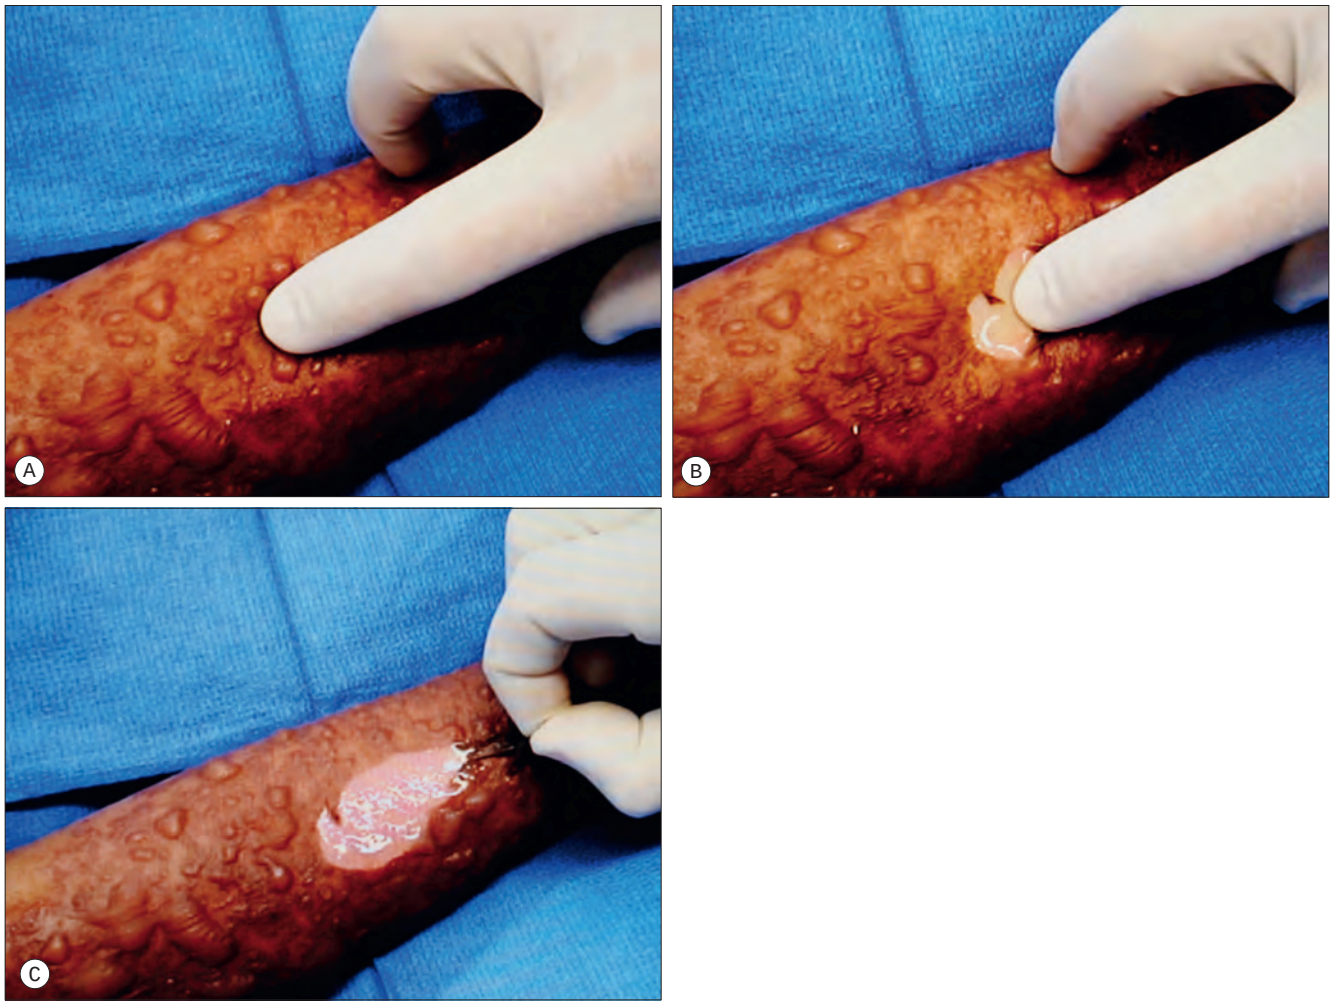

Fig. 42.1 (A–C) Nikolsky's sign. Epidermal separation induced by gentle pressure on the skin surface.

Mucosal involvement is extremely common in TEN, with two or more areas typically involved. These mucosal lesions are often most problematic in that they can cause significant immediate and long-term complications and typically persist (symptomatically) longer than cutaneous lesions.[6,16,17] Site involvement usually follows this order of frequency: oropharynx (93%), ocular (78%), genitalia (63%), and occasionally the anal mucosa.[70]

Mucosal involvement precedes skin lesions by 1–3 days in one-third of cases.[16,71] As such, any case presenting with skin involvement with no mucosal involvement should raise the suspicion for an alternative diagnosis. However it should be noted that detection of mucosal involvement often requires a significant index of suspicion: the fulminant skin findings can frequently distract from more subtle mucosal findings, such as enteral mucosal involvement and bronchial involvement, which are often more easily inferred from symptoms rather than direct visualization.

Fig. 42.2 Toxic epidermal necrolysis (TEN) is characterized by massive sloughing of the epidermal tissue.

DIAGNOSIS AND PROGNOSTIC EVALUATION

Histopathology

An early skin biopsy is essential for diagnosis. Skin manifestations vary from patient to patient and with the age of the lesion (Fig. 42.2). Advancing edges of the target lesions show scattered necrotic keratinocytes in the epidermis and only mild dermal inflammation. In older lesions and central zones of target lesions, the dusky appearance corresponds to areas of extensive keratinocyte necrosis, often with the formation of subepidermal

bullae and dermoepidermal separation. The surrounding erythematous zone shows papillary dermal edema, vascular dilation with endothelial cell swelling, and perivascular mononuclear cell infiltrate. Extravasated erythrocytes may be seen in the surrounding papillary dermis. The reticular dermis is normal.[17,22]

Epidermal and dermoepidermal suppressor or cytotoxic T lymphocytes, in addition to dermal infiltrates of helper T lymphocytes, have been demonstrated.[56,63,72] Hertl has confirmed that these epidermal cells are cytotoxic T cells.[73] Langerhans cells appear to be reduced in the epidermis, although numerous dermal macrophages are observed. A more intense dermal cell infiltrate is present in SJS, especially in postherpetic cases.[38] Dendritic lymphoid cells are observed, opposed to damaged dermal macrophages and necrotic keratinocytes. Furthermore, at the point where the cytoplasmic processes contact the keratinocyte, the plasma membrane of the keratinocyte is absent. Aberrant expression of HLA-DR on keratinocytes has been observed, a phenomenon that has been present in many other inflammatory skin disorders.[63,74]

COMPLICATIONS

TEN is frequently associated with serious complications. In many cases, the skin re-epithelializes from the dermal elements without significant scarring and with long-term affects typically limited to discoloration.[75] Scarring may be more prominent—and accompanied by contractures—if the disease progresses due to secondary infection or peripheral vasoconstriction from shock or vasopressor use. Nail plates are frequently lost and nail regrowth may be abnormal or absent.

Complications may also affect mucosal membranes throughout the body. One of the most severe long-term complications is ocular sequelae, which occurs in half of the survivors. Pseudomembranous or membranous conjunctivitis resulting from coalesced fibrin and necrotic debris can lead to ocular opacification, secondary infection, and blindness (Fig. 42.3).[4,76] Conjunctival scarring may also result in lacrimal duct destruction, leading to reduced tear production and keratoconjunctivitis sicca, a Sjögren-like syndrome. Finally, scar changes can lead to distortion of eyelid anatomy, which can result in ectropion, entropion, trichiasis, and symblepharon.[14,77]

Other systems that may be impacted include:

- *Oropharyngeal*: This is common and often results in pain on chewing, severe dysphagia, and odynophagia (Fig. 42.4). The mucositis is associated with an increase in secretions and sloughing mucosa, which can present an airway concern. Naturally, oropharyngeal involvement can interfere with oral intake, requiring direct enteral access for an alternate route of feeding. Buccal–gingiva epithelial fusing can occur, thus demonstrating the importance of good oral hygiene.
- *Respiratory*: Respiratory tract involvement occurs and is associated with increased mortality.[78,79] These complications include diffuse erythema to extensive confluent tracheal and bronchial erosion covered by fibrinous exudate. Epiglottal swelling necessitating intubation has also been reported. However bronchopneumonia has been found to be the most frequent complication, occurring in 50% of patients.[29,34,79]
- *Gastrointestinal*: The onset of intestinal symptoms generally occurs concurrently with the cutaneous lesions.[80] Epidermal and epithelial sloughing may extend into the gastrointestinal mucosa and may induce esophagitis with frequent subsequent stricture formation.[81] Gastrointestinal erosions macroscopically resemble ulcerative or pseudomembranous colitis, and massive hemorrhage requiring resection has been reported.
- *Urologic*: Male urethral involvement is fairly common, with visible involvement at the meatus. Long-term sequelae include urethral stricture and phimosis.
- *Gynecologic*: Vulvar involvement appears to be quite common in female patients, with reported incidences increasing over the past few decades as increasing

Fig. 42.3 Ocular involvement in toxic epidermal necrolysis (TEN) is common and can lead to blindness. Early and aggressive ocular care must be initiated to prevent pseudomembranes. (Arrows demonstrate membranous conjunctivitis.)

Fig. 42.4 Toxic epidermal necrolysis patient demonstrating significant oropharyngeal involvement.

awareness has resulted in improved detection and more frequent practice of routine screening exams. Mucosal erosions are clearly quite painful, and involvement of associated glandular structures can result in obstruction and dysfunction. Long-term sequelae can be particularly troublesome. Vaginal wall synechiae and clitoral hood adhesions can result in significant dyspareunia and sexual dysfunction.[82,83] Vaginal webbing and synechiae can result in dysfunctional menstruation with resultant infertility.[84–86] Consultation with a gynecologist is recommended for the majority of these cases.

Systemic and Other Nonmucocutaneous Complications

Although mucocutaneous erosions are the most common features of TEN/SJS, the disease may present with multisystem involvement. Renal manifestations like glomerulonephritis and acute tubular necrosis, as well as hepatitis and hepatocellular necrosis, have been described.[6,16,87] Hypoalbuminemia, asymptomatic hyperamylasemia, increased erythrocyte sedimentation rate, leukocytosis, thrombocytopenia, and normochromic and normocytic anemia are not uncommon.[29,78] Leukopenia is a frequent and poor prognostic sign.[6,17,34] This is due in part to depletion of the T helper/inducer lymphocyte population ($CD4^+$).[88] The white blood cell count generally returns to normal levels after 2–5 days. The cause of this immunosuppression is unclear.

MANAGEMENT

As previously stated, TEN is a life-threatening disease and is best managed in a burn ICU where a multidisciplinary approach, including goal-directed fluid resuscitation and nutritional support, is utilized.[23,34,35,89]

General Management and Resuscitation

Drugs suspected of having initiated the disease should be discontinued immediately. Administration of pain medication is of high priority, and antipyretic agents may be required. The use of broad-spectrum antibiotics should be carefully considered: Neutropenia is the only complication in which "prophylactic" antibiotics are indicated. Otherwise systemic antibiotics only should be used for documented infections or suspected sepsis.

Intravenous replacement of fluid losses through the exposed body surface is required. However, because patients do not develop the massive edema and fluid losses evident in burn patients, fluid resuscitation formulas commonly employed in the management of thermal injuries overestimate the actual need.[90,91] Ringer's lactate solution is given at a rate determined by close monitoring of the patient's condition, resuscitation indexes, and urine output. Once wound coverage is accomplished, fluid requirements usually decrease.

Central line placement should be avoided if possible to reduce the risk of infection and sepsis. To further minimize this risk, lines should be placed in areas of uninvolved skin. Invasive devices are removed as soon as possible, and oral and nasogastric routes are utilized at earliest convenience. Environmental temperature should be raised to 30–32°C to reduce metabolic energy expenditure. Heat shields and infrared lamps are beneficial in patients' rooms, bathrooms, and operating rooms.

Stress ulceration prophylaxis is advisable.

Immunomodulation Therapy

Because the pathophysiology of TEN appears to be initially immunologic, it is logical to consider immunosuppressive therapy as an early treatment modality. The following sections will briefly review the literature with regards to use of corticosteroids, cyclosporine A, intravenous immunoglobins, and thalidomide.

Corticosteroid Therapy. Corticosteroid treatment of TEN has produced much controversy. In relation to the delayed hypersensitivity reaction or antibody-dependent cytotoxicity theories of pathogenesis, corticosteroids would seem to be an appropriate form of medical therapy. However the practice of administering continuous high-dose corticosteroid in an attempt to stop the progression of the disease is widely rejected.[14,16,17,78,92,93] Rational assessment of the benefit of corticosteroids is not possible due to the lack of randomized, controlled, prospective trials. Many authors feel that steroids enhance the risk of sepsis, increase protein catabolism, delay wound healing, cause severe gastrointestinal bleeding, prolong hospitalization, and increase mortality.[29,34,90,94] One study found no decrease in the progression of SJS with steroids, but instead found significant morbidity.[94] In a prospective – although not randomized – study, increased survival (66%) was seen in matched patients who did not receive steroids compared to only 33% survival in those who did receive steroids.[34] Pediatric SJS patients treated with steroids had a longer hospital stay and a complication rate of 74% compared to 28% in those without steroids.[93] Another study demonstrated 80% mortality associated with steroid therapy, which was reduced to 20% when steroids were withheld. In several studies, patients with antecedent glucocorticoid therapy before the onset of TEN showed no significant survival benefit, and corticosteroid use itself has been linked to an increased risk for developing TEN.[11,31,95,96] Advocates of corticosteroid therapy suggest that improved results are possible when steroids are applied in a limited "pulse" dose early in the course to interrupt the active necrolytic process and limit complications. Kardaun et al. studied 12 patients over a 10-year period and suggested that short-term dexamethasone pulse therapy was safe and may contribute to a reduced mortality rate.[97] This was followed by the largest study of this approach, the EuroSCAR, which did identify a trend but not a statistically significant improvement with the early pulse of systemic corticosteroids.[98] Thus corticosteroid therapy remains controversial in this disease due to the absence of strong evidence of efficacy.

Cyclosporine A. Cyclosporine A is an agent that has the properties of both being a powerful immunosuppressant and an antiapoptotic. The mechanism of action is inhibition of the synthesis of interleukin-2 by selective inhibition of calcineurin, thus arresting the proliferation of T helper cells.[99] In the only case series, Arevalo et al. observed a significantly shorter time to disease arrest (24–36 h) and time to re-epithelialization when compared to historical

controls. This study was followed by a few small studies suggesting a potential benefit of cyclosporine A. In 2010, a phase II trial by Valleyrie-Allanore et al. found a treatment of 3 mg/kg per day of oral cyclosporine for 10 days followed by a tapering schema over the next month was not clinically significant.[100] However, mortality appeared to be reduced when compared to predictive mortality. Although intriguing, the currently published studies do not have similar methodologies, varying with regards to the dosage administered, route of administration, and duration of therapy. Furthermore, cyclosporine A therapy has been associated with a septicemia rate of 55%.[101] Therefore, a well-designed prospective clinical trial is warranted prior to advocating the use of cyclosporine A in the treatment of TEN.

Intravenous Immunoglobulin. Intravenous immunoglobulin (IVIG) has been suggested as a means of interrupting the autoimmune process fueling TEN. Furthermore, some have proposed that pooled human immunoglobins may contain a Fas blocking antibody, which would directly disrupt the keratinocyte apoptosis trigger.[102] Unfortunately, clinical data has been conflicting, creating difficulty in advocating IVIG treatment for TEN. To date, there have been 12 noncontrolled clinical studies examining the efficacy of IVIG in the treatment of TEN.[103–105] Interestingly, the data suggests that IVIG dosages of greater than 2 mg/kg may be superior to less than 2 mg/kg. Huang et al. performed a meta-analysis on the efficacy of IVIG therapy in TEN patients.[106] In adults, the high-dose IVIG group had a significantly lower mortality rate when compared to the low-dose IVIG group. However, the multivariate logistic regression model found the dosing of IVIG did not correlate with mortality when controlling for age, total BSA involvement, and delay in treatment.[21] This finding was supported by the largest clinical study to date, EuroSCAR, which failed to demonstrate efficacy of IVIG in the treatment of TEN.[98]

Despite these findings, some continue to advocate for the use of high-dose IVIG (3 mg/kg total dose give over 3–4 days) in the treatment of TEN based on the low complication risk and lack of alternative therapies. As in the case with cyclosporine A, a well-designed controlled multicenter clinical trial is warranted prior to advocating the use of human immunoglobins routinely in the treatment of TEN.

TNF-α Inhibitors, Thalidomide. The primary mechanism in the pathogenesis of TEN is keratinocyte apoptosis. Accordingly, TNF-α has been implicated in the pathogenesis of TEN. Thalidomide, a potent inhibitor of TNF-α, would appear to be a logical therapeutic agent in the treatment of TEN. Unfortunately, Wolkenstein et al. had to prematurely terminate a randomized clinical trial of thalidomide versus placebo in the treatment of TEN due to excess mortality in the treatment group.[107] Ten of 12 patients expired in the thalidomide group compared to three of 10 in the control group. The authors theorized that thalidomide may have paradoxically increased the production of TNF in the treatment group, a previously reported phenomenon of thalidomide administration. Therefore, thalidomide as a treatment for TEN should not be initiated owing to the detrimental effects, but this does demonstrate the usefulness of randomized, double-blinded, placebo-controlled clinical trials. Despite the failure of thalidomide, investigators are still exploring the use of TNF-α antagonists and inhibitors (infliximab, etanercept, etc.), in the treatment of TEN.[108,109] Unfortunately, these new therapies have only been reported in case reports and thus cannot be supported for routine use in this patient population.

Until these treatment modalities have proved their efficacy in controlled trials, the gold standard of treatment for TEN patients consists of a multidisciplinary approach as used in severe burns, focusing on wound care, infection control, and prevention of complications.

Surgical Approach. Débridement of necrotic epidermis and coverage of the large wound surface with biological or synthetic dressings have been advocated by several authors.[89,110,111] Sloughed epidermis should be removed in order to reduce bacterial growth and the risk for infection. The exposed and tender dermis should be covered. Débridement is best undertaken under general anesthesia as soon as diagnosis by histology is established. Blood loss associated with débridement is minimal, so over-resuscitation must be avoided.

Synthetic dressings, such as Biobrane, and biological dressings, such as homograft (cadaver allograft) and porcine xenograft skin, greatly reduce the pain, decrease fluid loss, and promote healing. Biobrane and similar products should be used with caution when covering wound areas greater than 40% TBSA secondary to the increasing incidence of local infections. Porcine xenograft adheres well to the skin and is commercially available in large quantities.[91,112] Homograft is more likely to become vascularized and therefore reduces the number of graft changes.[113] However this must be weighed against the potentially poor cosmetic results of vascularized homograft (Fig. 42.5). Grafted areas must be immobilized and protected from shear forces. In both adults and children, continuous rotation or air fluidized (Clinitron) beds frequently are used.

Topical Therapy. As separation occurs at the dermal–epidermal junction, varying depths of viable dermis remain. If this dermis can be protected from toxic detergents,

Fig. 42.5 Homograft vascularization occurring over a second-degree thermal injury, resulting in a poor cosmetic result.

desiccation, mechanical trauma, and wound infection, then rapid re-epithelialization by proliferation of basal keratinocytes from the skin appendages will occur.[90] Bacterial proliferation on the unprotected wound surface with invasive infection leads to full-thickness skin necrosis. Hydrotherapy and topical antimicrobials provide débridement and infection control that should be initiated early in the course of the disease. Effective topical antimicrobial agents include silver sulfadiazine cream, silver nitrate solution, chlorhexidine gluconate solution, and polymyxin-bacitracin ointment.[16,37,110] While silver sulfadiazine is widely used, concerns that its sulfonamide component can exacerbate the disease process remain a theoretic concern even though these concerns have not been confirmed in the literature. Additionally, an inhibitory effect on epithelialization and leukopenia requiring discontinuation has been observed. Alternatively silver nitrate solution does not contribute to the ongoing drug reaction, and epithelialization is not inhibited. For patients with contaminated wounds due to delayed initiation of treatment, silver nitrate soaks can reduce contamination and prepare the wound for eventual biological dressing. Silver nitrate solutions are hyponatremic and thus associated with approximately 350 mmol of sodium loss per day/m^2 treated. Serum electrolytes and osmolarity must be carefully monitored.

Chlorhexidine gluconate and polymyxin ointment are effective against Gram-negative organisms, including *P. aeruginosa*, with low incidence of sensitivity. Moreover, chlorhexidine gluconate also shows bactericidal effects against Gram-positive organisms.

Oropharyngeal mouth erosion resulting in severe dysphagia can be alleviated by the use of viscous lidocaine or cocaine rinses and thus ease oral administration of nutrients and fluids. Oral debris should be removed and the mouth rinsed or sprayed with antiseptic several times a day.[22] Oral nystatin prevents intestinal overgrowth of *Candida* and decreases the risk of *Candida* sepsis.[113]

Pulmonary involvement requires close supervision, with careful toileting including bronchoscopy, incentive spirometry, mobilization, and coughing to prevent infections and complications. If mechanical ventilatory support is necessary, the prevention of bronchopulmonary infection gains even more importance. Daily monitoring by blood assessment, including blood gas analysis, chest X-ray, and bacteriological culture, are required to initiate timely antibiotic therapy or ventilatory support. Measures to prevent thromboembolism, such as low-dose or low-molecular-weight administration of heparin, should be instituted on admission.

Ocular involvement should be assessed daily by an ophthalmologist. Conjunctival crusting can be minimized by the application of saline eye drops every hour. Any adhesions should be broken using a blunt instrument and bland eye drops or ointment applied frequently. Documented ocular infections are treated with organism-specific antibiotic therapy. Lacrimal duct obstruction may be detected early by performing Schirmer's test. There are a wide range of ophthalmic treatment options, a review of which would be beyond the context of this chapter. One reasonable, practical approach is the "Triple-TEN" protocol described by Tomlins et al., which includes (1) subconjunctival steroids to blunt local inflammation, (2) amniotic membrane application, and (3) insertion of a scleral shell spacer to prevent symblepharon formation.[115] Regardless of the specific treatment options taken, involvement of an ophthalmologist is clearly indicated.

Although it is not common in TEN, genitourinary mucosal involvement should be treated acutely with supportive care: pain control, hygiene, and topical treatments for pain relief and lubrication. Urinary catheterization needs to be weighed against the clinical stability and clinical scenario of the patient. Does the need for precise urine output outweigh the risk of increased infections that could occur with the placement of a catheter? Long-term sequelae include urethral stricture and phimosis, which can usually be managed with serial dilation and circumcision, respectively.

Vulvar involvement should also be managed proactively to minimize symptoms and (theoretically) attenuate the risk of long-term sequelae. The use of some topical medication options has been suggested, but none of these is considered the standard of care at this point. Mechanical treatments should be considered to prevent prolonged apposition of opposing inflamed mucosal surface to avoid fusion and synechiae. Vaginal dilators can be used to avoid fusion, although monitoring and regular changing are necessary to avoid infection. Finally, menstrual suppression should be considered to minimize the risk of vaginal adenosis.[114] Depending on the extent and severity of the involvement of the vaginal area, consider a consultation with a gynecologist.

Nutritional Support

Enteral nutrition should be initiated immediately once the patient is resuscitated. Due to the frequent presence of oral mucosal ulcerations, patients may be reluctant to take nutrition orally and thus require a nasogastric tube placement. Unlike burned patients who have significantly elevated metabolic rates, these patients appear to have metabolic rates only slightly above basal requirements. Weight stabilization and a positive nitrogen balance have been achieved in adults with 2500 kcal/day.[90,110]

Soft-Tissue Infections and Other Acute Skin Disorders

Staphylococcal scalded skin syndrome, necrotizing fasciitis, and purpura fulminans are examples of a group of conditions characterized by extensive soft-tissue loss, rapid onset of critical illness, and death. Early, accurate diagnosis is essential to initiate appropriate action, such as extensive surgical excision in the case of necrotizing fasciitis or crepitant soft-tissue infections. Burn care centers, with their acute and reconstructive capacities, have much to offer these patients with extensive skin loss.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome is the severe condition caused by exfoliative staphylococcal toxins and is characterized by systemic signs and symptoms and generalized involvement of the skin (Fig. 42.6). It is important to make a diagnosis early, particularly to differentiate it from TEN, which has a different management and much greater

Fig. 42.6 Staphylococcal scalded skin syndrome is characterized by diffuse, erythematous lesions with bullae formation (see left forearm). Epidermis is shed in sheets with minimal abrasion. The wounds are partial thickness and heal without surgical intervention.

mortality. Staphylococcal scalded skin syndrome is predominantly a disease of infancy (Ritter's disease) and early childhood, with most cases occurring before the age of 5 years.[116] Newborn nurseries are often the sites of outbreaks. Attendant staff may be infected or colonized with *Staphylococcus aureus* strains producing epidermolytic toxin, thus emphasizing the importance of standard hygienic measures. Adult staphylococcal scalded skin syndrome is rare and usually associated with compromised renal function. Mortality is generally only 4%, but can be much higher in adults (40%) depending on underlying diseases.[116,117]

Pathology

Two distinct epidermolytic toxins (ETA and ETB), are responsible for the blistering in staphylococcal scalded skin syndrome.[81] ETA is heat-stable, whereas ETB is heat-labile and encoded by a bacterial plasmid. Most toxigenic strains of *S. aureus* are identified as group 2 phage.[118] The exfoliative toxin is metabolized and excreted by the kidneys, leading to a predisposition of patients with renal immaturity (children) or renal compromise. The exfoliative toxins produce blistering by disrupting the epidermal granular cell layers through interdesmosomal splittings but without epidermal necrosis and with very few inflammatory cells. The exact mechanism of action of the toxins has not been determined, although it is felt that the toxins directly affect desmosomes. One might be proteolytic disruption of desmosomes with the toxin or part of its sequence acting as a serine protease.[116,119,120]

Presentation

Onset may be marked by fever, malaise, and irritability. Scarlatiniform erythema is often accentuated in flexural and periorificial areas. The skin is generally tender to touch, and sheets of skin may peel away in response to minor trauma (Nikolsky's sign). Blisters appear within 24–48 hours of rupture, leaving a characteristic moist erythematous epidermal base. Severe mucosal involvement is not a typical feature.

Diagnosis

Diagnosis of staphylococcal scalded skin syndrome can be made rapidly with a skin biopsy. The characteristic intraepidermal level of splitting is seen, with the split occurring at the granular layer level (stratum granulosum) with no epidermal necrosis or inflammatory cells in the corium. Immunofluorescent studies of the skin are negative. A Tzanck preparation from a scraping of the base of a freshly denuded area will reveal the affected cell population (i.e., acantholytic keratinocytes).[118] Bullae, denuded skin, and blood are usually sterile, however, and staphylococci can usually be cultured from nares, conjunctiva, or pharynx.[121]

Management

With diagnosis, antibiotics should be started, and semisynthetic penicillinase-resistant penicillin analogs are indicated (e.g., meticillin or oxacillin) since the majority of group 2 staphylococci show resistance to penicillin. Administration of steroids to these patients is contraindicated.[118] After screening for colonization, decontamination of colonized areas, especially the nasopharyngeal region in patients and nursing staff, may be advisable to prevent further spread. Fluid resuscitation is usually required at a lesser volume compared to a burn patient with a similar involved BSA. Fluid substitution should be guided by urine output, hemodynamic parameters, and electrolyte and colloid status.

Until skin barrier function is restored, patients should receive appropriate wound dressings to prevent secondary wound infection. Topical agents are soothing and bacteriostatic. It needs to be pointed out that the wound initially is not colonized or infected, so alternatively, large areas can be more effectively managed with biological or synthetic dressings. They have the advantage of eliminating the need for frequent dressing changes, which can be particularly traumatic for young children. Mortality usually is low but may occur in very young and adult patients, usually from sepsis or electrolyte imbalance on the basis of underlying disease.[118] Complete wound healing is usually observed within 7 days, and scarring and altered pigmentation are not common.

NECROTIZING FASCIITIS AND BACTERIAL MYONECROSIS

Necrotizing fasciitis is a soft-tissue infection characterized by widespread necrosis of fascia and subcutaneous tissue, which may progress to muscle and skin necrosis. Overall mortality may still be as high as 50%.[111,122] Most cases of necrotizing fasciitis are due to polymicrobial infection including both anaerobic Gram-positive cocci and Gram-negative bacilli. *Streptococcus*, *Staphylococcus*, *Enterococcus*, and *Bacteroides* are commonly found. Infection with many bacterial species may result in bacterial myonecrosis. However, gas gangrene by *Clostridia* spp. results in severe systemic toxicity and higher mortality than necrotizing fasciitis. A deep contaminated wound frequently precedes the severe soft-tissue infection. Streptococcal myositis has a mortality rate of between 80% and 100%.[122,123] Risk factors for both necrotizing fasciitis and bacterial myonecrosis have been identified as diabetes mellitus, intravenous drug use,

age greater than 50 years, hypertension, and malnutrition/obesity. The presence of three or more of these risk factors was found to give a predictive mortality rate of 50% (Fig. 42.7).[124]

Diagnosis

Early diagnosis is of extreme importance and consequence. Initial presentation is deceptive because the findings may be localized pain and edema without discoloration of the skin. Later, induration and erythema may be evident. Paresthesia of overlying skin and eventual dusky discoloration and local blistering may occur in the later course. Severe toxemia may develop, usually out of proportion to the local signs. Severe systemic alterations are characteristic of myonecrosis. Gas inclusion may be evident in subcutaneous tissues on X-ray. Computed tomography (CT) and magnetic resonance imaging (MRI) may help in the diagnosis and provide information on the nature and extent of the infection.[125] Frozen section biopsies may provide early histological evidence of infection.[126] Gram stains and microbiological testing are very important diagnostic tools and guide antibiotic treatment. However, a definite distinction between necrotizing fasciitis, myonecrosis, and other soft-tissue infections often can only be established during surgery.

Management

The key to successful management of necrotizing infections is early diagnosis and radical surgical intervention. Surgical exploration involves complete excision of all necrotic tissues. If more than one operation for débridement of infected necrotic tissue is needed, mortality increases from 43% to 71%; this outcome drastically highlights the importance of adequate initial necrosectomy.[127] In patients with many risk factors, early amputation of the extremity, especially in cases of myonecrosis, should be considered. Broad-spectrum antibiotics are started preoperatively, although high-dose penicillin is appropriate for clostridial infections. However, antibiotic treatment is no substitution for surgical intervention. Adequate fluid resuscitation and nutritional support are also required. Wounds are packed open with antiseptic-soaked dressings, which need to be changed frequently. Kaiser and Cerra have reported unsatisfactory results with either early application of porcine xenografts or burn wound topical antimicrobials.[128] Complete control of local and systemic infection is required before wound closure is addressed.

As in burns, secondary infections must be prevented by proper wound management. Biological or synthetic dressings offer the advantages of decreased pain, decreased fluid loss, and prevention of secondary infection. Frequently large areas of skin and soft-tissue loss result from this disease and will eventually require extensive surgery to achieve adequate closure.

Some authors advocate the use of hyperbaric oxygen and claim that it results in decreased mortality and reduced need for débridement; however most of these reports are case reports or uncontrolled trials, and adequate prospective controlled trials in patients are still lacking.[129,130] In animals, hyperbaric oxygen therapy alone did not improve survival or bacterial colonization, but did show adjuvant

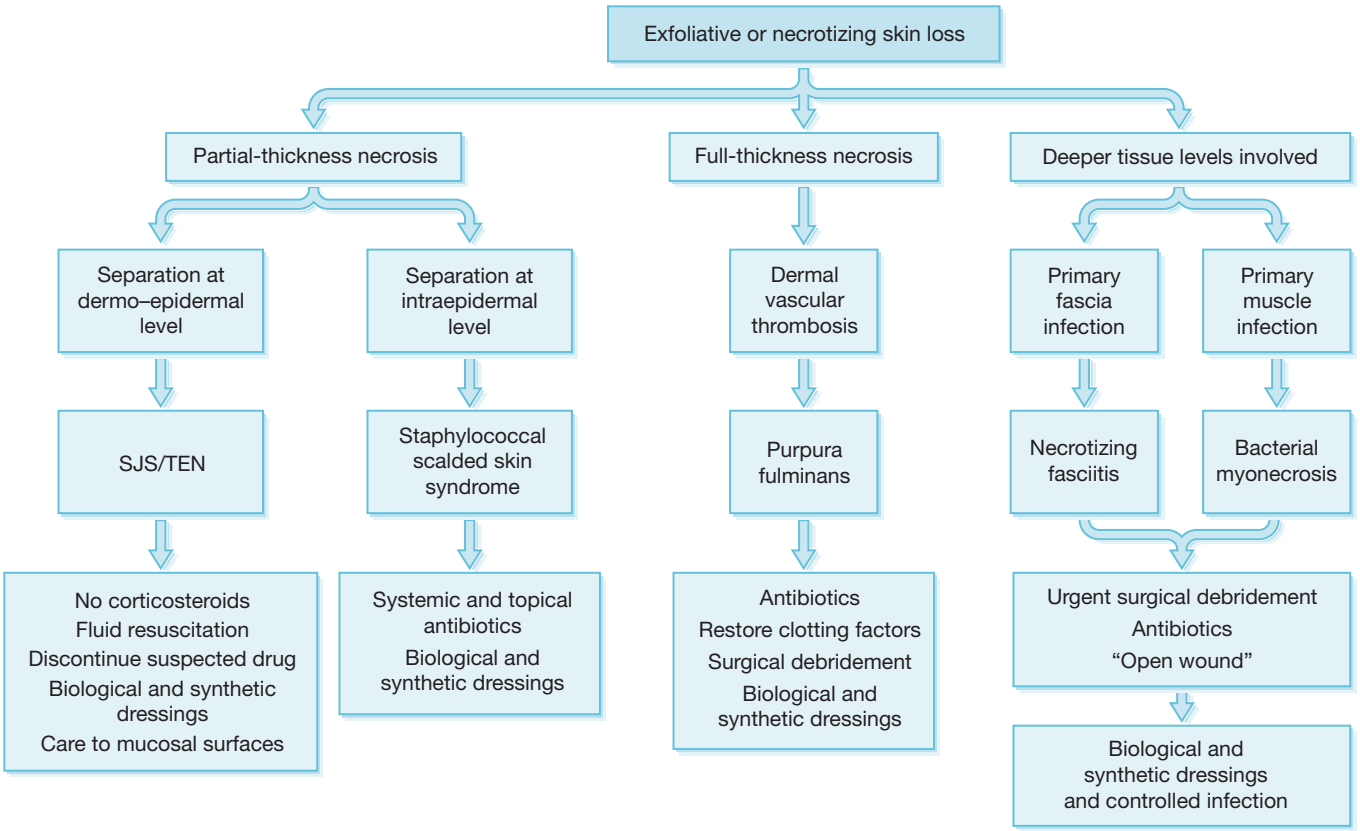

Fig. 42.7 Flowchart of management of exfoliative and necrotizing conditions of the skin.

effects to antibiotic treatment.[131] In summary, hyperbaric oxygen therapy, if available, should not delay radical surgical débridement and should be used as an adjunct to radical surgery and antibiotic therapy.[129,132]

PURPURA FULMINANS

Purpura fulminans is a term that describes an acute syndrome of rapidly progressive hemorrhagic necrosis of the skin due to dermal vascular thrombosis associated with vascular collapse and disseminated intravascular coagulation (DIC).[133] It may occur in individuals with dysfunction of the protein C anticoagulant system, with acute severe infection, or idiopathically without any coagulation dysfunction or infection.

It has been associated with systemic infection by *Meningococcus*, Gram-negative bacilli, *Staphylococcus*, *Streptococcus*, and *Rickettsia* organisms. Skin necrosis begins in a region of dermal discomfort, which rapidly progresses to evanescent flush, followed by petechiae. Hemorrhagic bullae progress to frank skin necrosis. The process generally involves the skin and subcutaneous tissues, without involvement of muscle. Skin involvement is frequently an early manifestation of the disease process. Skin biopsy will therefore allow an earlier diagnosis. Mortality in the acute phase is 18–40%.[134]

Management is directed at halting progression of the underlying infectious disease, preventing secondary infections, and removing nonviable tissue. Early heparin administration and replacement of clotting factors have proved useful to stop intravascular clotting.[134] Shock from blood extravasation and sepsis require extensive volume replacement. Limb vascular and compartmental pressure should be monitored closely to enable early escharotomy and/or fasciotomy, when needed. Skin lesions resulting only in blisters should be treated with topical antimicrobials (e.g., silver sulfadiazine) to prevent secondary infection. Nonviable tissue should be removed as soon as the patient's condition allows. Small areas can be covered with autografts but because large areas are frequently involved, allograft or xenograft skin coverage may be required. Limb amputations may be frequently required due to vascular compromise, as well as revisions for progression of disease.[135] Isolation of the affected patient, as well as monitoring and prophylactic treatment of patients and staff, may be necessary to prevent further spread and outbreaks of the disease, especially in the case of meningococcal infection.

CALCIPHYLAXIS

Calciphylaxis is a rare condition that is characterized by the development of extraskeletal calcifications resulting in tissue necrosis. Although the exact etiology is unknown, the condition appears to be most commonly associated with disorders that alter calcium/phosphate homeostasis. Thus the condition is usually diagnosed in individuals undergoing renal replacement therapy or who have recently undergone renal transplantation. Despite the close association with renal failure, Nigwekar et al. have identified a subgroup of individuals with the same pathological condition but without end-stage renal failure and coined the term "nonuremic calciphylaxis" (Fig. 42.8, Box 42.1).[136]

Fig. 42.8 Early calciphylaxis lesion. (Courtesy of Dr. Shawn Fagan.)

Box 42.1 Conditions Associated With Non-Uremic Calciphylaxis

- Primary hyperparathyroidism
- Breast cancer + chemotherapy
- Liver cirrhosis
- Cholangiocarcinoma
- Crohn's disease
- Rheumatic arthritis
- Systemic lupus erythematosus

First described by Bryant and White in 1898 and later investigated by Selye in 1962, it was not until 1976 that the true clinical significance of the syndrome was formally recognized by Gipstein et al. The clinical syndrome of calciphylaxis is characterized by:[137,138] (1) painful purpuric cutaneous lesions (Fig. 42.9), (2) histological evidence of systemic medial calcifications of arteries (tunica media), and (3) histological evidence of small-vessel mural calcification with or without endovascular fibrosis leading to vascular thrombosis and tissue necrosis.

As previously stated, the exact pathophysiology of calciphylaxis is unknown, although the best theory was offered by Selye et al. in 1962. Utilizing a rat model, he suggested that calciphylaxis was a condition of hypersensitivity caused by exposure to "sensitizing agents" (nephrectomy/parathyroid hormone) and "challengers" (egg albumin/metallic salts) over a defined period of time. Simply stated, calciphylaxis appears to be a clinical syndrome induced by a series of events that predispose the patient to extraskeletal calcifications. Most recently, Nigwekar et al. have suggested that the matrix protein GLA(MPG) may serve as a biomarker.[139] MPG is found in the walls of blood vessels and cartilage and functions to prevent calcium buildup. It requires activation by vitamin K to function well, and it is hypothesized that normal activation is impaired in calciphylaxis. Further studies are required to solidify the role of MPG in calciphylaxis, but the work appears promising.

Clinically, calciphylaxis affects approximately 1–4% of the population with underlying end-stage renal disease.[140]

Fig. 42.9 Proximal calciphylaxis. (Courtesy of Dr. Shawn Fagan.)

The condition has been reported in age groups ranging from 6 months to 83 years of age. The condition appears to affect predominantly Caucasian women, with a female to male ratio of 3:1. Unfortunately the mortality rate associated with calciphylaxis is as high as 60–80% and appears to be related to the distribution of cutaneous lesions. Distal lesions have a reported mortality rate of 42%, whereas more proximal lesions (trunk, abdomen, buttocks, and proximal extremities) have a reported mortality rate approaching 72%. The association between mortality rates and lesion distribution may in fact be related to the degree of systemic involvement. The overall mortality rate from calciphylaxis appears to be closely related to the extent of internal organ involvement and development of sepsis from infected cutaneous lesions.

The diagnosis of calciphylaxis should be suspected in any patient with painful cutaneous lesions and a history supportive of the clinical syndrome. Although diagnostic lab testing and imaging are not helpful, the diagnosis can be formally established with a tissue biopsy.

Once the diagnosis is established, the treatment should be initiated using a multidisciplinary approach. The treatment should be based on improving the underlying condition, such as reformulation in hemodialysis or potentially administering sodium thiosulfate, which acts as an antioxidant and chelator of cations. Unfortunately, despite the best medical efforts, treatment usually becomes supportive from an analgesic and wound standpoint. Wound management should be aggressive to avoid local wound infections. The primary goal is to establish a healthy wound bed without evidence of disease progression prior to definitive closure.

Conclusion

Inflammatory and infectious conditions of the skin and underlying tissues represent a major diagnostic and therapeutic challenge. The team approach to their care is essential, and wound management is paramount. Burn centers are ideally suited to deal with patients with these conditions and should be considered as the appropriate site of referral for these critically ill patients.

43 Burn Injuries of the Eye

KAREL D. CAPEK, DEREK M. CULNAN, KEVIN MERKLEY, TED T. HUANG, and STEFAN TROCME

ὁ λύχνος τοῦ σώματός ἐστιν ὁ ὀφθαλμός
ὅταν οὖν ὁ ὀφθαλμός σου ἁπλοῦς ᾖ, καὶ ὅλον τὸ σῶμά σου φωτεινόν ἐστιν.
ἐπὰν δὲ πονηρὸς ᾖ, καὶ τὸ σῶμά σου σκοτεινόν

Introduction

Both immediate and delayed presentations exist for eye problems in burned patients. Accordingly, in burns, the structure and function of a normal eye can be disrupted by concurrent blunt or penetrating injury, electrical current, thermal energy, or chemical agents. After the initial insult, foreign bodies, ongoing chemical injury, deterioration of the facial burn wound, infection, and environmental exposure can cause additional damage or progression of existing pathology. Although many providers may view comprehensive eye examination as an esoterica outside their skillset and purview, the frequency and acuity of sight-threatening complications necessitate the burn team learning the basics of eye evaluation.[1]

Selected Anatomy

The organ of sight arises through reciprocal interaction between the optic vesicle (neuroectoderm) and the lens placode (facial ectoderm). The full-thickness neuroectoderm protrudes toward the surface, inducing the primordial lens, and invaginating to form the optic cup. The lens vesicle, separating from the surface ectoderm, induces corneal development.[2] The upper and lower eyelids develop from primordial eyelid folds, fusing transversely from 8 weeks to 5 months, protecting the nascent ocular surface from initial environmental exposure as the fetal urinary system begins to contribute to the amniotic fluid composition.[3,4]

Eyelids are four-layered structures of skin, orbicularis muscle, tarsus with fibrous septae, and palpebral conjunctiva. The skin of the eyelids is thin and elastic in the normal state. Upper eyelid skin folds are formed from terminal skin attachments of underlying levator muscle, which functions with Müller's muscle to open the upper eyelid. The inferior rectus muscle provides analogous function via the capsulopalpebral fascia and inferior tarsus, retracting the lower lid with down-gaze.[5,6] The orbicularis muscle can be divided into pretarsal, preseptal, and orbital segments based on the structure they overlay: tarsus, orbital septum, or orbital rim. The pretarsal and preseptal parts are used in blinking and voluntary winking, while the orbital segments are used in forced closure. Motor innervation is via the zygomatic and temporal branches of the facial nerve. Epidermal appendages, including follicular sebaceous glands (of Zeiss), modified apocrine sweat glands (of Moll), and eyelashes, are located at the anterior margin of the mucocutaneous junction. Posteriorly, the fibrous tarsi harbor the Meibomian glands (about 50 in the upper lid and 25 in the lower lid) that secrete lipid-rich material into the tear film.

The tear film is a trilaminar structure; moving from the ocular surface externally, there is mucus on the cornea and conjunctiva, covered by an aqueous layer, with a lipid layer most externally. A healthy tear film remains stable for at least 10 s and maintains more than 300 μm of meniscus height.[7] The lacrimal gland, located laterally and superiorly in the orbit, produces the aqueous phase of the tear film, along with accessory lacrimal glands (of Krause and Wolfring) located in the superior and inferior fornices. The lipid layer is secreted by the Meibomian glands, stabilizing the tear film and reducing evaporative loss. A complex protein mixture within the tear film confers antimicrobial, inflammatory, and antiinflammatory properties and regulates corneal epithelial cell function.[8]

The conjunctiva covers the inner surface of the eyelids and the anterior sclera, reflecting between the two at the superior and inferior fornices. It is composed of stratified nonkeratinized squamous and columnar cells interspersed with goblet cells upon a continuous basement membrane and lamina propria. Other tissues include accessory lacrimal glands and immune surveillance cells; the lymphatic drainage of the conjunctiva is via the submandibular, parotid, and preauricular nodes. The limbus is the border between the conjunctiva and corneal epithelium. Circumscribing the limbus, the palisades of Vogt harbor the corneal epithelial stem cell niche.[9,10]

The corneal epithelium is approximately 6–7 cell layers (50 μm) tall and composed of stratified squamous epithelium with minimal keratinization. The basal layer is mitotically active and replenishes the more external layers as they are continuously sloughed. The corneal epithelial stem cell niche, at the limbus within the palisades of Vogt, allows reepithelialization when the entire basal layer is lost, as in severe burn injuries or toxic epidermal necrolysis. This mechanism requires cell proliferation and migration from the limbus to the center of the cornea and can take weeks to fully reepithelialize the cornea, compared with days when the basal corneal epithelial layer remains intact. The corneal epithelium produces and rests upon a basement membrane.[11] The layers deep to this basement membrane comprise the corneal stroma. The first 8–12 μm of stroma is called Bowman's membrane and is composed of randomly oriented collagen fibers. The stroma is approximately 500 μm (0.5 mm) thick. Precise arrangement of about 200 collagenous lamellae confers transmittance of visible

light.[12] Fibroblasts and immune surveillance cells populate the stroma. A deep layer, Descemet's membrane, about 10 μm in thickness, provides posterior structural integrity. Upon this membrane rests the corneal endothelium, rich in mitochondria and nonproliferative, which maintains corneal dehydration (and transparency) via active transport of solute into the aqueous. The cornea provides about two-thirds of the refractive power of a normal eye, approximately +40 diopters.

Examination

Eye examination in a burn ICU requires several modifications from the standard clinic setting. Clinicians must adapt to the overall patient condition and support machinery, which may include multiple intravenous and enteral access lines, ventilator and dialysis support, bulky wound dressings, difficult patient positioning, and, frequently, severe comorbid injuries and burns of the face. This is not the "comfort zone" for the ophthalmologist, but the frequency and acuity of comorbid eye involvement necessitate adaptation and innovation.[13] An assessment of visual function can be made with a near vision card, finger counting, or, at a minimum, light perception. Patients with endotracheal tubes can generate various responses, head nod or hand signal, to visual acuity testing under appropriate sedative/analgesic conditions. There are a variety of portable slit lamps that can be employed. Our preference is a handheld lens (20 diopter or equivalent) and penlight. With practice, the penlight may be axially directed through the lens or shone indirectly upon the ocular surface to section through the anterior segment, thereby providing fine detail of stromal and corneal epithelial problems. Loupes provide additive magnification when used with a handheld lens. Topical ocular surface anesthesia is usually employed.

If the injury was associated with an explosion, with flying debris or blunt/penetrating trauma to the eye and periorbita, an open globe injury may result. In this situation, examination must be performed without pressure on the globe until corneal or scleral perforation can be excluded. Pressure applied to an open globe could cause (further) herniation of intraocular contents and detract from potential recovery. If an open globe–suspect injury is identified, pupillary light response and visual acuity should be grossly documented (at least light perception/hand motion/finger counting), photographs obtained, and a shield placed over the eye sufficient to transmit any applied pressure to the osseous orbital rim rather than the orbital contents. Immediate ophthalmological consultation is indicated to evaluate a possible open globe.

Once an open globe injury is excluded, cotton swabs, Desmarres retractors, or an eyelid speculum are useful and often necessary due to facial burns and lid edema. "Swelling" is never an excuse to defer examination of the ocular surface because any delay in the recognition of significant injuries subjects a patient's visual recovery to avoidable jeopardy. Superficial foreign bodies can usually be removed by saline irrigation alone if identified quickly postburn. Fluorescein dye (strips or equivalent) should be available in the burn unit and used if there is any suspicion of corneal or conjunctival pathology.[14] The ocular surface should be irrigated to remove any discharge or ointment. A normal healthy cornea should appear clear and "glassy" with a sharp light reflex. A hazy light reflex can usually be appreciated in early-stage keratopathies. We generally apply dye in a balanced salt solution to the lateral canthus/inferior fornix and then have the patient blink a few times. Next the eye is opened and examined for epithelial irregularities and negative staining. Excess dye is then rinsed away with balanced salt solution. A normal healthy cornea will be devoid of stain; dye retention signifies pathology.[15–20] Areas of confluent, homogeneous stain signify epithelial defect (Fig. 43.1C). "Lacey" staining patterns usually signify epithelial keratopathy (Fig. 43.1B). Early-stage epithelial lesions of exposure and herpetic keratopathies are often difficult to appreciate without the assistance of dye. Adjustable-intensity pocket LED flashlights often have fairly cool light, which sufficiently highlights fluorescein; otherwise, a cobalt-blue filter or near-ultraviolet handheld light can be used. Photographs of findings often allow more comprehensive review while minimizing patient discomfort.

Indirect ophthalmoscopy via adilated pupil is occasionally useful and indicated in the burn unit. In cases of nonaccidental trauma, distinctive retinal lesions may be observed and should be documented with fundus photography for potential medicolegal review.[21] In the first 48–96 hours following carbon monoxide intoxication, cerebral swelling and herniation syndromes are frequently causes of death.[22–24] Funduscopy may show papilledema, which can be graded in severity.[25] In cases where persistently positive blood cultures raise clinical concern for hematogenous seeding, infectious microemboli can occasionally be visualized on thorough funduscopy.[26–29] Similarly there is a spectrum of retinal findings with disseminated candidiasis, defined as *Candida* isolated from three or more sites (urine, sputum, wound, blood, or eye).[30–32] Because choroidal blood flow is much higher than retinal blood flow,[33] these hematogenous lesions more frequently occur within the choroid and are initially observed underlying the retinal layers as gray-white round lesions, rather than occlusive lesions within the retinal vessels proper.[34–37] These lesions, termed chorioretinitis, enlarge as the infection progresses and may erupt into the vitreous.[38-40] This distinction is important because the stage/level of involvement determines treatment choices (ranging from intravenous antimicrobial therapy, intravitreal antimicrobial instillation, to vitrectomy for significant vitreitis).[39–47]

Applied Pathology

Thermal injuries to the eye concurrent with the burning event are, fortunately, rare. The typical presentation is decreased vision, eye pain/foreign body sensation, perilimbal hyperemia, and epithelial defect with fluorescein staining. If detected early, a corneal epithelial lesion, analogous to a blister, may be present and is usually translucent to opaque. Upon sloughing, an underlying epithelial defect of varying depth is apparent.[48] In the setting of closed-space (house) fires, it is difficult to determine whether a corneal injury is thermal or (gaseous) chemical in nature, and copious irrigation is recommended. In addition to tissue

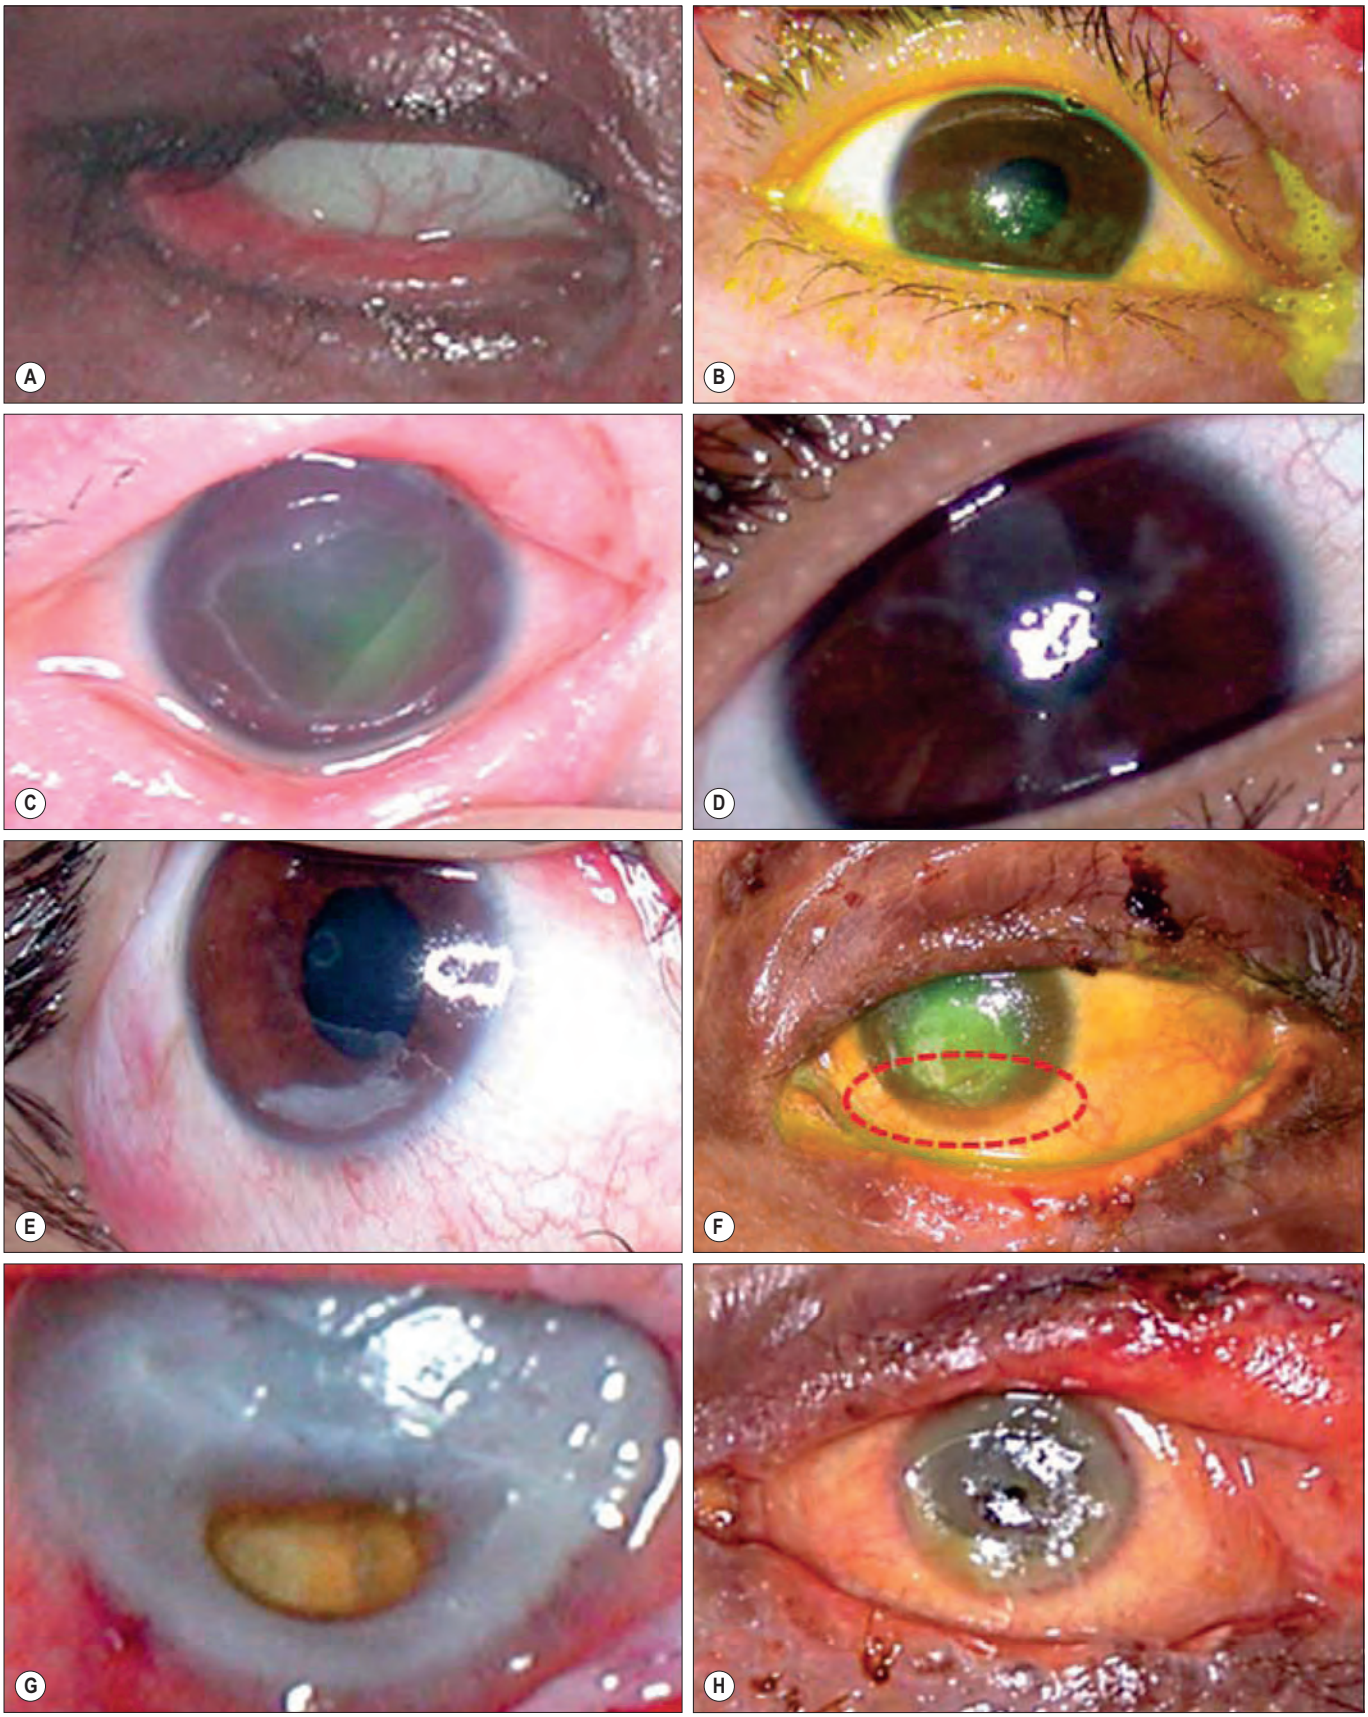

Fig. 43.1 Spectrum of exposure-related ocular surface disease encountered in the burn unit. A, Lagophthalmos. B, Exposure keratopathy. C, Epithelial defect. D, Herpetic keratitis. E, Corneal ulcer. F, Same, with hypopyon. G, Descemetocele. H, Corneal perforation.

destruction, eyelid burns compromise the skin barrier function and predispose to burn wound cellulitis and infection. Development of a preseptal inflammatory process (eyelid swelling, hyperemia, and pain) is frequent after eyelid burn injury, and microbiological cultures help in determining whether this process is sterile or infectious. If infected, it is termed preseptal cellulitis.[49–53] When observed, it is crucially important to evaluate extraocular muscle mobility and function. If the orbital septum is compromised, an orbital cellulitis or abscess may develop, which is an eye-threatening emergency.[54–62] Typical presentation of orbital cellulitis or abscess includes reduced extraocular movements and pain on extraocular muscle testing. Ophthalmological consultation, systemic antimicrobial therapy, and frequent reexamination are indicated. Surgical débridement may be needed for orbital abscess.

Chemical eye injuries are a true ophthalmological emergency.[63–65] Frequent and copious eye irrigation is generally indicated. Solid chemical particles should be removed by irrigation as rapidly as possible with upper and lower lid eversion and examination. Alkali injuries may need prolonged irrigation, up to several hours. Wound pH can be litmus tested, preferably 2–5 minutes after cessation of irrigation as early false-normal results may occur. Insertion of an irrigation aid, such as Morgan lenses, can provide continuous irrigation for several hours; these can also be useful for continuous antibiotic delivery in cases of refractory bacterial keratitis.[66–68]

Patients with Stevens–Johnson syndrome/toxic epidermal necrolysis (TEN) are treated in the burn unit, and eye involvement is seen in more than 60% of these cases. At worst, they present with complete corneal slough, membranous conjunctivitis, and lash auto-epilation (Fig. 43.1C). The natural history is scar formation at involved areas, symblepharon, forniceal shortening, corneal opacification/scarring, mucocutaneous junction loss/keratinization, entropion, and chronic, severe, dry-eye symptoms. Mounting evidence indicates that ocular surface recovery may be hastened, with improvement in vision, by prompt coverage of the ocular surface with amniotic membrane.[69–77] Patients with these conditions should receive definitive treatment at burn units where amniotic membrane transplantation is available and applied immediately when ocular surface involvement is apparent.[70,78]

ELECTRICAL INJURY

As with the systemic response, there are a number of unique ocular aspects of electrical burn injury. Cataract formation following electrical injury has been recognized for more than a half a century.[79–96] While the mechanism is not fully understood, within the lens (and other ocular tissues) there is substantial intercellular electrical coupling.[97–101] These reports note that electrical cataract tends to present within 12 months of the electrical burn event and that visual outcome following cataract extraction can be good in the absence of other eye pathology. Other findings, such as chorioretinal atrophy, are seen less frequently.[102,103] For both patient care and medicolegal reasons, electrical injury patients should be evaluated for cataract via dilated exam at admission, discharge, and 6 and 12 months postinjury.[104]

EXPOSURE KERATITIS AND EYELID BURNS

Eyelid burns and singed eyelashes identify a group of patients at high risk for ocular surface problems, with likelihood ratios (LR+), if present, for the development of corneal ulceration of 12 and 6.9, respectively.[105] Punctate epitheliopathy, or keratopathy, is usually the earliest stage of per se corneal injury, and, if present, it confers an LR+ for the development of corneal ulceration of 6.4. These subtle irregularities on the normally glassy corneal surface can be discerned with magnification and are accentuated by the application of fluorescein dye (Fig. 43.1B). The severity of epitheliopathy ranges from scattered, superficial submillimeter dots to a homogeneous area of abnormal epithelium, confluent keratopathy. The latter is essentially an epithelial defect prior to sloughing of the diseased epithelium. While keratopathy may be caused by direct thermal or chemical injury of the eye, it is much more frequently observed with corneal exposure resulting from the contraction of eyelid burn wounds/scars. It generally develops around 1 week postburn, and careful observation of the sleeping patient demonstrates incomplete resting eyelid closure, with scleral or corneal show (Fig. 43.1A). Any patient with incomplete lid closure, best observed while asleep, should undergo detailed examination of the ocular surface. Bell's phenomenon, up-gaze with lid closure, is absent in 25% of patients and does not reliably protect the ocular surface when present; however, an intact Bell's phenomenon may somewhat mitigate the severity of exposure keratopathy.

EPITHELIAL DEFECTS

An epithelial defect is present when an area of the cornea has lost epithelium (Fig. 43.1C). It is denoted by a subtle ridge where epithelium remains and by a solid area of fluorescein staining. This can be either full or partial thickness. Partial-thickness epithelial defects can heal rapidly from the remaining basal layers, whereas full-thickness injuries must heal from the periphery. Typically the epithelial defect seen from incomplete eyelid closure (exposure) is transverse, linear, and centered over the inferior third of the cornea. Careful daily examination of epithelial defects is required in burn patients, as is correction of underlying causes. If magnified examination reveals stromal opacification (i.e., any finding other than clear cornea at and around the epithelial defect), then a corneal ulcer is present and there is a high risk of vision loss. All indicated diagnostic and therapeutic maneuvers should be employed without delay.

CORNEAL ULCER

We define a corneal ulcer as an epithelial defect with any associated stromal infiltrate (Fig. 43.1E). Corneal transparency, or lack thereof, is an important finding with histopathological correlates. Transparency is lost when the stroma becomes hydrated. In burns, this is typically in response to injury or infection. This occurs when the keratinocyte basement membrane has been compromised, a process that can develop independent of phagocytic cells via production of active matrix metalloproteinase-9 (MMP-9) and then MMP-2 by corneal cells.[106] The active form of

these enzymes has also been observed in the tear fluid from ocular burn and infectious ulceration patients.[107] Altered capillary permeability and the evolving wound-healing response occur in a manner akin to skin wound healing. This includes phagocytic infiltration, tissue destruction and pathogen clearance, reepithelialization, and myofibroblast-mediated scar formation. The disorganized collagen formed as part of scar formation lacks the regular arrangement and spacing of a healthy, clear corneal stroma. As a result, it appears white/gray and reflects rather than transmits visible light, causing vision loss. Transparency can also be lost due to corneal endothelial dysfunction. Impaired function of the endothelial adenosine triphosphate (ATP)-dependent transport of solute from the stroma into the aqueous humor causes abnormally increased hydration of stromal proteins. The associated epithelial defect should be measured daily at a minimum on magnified exam because stability and reepithelialization indicate treatment response. Inhibition of serine proteases may slow epithelial migration, although inhibition of MMPs may actually facilitate reepithelialization.[108–112] The majority of corneal ulcers can be prevented in burned patients via early release and skin grafting of full-thickness eyelid burns.[113] Most corneal ulcers in burned patients are sterile, but the occurrence of bacterial superinfection is not uncommon.[114] For this reason, and because treatment of infectious corneal ulcers is aided by the provision of directed antibiotics, swab or scraping culture of corneal ulcers is a routine part of our diagnostic protocol. Corneal scraping is accomplished with ophthalmic tetracaine drops, sedation (usually intravenous ketamine), loupe magnification, adequate lighting, and either a #69 or the rounded belly of a #15 blade. Carefully, the margin of the corneal ulcer is scraped, maintaining the edge of the blade almost parallel to the corneal surface to avoid any penetrating injury. The specimen, often visible only with loupes, is plated on blood and chocolate agars (for the broadest spectrum of bacterial growth), Sabouraud's agar (for fungal organisms), and several glass slides, for Gram's stain (for bacteria), Giemsa stain (for cellular features and viral cytopathic effect), and potassium hydroxide stain (for fungal elements).[115] Rapid review of the slide specimens, if positive, enables immediate initiation of directed topical antimicrobial agents.[116–118] Initial response to treatment is nonprogression (stabilization) in the size of the epithelial defect and underlying stromal infiltrate. With continued healing, these gradually become smaller. Therefore every follow-up examination should scrupulously document the sizes of the epithelial defect and stromal infiltrate.

BACTERIAL KERATITIS

Bacterial corneal ulcers can occur in otherwise healthy patients, as with prolonged use of contact lenses, but burned patients are at particular risk because of lost eyelid function, ocular surface exposure, local contamination from colonized/infected skin wounds, and disruption of host immunity, among other factors.[119] *Acinetobacter* spp. have been reported, as well as *Staphylococcus* spp. and *Pseudomonas* spp.[120,121] Pathogen virulence factors play important roles in the outcome of these infections, and more virulent bacteria may be selected during the recovery of severely burned patients.[122] Bacterial keratitis typically follows a more fulminant course than sterile corneal ulcers caused by exposure (Fig. 43.1F).

FUNGAL KERATITIS

Burn patients are in jeopardy for developing secondary infections of persistent exposure-related epithelial lesions. Not infrequently, fungal organisms are isolated as colonizers or active pathogens from burn wounds of the face and eyelids; thus facial wound microbiology determines the risk of secondary infection at ocular surface lesions. We have seen secondary *Candida* keratitis (ulcer) arising in this manner. Fungal keratitis is typically more indolent and is unresponsive to antibacterial treatment. With magnification, satellite lesions may be observed around the primary lesion. Diagnosis can be made through scraping, potassium hydroxide prep, and fungal culture. Rarely a corneal biopsy is necessary to establish the diagnosis if a high clinical suspicion for fungal keratitis exists while cultures remain negative. In refractory cases, débridement and corneal transplant may be necessary.[123]

VIRAL (HERPETIC) KERATITIS

The systemic response to burn injury entails profound alterations in host immunity, including markedly reduced novel immunoglobin generation and adaptive cell-mediated immunity.[124–143] Type 1 T-helper (T_H1) cellular response, activated macrophage cell killing, is associated with clearance of systemic virus and survival in animal models. Elegant studies by Suzuki et al. demonstrated that, post-burn, chemokine CCL2 (a.k.a. monocyte chemoattractant protein-1) stimulates a subset of natural killer T cells to produce interleukin-4, an early signal in a cascade ultimately producing T_H2 cytokines and abolishing the beneficial T_H1 response.[144–159] This situation leads to increased susceptibility to Herpesviridae. Herpetic keratitis (reactivation) in burned patients is both a sight-threatening problem and a marker of profoundly altered immunity. Dendritic (branching) epithelial defects and stromal infiltrates are typical of herpetic keratopathy (Fig. 43.1D). Allowed to progress, these enlarge forming a "geographic" corneal ulcer with an irregular border. Real-time polymerase chain reaction testing of corneal swab specimens is invaluable for diagnosis, providing rapid (within hours) information about the presence and type of Herpesviridae infection.[160] Although tear specimens have also been studied, the diagnostic yield is substantially lower.

ORBITAL COMPARTMENT SYNDROME

Orbital compartment syndrome (OCS) presents when the globe is compressed by swelling of the orbital contents and is unable to decompress itself. The natural variation in eyelid laxity provides a variable individual susceptibility to this problem; if the globe is able to be moved anteriorly to accommodate the swelling, intraocular hypertension may not develop. Acute intraocular hypertension can lead to anterior ischemic optic neuropathy (AION), with loss of vision. In the setting of severe burns, it can rapidly cause complete loss of vision bilaterally.[161] Decreased arterial

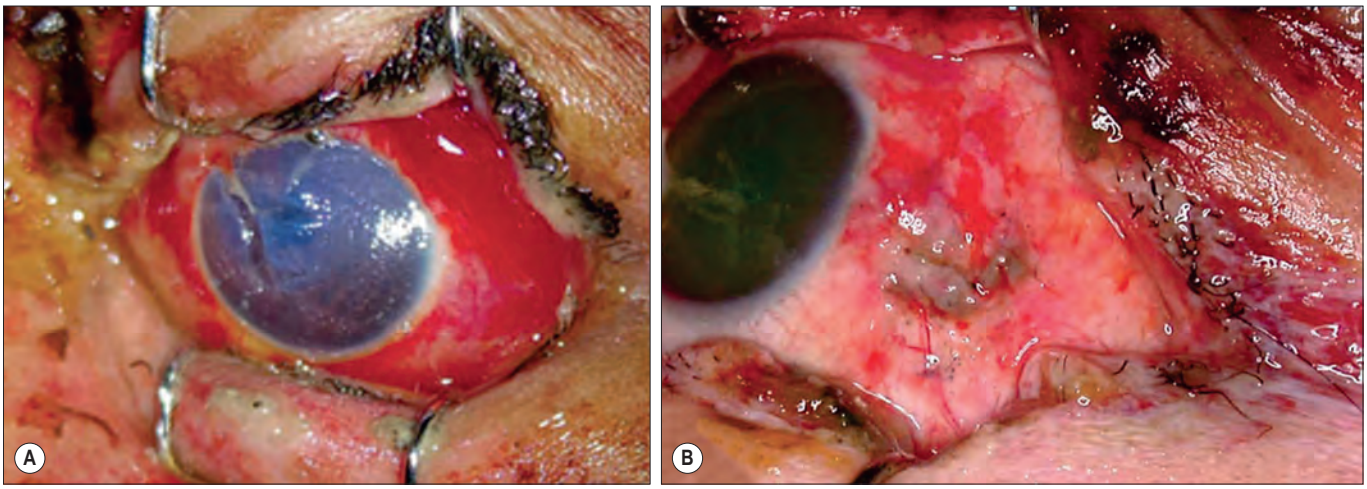

Fig. 43.2 A, Corneal laceration. B, Scleral laceration.

pressure further compounds the risk of AION infarction. Orbital compartment syndromes are occasionally observed in the first 24–96 hours after severe burn injury requiring large-volume resuscitation.[162] The development of compartment syndromes in unburned extremities or abdomen should prompt evaluation of the intraocular pressure; urgency is increased if there is concomitant arterial hypotension. Burns of the face and periorbita can lead to prodigious swelling and OCS in the absence of massive fluid resuscitation.[163] Full-thickness flame burns (charring) of the periorbital skin can prevent the normal swelling of the underlying tissues, thus facilitating OCS. Intraocular pressure can be evaluated grossly by direct palpation of the globe, by evaluating the mobility of the globe against the lower lid (the globe is tightly pressed against the conjunctival surface of the lower lid in OCS), or more exactly with a tonopen or Schioetz tonometer. Intraocular pressure is sensitive to extrinsic forces, so it is essential that the technique used to open the lids not compress the globe or a falsely elevated intraocular pressure reading may result. Measured at the cornea, intraocular pressures of 30 mm Hg or higher are cause for concern and frequent reevaluation. Avoiding excessive fluid/volume expansion and elevation of the head of the bed can help reduce intraocular pressure. If the globe is hard on palpation, the lower lid tightly apposed to the globe, or intraocular pressure remains at 30 mm Hg or higher, release of OCS is indicated to preserve vision and prevent AION. The intraocular pressure threshold for release should be somewhat lower when patients have ongoing arterial hypotension because tissue perfusion is a balance between arterial and tissue hydrostatic pressures.

AMBLYOPIA

Amblyopia is concerning in the burn unit primarily when prolonged eyelid closure or near-closure is requisite to treat ocular surface lesions in prepubertal children. Loss of visual stimuli leads to loss of capacity to perceive visual stimuli.[164–169] Amblyopia presents with decreased visual acuity in the absence of structural or refractive lesions. In practice, it is better to treat both eyes equally (e.g., tarsorrhaphy) if eyelid destruction and ocular surface exposure are present. In cases where vision is unilaterally affected, it is possible to intermittently patch, or treat with cycloplegics, the "good" eye, in an attempt to prevent amblyopia.[169] Involving an ophthalmology consultant is prudent when vision-preserving eyelid procedures raise concerns for iatrogenic amblyopia.

DESCEMETOCELE, CORNEAL PERFORATION, AND OPEN GLOBE

The posterior 50 μm of corneal stroma is Descemet's membrane. This posterior layer of corneal stroma, while thin, possesses a high degree of strength. When stromal destruction is near full thickness, the aqueous humor of the anterior chamber may be contained by this structure alone. Termed a descemetocele, it is a sign of an impending corneal perforation (Fig. 43.1G). Often an aqueous leak can be appreciated if fluorescein dye is applied over the area; the leaking aqueous humor dilutes and carries the dye into the tear lake (positive Seidel test). Corneal perforations (Fig. 43.1H) and lacerations (Figs. 43.2A and B) can be similarly recognized if the aqueous leak is not massive. With a massive loss of aqueous humor, the eye loses intraocular pressure, becoming "flat." Loss of intraocular pressure, or marked intraocular hypotension below 8 mm Hg, can result in choroidal detachment and loss of retinal function. Early application of tissue adhesive to descemetocele or acute perforation reduces the rate of eventual enucleation.[170,171]

Interventions

Topical lubricants provide protection to an at-risk ocular surface. We generally prefer petroleum-based or water-based ointments. The preservative present (a mild chemical toxin) in multidose artificial tear formulations can cause or exacerbate corneal injury if used more frequently than four times a day.

Topical antimicrobials are recommended if clinical findings or confirmatory microbiologic evidence exists of ocular

surface infection. For limited burns, erythromycin ointment provides antimicrobial coverage and lubrication. In major burns or with severe associated facial burns, high colony count, not infrequently Gram-negative, colonization often occurs of the eyelids and surrounding skin. In these patients, our first-line preference is bacitracin/polymyxin B ointment. We provide empiric coverage of corneal ulcers and significant epithelial defects with quinolone drops (moxifloxacin is preferred but more expensive) while culture data are pending. Fortified antibiotics (vancomycin, ceftazidime, or tobramycin) are used on a case-by-case basis, generally when positive culture data are available or pending, and clinical progression is observed while on empiric treatment. Fungal keratitis occurs infrequently, but, in severe burns, when culture data suggest yeast colonization of facial wounds near the eyes, we provide natamycin prophylaxis. Voriconazole eyedrops can similarly be compounded to fortified antibiotic drops and may be useful in the treatment of documented fungal keratitis. Herpetic keratitis in burned patients is treated with systemic antivirals; topical antivirals (ganciclovir or trifluridine) can be added to more quickly halt the progression of corneal injury. A direct comparison between systemic and topical treatments has not, to our knowledge, been performed in burn patients.[172] Due to altered host immunity discussed earlier, burn patients are in jeopardy of developing disseminated Herpesviridae, and topical monotherapy is not generally employed.

BANDAGE CONTACT LENS

Lenses useful as corneal bandages are characterized by low diopteric power, soft structure, and high gas permeability, and are often labeled "extended-wear" (e.g., Bausch and Lomb Night and Day or Acuvue Oasis). These are occasionally useful in facilitating reepithelialization and protecting corneas damaged by exposure. Once in place, these lenses should be evaluated frequently and discontinued or replaced when no longer effective. Due to risk of infection and other complications, it is prudent to involve an ophthalmology consultant when bandage contact lenses are employed.[173–177]

LATERAL CANTHOTOMY

Lateral canthotomy should be performed in cases of OCS, described earlier. Structure is provided to the lids by the canthal tendons, inserting on the upper and lower tarsi medially and laterally. The lateral origin is palpable as a bony prominence at the lateral orbital rim, called Whitnall's tubercle. Lateral canthotomy is performed by dividing the skin and lateral canthal tendon, freeing the lower lid from its bony attachment. Lidocaine 1% or 2% with epinephrine is infiltrated lateral to the lateral canthus and the skin is clamped parallel to the palpebral fissure, then divided with scissors anteroposteriorly. The lower lid is grasped and pulled away from the globe, placing the lateral canthal tendon on stretch, making it easier to locate and divide. The canthal tendon is divided with scissors anteriorly to Whitnall's tubercle on the orbital rim.[178,179] A successful lateral canthotomy leaves the lower lid freely mobile and no longer apposed to the globe. Afterward, the intraocular pressure should be reevaluated.

EYELID CLOSURE AND RECONSTRUCTION

Because the vast majority of burn-related eye disease results from exposure of the ocular surface, techniques facilitating eyelid closure are of central import. Temporary closure can be accomplished with Steri-Strips and cyanoacrylate skin adhesive; this closure may last 24–48 hours. Cyanoacrylate adhesive can also be used to temporarily close the lids by joining the lashes and eyelid margins of the lateral parts of lids;[180–186] in practice, this method of temporary eyelid closure lasts a few days. A temporary suture tarsorrhaphy can be constructed either with bedside sedation and local anesthesia or in the operating room. Tarsorrhaphy increases the rate of corneal epithelial wound healing.[174,187–189] Several techniques have been described; some permit facile reopening and reclosure if frequent eye examination is deemed necessary.[190–206] Chromic gut sutures often do not require removal and are occasionally used in our practice.[207] A tarsorrhaphy becomes progressively more "permanent" as deepithelialized surfaces of the eyelids are apposed. Several methods exist to create what we term "semi-permanent" tarsorrhaphy; these are indicated when large areas of full-thickness injury to the eyelids necessitate multiple reconstructive operations or after the failure of previous temporary suture tarsorrhaphy.[208] Less durable outcomes are associated with mattress sutures or bolster techniques than an internal fixation technique by which the gray line is split in the region of the planned tarsorrhaphy and the posterior and anterior laminae of the upper and lower lids are sutured to each other.[209] It is vitally important to avoid placing knots in contact with the corneal surface because these can cause abrasion injuries and corneal ulcers.

The forces of scar contraction powerfully influence eyelid function and, when tarsorrhaphy (including temporary) is indicated, often eyelid release and tissue interposition will also be required to preserve sight (Figs. 43.3A and B).[113] Essentially the procedure is a reverse blepharoplasty: the skin and scar of the lid is incised in the tarsal crease, and the upper lid mobilized inferiorly. Overcorrection is needed at the time of surgery because recurrent contraction in 2–3 weeks is the rule. The resulting defect can be covered with a split-thickness skin graft and secured with a combination of fibrin glue, sutures, or cyanoacrylate adhesive. If necessary, a secondary procedure is employed for the lower lids, although full-thickness skin autografts may be substituted to close the defect after release.[210] While release and skin graft interposition may protect a fresh tarsorrhaphy from disruption due to scar contraction at the eyelids, these grafts eventually contract despite all efforts at preservation.[211–215] Contraction and recurrence of cicatricial ectropion necessitate a series of repeated releases until both ocular surface and eyelid function stabilize. In cases of massive burns, when eyelid release is required and no sufficient donor site for sheet grafting of the upper lids can be spared, it is possible, despite burned skin, to mobilize the midportion of the brow and upper lid inferiorly from the medial and lateral brow in a myocutaneous V-Y inferior advancement flap, akin to this flap's utilization in oncological reconstruction.[216–218] This procedure may provide the release needed to allow formation of a stable tarsorrhaphy for ocular surface protection in critically injured patients.

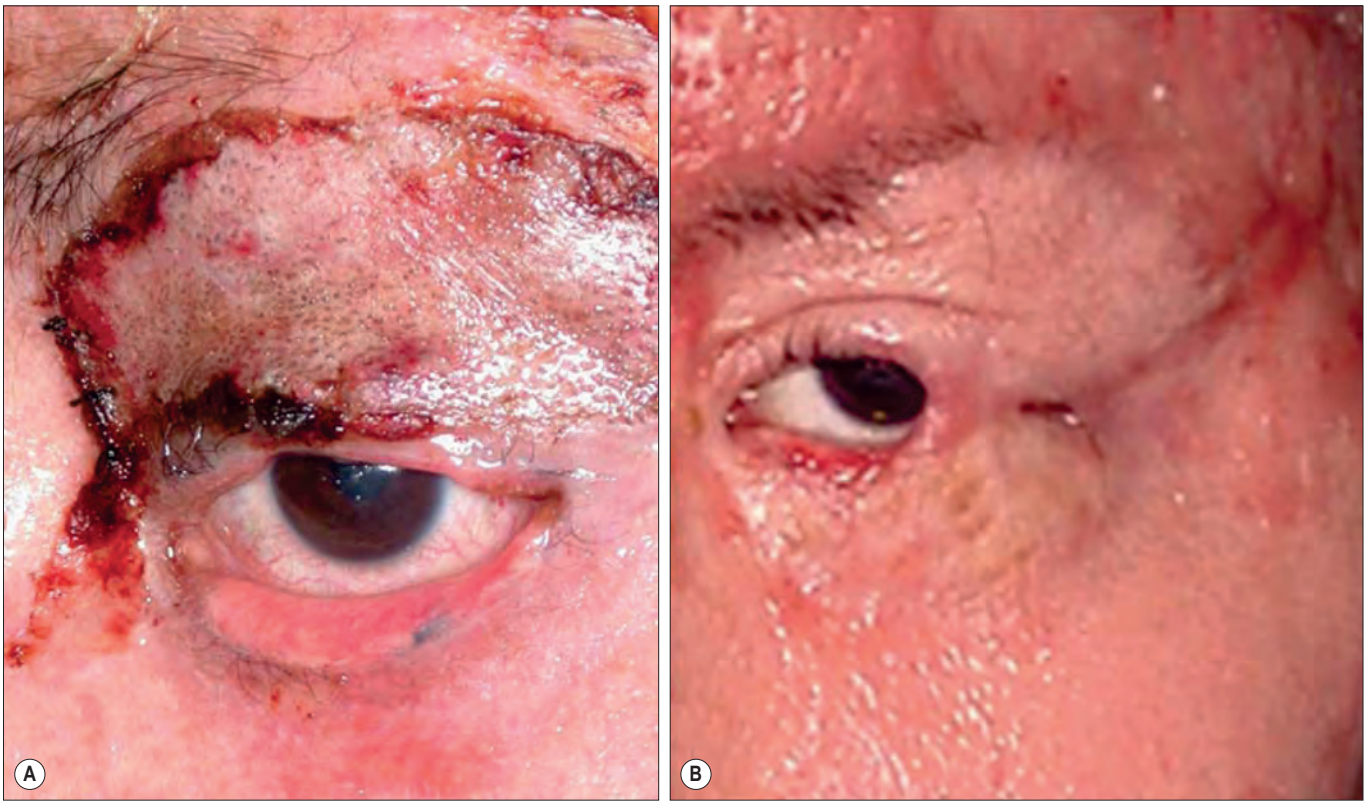

Fig. 43.3 A, Upper eyelid release, grafting, and lateral tarsorrhaphy. B, Follow-up.

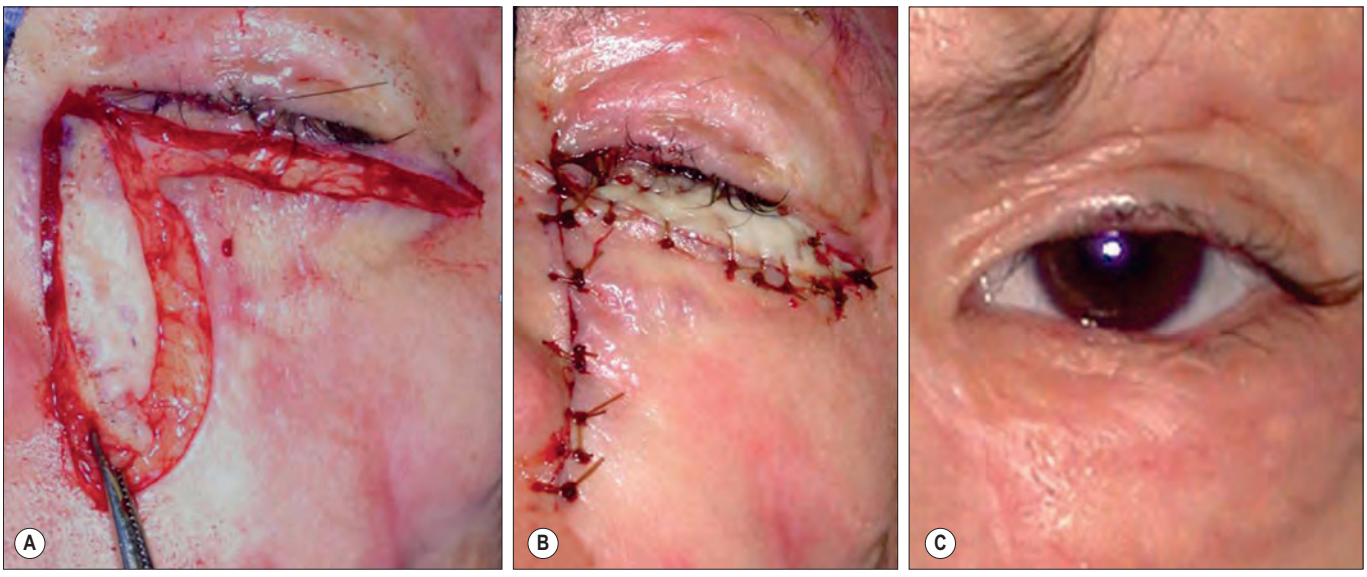

Fig. 43.4 Cicatricial ectropion of the lower lid; reconstruction with nasolabial island pedicle flap. A, Flap dissection. B, Flap inset. C, Follow-up.

Huang et al. suggest use of local skin flaps, when possible, to overcome the difficulty of autograft contraction and recurrent cicatricial ectropion. The lower lid may be treated with a superomedially based island pedicle flap from the nasolabial fold (Figs. 43.4A–C). This flap is quite durable, and the donor site heals with little morbidity.[219] If burn scar of the skin surrounding the donor site precludes closure, a split-thickness autograft can be used. Flaps available for the upper lid include paramedian forehead flap and orbicularis oculi myocutaneous flap from the lower lid with a laterally based pedicle (Fig. 43.5A–C).[220,221] The lower lid donor site defect of the latter may be closed with the previously discussed nasolabial fold island pedicle flap. Occasionally the tissue destruction resulting from burn injury is so severe that the structural integrity of the tarsal plate is compromised. This leads to lid dysfunction often recalcitrant to the preceding methods of treatment.[222] To address this, tarsal compromise must first be recognized. It can be replaced

using suitable cartilage, often harvested from the conchal bowl. Placed in a preseptal location[223] during eyelid contracture release and covered with a skin flap, this technique can be used in cases of subtotal eyelid loss so long as intact palpebral conjunctiva remains. Replacing lost conjunctival tissue is infrequently necessary postburn. This deformity can present with entropion and significant ocular surface injury and is frequently seen after Stevens–Johnson syndrome or TEN. We have successfully employed the technique of preseptal cartilage graft with skin resection (blepharoplasty) to rotate the lash line and scarred/keratinized mucocutaneous junction away from the corneal surface.[224] We have not yet had occasion to resort to conjunctival replacement procedures, such as buccal or nasal mucosal free grafts or nasal septal composite cartilage-mucosa grafts.[225,226]

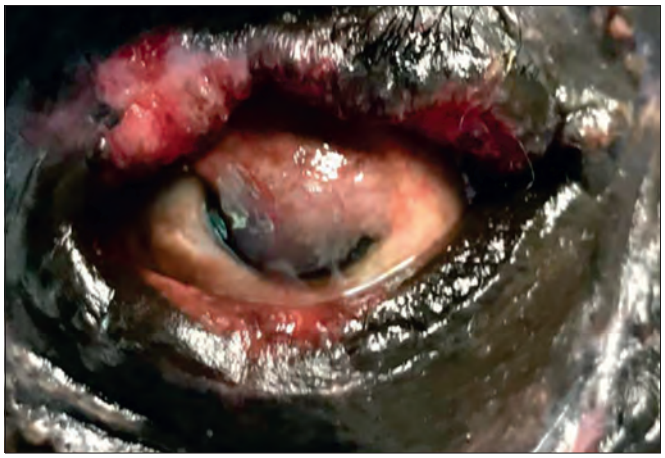

Fig. 43.6 Gundersen (conjunctival) flap.

CONJUNCTIVAL (GUNDERSEN) FLAPS

When corneal ulceration and epithelial loss are catastrophic and refractory to the previously described therapeutic measures, it is possible to mobilize the bulbar conjunctiva over the cornea (Fig. 43.6). These flaps provide a supply of vascularized tissue to create scar, deliver systemic antimicrobial therapy to the wound, and stabilize an impending perforation (e.g., descemetocele). A fornix flap is constructed by suture of the mobile conjunctiva in the inferior and superior fornices.[227] This flap may last 1–2 weeks before retracting and does not require any dissection. If small strips of apposing conjunctiva are excised, a more durable fornix flap may be held in place by adhesions similar to those formed via semipermanent tarsorrhaphy. Khodadoust described a microsurgical conjunctival flap, but its placement is more demanding than other options.[228] The classic Gundersen flap mobilizes the superior bulbar conjunctiva over the entire corneal surface, beginning through a transverse incision of the conjunctiva in the superior fornix. After the superior bulbar conjunctival flap is raised, a perilimbal peritomy is performed, the cornea deepithelialized, and the flap brought down over the cornea by securing its inferior edge between the 4 and 7 o'clock positions of the peritomy.[229,230] The superior aspect of the flap is sutured to Tenon's capsule between the 10 and 2 o'clock positions of the peritomy, and the entire superior surface of the globe is left denuded of conjunctiva, which rapidly reepithelializes. This flap is useful if performed with scrupulous avoidance of "buttonholing," as holes created in the flap invariably expand and allow corneal exposure. The goal of a Gundersen flap is to provide long-term corneal coverage, prevent perforation, and preserve an intact globe for later vision restoration.[231]

RECONSTRUCTION OF THE LACRIMAL APPARATUS

Rarely burn injury or resulting scarring compromises the normal flow of tears through the lacrimal system. Although a Jones tube or lacrimal stent may be useful in other settings, in the burned patient, scarring and markedly abnormal function of the eyelids combined with discharge due to chronic conjunctivitis render these tubes prone to clogging. The foreign body may also trigger local infectious complications.[232] Instead we employ a conjunctival mucosal flap to create a fistulous tract for tear drainage.[233] In cases where the punctum and upper lacrimal drainage apparatus are destroyed, this flap can be placed within the lacrimal sac, termed mucosal conjunctivodacryocystostomy. When the upper and lower lacrimal drainage structures are dysfunctional, the mucosal flap can be drained directly into the nasal or maxillary sinus cavities, mucosal conjunctivorhinostomy, and mucosal conjunctivoantrostomy, respectively. Refractory epiphora has been amenable to these treatments in 16 of 17 reported cases.[234]

CORNEAL TRANSPLANTATION

A stable ocular surface is generally requisite to achieve a successful corneal transplant.[235,236] Eyelid malposition must be corrected and epithelial defects and corneal ulcers closed and in a stable, if scarred, state. Corneal neovascularization frequently follows healing of corneal ulcers. If present, it will increase the risk of corneal allograft rejection, as does the presence of nonnative immune surveillance (Langerhans) cells.[237–239] Herpetic keratopathy is a further risk factor for rejection.[240] Thus a lamellar graft (partial-thickness corneal allograft) is preferred, because it preserves the patient's native endothelium from graft rejection.[241–245] Lamellar grafts are also more tolerant of elevated intraocular pressure, although they can undergo epithelial or stromal rejection.[246–249] As a salvage procedure, tectonic grafts can be used in the setting of frank perforation or descemetocele.[250–253] The purpose of these procedures is to maintain a closed globe and intraocular pressure. Amniotic membrane multilayer grafts may be useful as a temporizing measure and may play an antiinflammatory role in decreasing the rate of rejection of allografts placed in an emergent setting.[254–256] Rarely destruction of the eyelids, ocular surface, and/or ocular surface may lead to the situation in which the potential for vision exists, but no native reconstructive options exist. These cases may benefit from evaluation by centers experienced in the performance of and postoperative care for keratoprosthesis surgery.[257–300]

44 The Burn Problem: A Pathologist's Perspective

HAL K. HAWKINS

Videos available at www.expertconsult.inkling.com

Introduction

A large burn is not a simple injury but a very complicated disease. This statement, restated from its publication in 1840, holds true with additional force in 2016.[1] Massive destruction of skin tissue by burns stimulates many complex reactions that are still only partly understood. Malfunction of every organ system complicates the responses of patients to large burns. These malfunctions can be clarified by examination of the body after death. Postmortem examination also may reveal unsuspected infections or adverse effects of therapy. In addition, postmortem examination leads to review of the circumstances of injury and of the causal sequence in which complications occurred. Analysis of an entire case from the point of view of pathogenesis often clarifies the nature of the patient's most significant problems. The manner of death is accident in most cases, but collection of additional information on the circumstances of the initial injury sometimes reveals evidence of homicide. After presentation of the major systemic problems that occur in burn patients, this chapter reviews some of the observations made at autopsy organized by organ system. It also surveys experimental evidence that bears on pathogenic mechanisms relevant to disease processes seen at autopsy. The observations reviewed here are drawn from the experience of more than 300 autopsies performed on burned children who died at the Shriners Burns Hospital in Galveston, Texas, from 1971 to the present.

Systemic Reactions to Burns

HYPOXIA AND ISCHEMIA

Immediately after burn injury, massive loss of intravascular fluid into the burned tissue begins to occur.[2,3] Unless this fluid loss is replaced very promptly and carefully, serious hypovolemia develops.[4–6] *Hypovolemia* and the resulting reduction of tissue perfusion to levels less than that necessary for cellular survival, which is defined as *ischemia*, causes necrosis of certain cells. Typically, the cells first affected by ischemia are those with the greatest oxygen demand, including neurons in the brain, cardiac myocytes, intestinal epithelial cells, and proximal tubular epithelial cells in the kidney. After the death of selected cell types or whole segments of organs (infarcts), responses are generated that often lead to further injury of remote organs. Cellular necrosis stimulates an intense acute inflammatory reaction. In the skin, the tissues at the base of the zone of necrosis become acutely inflamed. Cytokines released by inflammatory cells and surviving cells in the tissue have effects throughout the body. In addition, in endothelial cells injured by hypoxia, the enzyme xanthine dehydrogenase is converted to xanthine oxidase, which releases superoxide during degradation of adenosine, which in turn is released by necrotic cells.[7,8] Superoxide, released into the circulation by this metabolic process and by neutrophils, can injure the lung by damaging both endothelial and epithelial cells and allowing protein-rich fluid to exude into alveoli. In experimental models of burn injury, as well as in models of ischemia–reperfusion injury, the lungs have been shown to be injured by these processes.[9,10] Ischemia caused by reduced perfusion may lead to necrosis of pancreatic acinar epithelium and acute pancreatitis. Thermal injury to skeletal muscle, or lack of perfusion of muscle, may lead to local exudation of fluid and development of such high pressures in fascial compartments that arterial perfusion is prevented. This "compartment syndrome," unless relieved by prompt surgical intervention, leads to necrosis of muscle throughout the entire compartment.[11] The consequences of massive necrosis of muscle often include secondary injury to the lungs, owing to release of reactive oxygen species, and myoglobinuria with secondary renal damage.[12] At the time of injury, patients frequently inhale carbon monoxide, which compromises the oxygen-carrying capacity of the blood. The resultant tissue hypoxia can cause death at the scene, and if the patient survives, it can be sufficient to lead to irreversible neuronal injury, cerebral edema, and brain death days later. *Hypoxemia*, sometimes related to carbon monoxide intoxication, also contributes to cardiac and renal injury. In addition, when fires occur in closed spaces, the "flashover" process consumes all available oxygen so that the patient's environment may contain too little oxygen to sustain life. Occasionally, a burn victim is found without pulse or respiratory effort, probably as a consequence of hypoxia, and is revived by cardiopulmonary resuscitation (CPR). In such cases, ischemic and hypoxic injury may be profound in multiple organs.

INFECTION

Necrotic skin provides an excellent environment for proliferation of bacteria and fungi, and as long as necrotic tissue remains, the risk of infection remains high. Immunosuppression contributes to this risk, and burn patients develop serious infections with agents usually encountered only in patients treated with immunosuppressive drugs. The mechanisms of this immunosuppression are still under investigation but include excessive secretion of glucocorticoids,

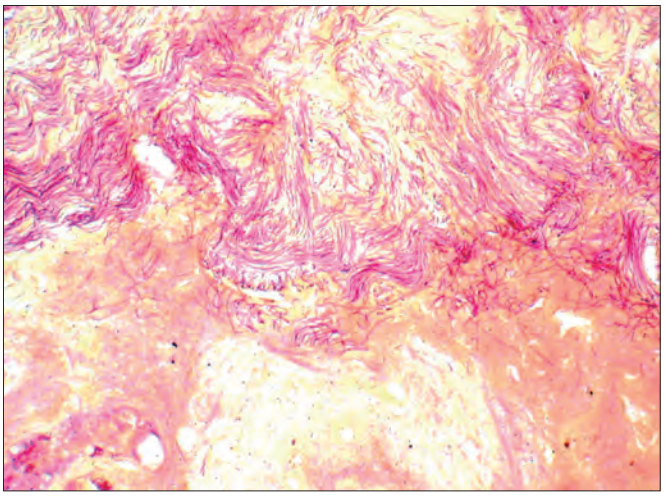

Fig. 44.1 Micrograph showing a dense cluster of filamentous Gram-negative rods within necrotic skin in a patient with severe wound infection from whom *Pseudomonas aeruginosa* was recovered in culture. Tissue Gram stain.

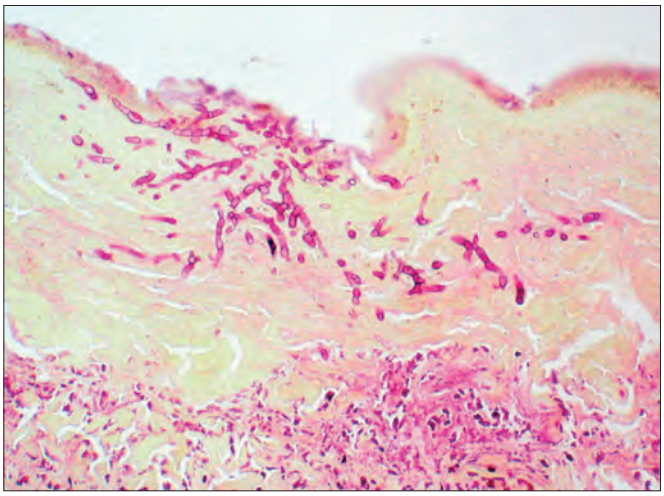

Fig. 44.2 Micrograph showing fungal hyphae within necrotic tissue extending close to the boundary with intact, viable dermal tissue. Periodic acid–Schiff stain.

abnormal cytokine signaling, and altered maturation of neutrophils and macrophages. When burn wounds become infected and large numbers of bacteria accumulate, those with high pathogenic capacity invade the adjacent viable tissue, produce further necrosis, and gain access to the circulation. This is the condition of burn wound sepsis, which historically has been the leading cause of death in burn patients. In Linares' series of 115 autopsies, sepsis was present in 73%, as documented by positive blood culture and demonstration of invasive infection of viable tissue.[13] When pneumonia was found at autopsy in such a case, the cause of death was classified as burn wound sepsis, with pneumonia as a contributing cause. In more recent cases, pneumonia has been considered the primary cause of death. In 80% of these fatal cases of sepsis, the burn wound was the source of the infection. The most important pathogens were *Pseudomonas aeruginosa, Staphylococcus aureus, Klebsiella pneumoniae, Escherichia coli, Enterobacter* spp., and *Candida* spp. More recently, antibiotic-resistant *Acinetobacter* has emerged as a frequent cause of fatal sepsis. Burn wound sepsis is recognized clinically when a burn wound is the site of proliferating microorganisms exceeding 10^5/g of tissue and there is histologic evidence of active invasion of subjacent unburned tissue.[14]

It is important to assess the presence and extent of infection within the burn wound, both by careful clinical examination of wounds and by biopsy of suspicious areas. A high index of suspicion serves burn patients well. All biopsy and excision specimens in our institution are sampled and studied histologically using special stain, a tissue Gram stain for bacteria, and methenamine silver for fungi. In large excision specimens, samples are taken from sites of especially deep tissue injury and sites that show abnormal discoloration of dermal or subcutaneous tissue. When infectious microorganisms are found, it is important to determine their location with respect to the boundary between living and necrotic tissue. This boundary may be irregular but is generally distinct and marked by inflammation in wounds that are several days old, and it may be indistinct in very fresh specimens because karyolysis takes some time to develop in burn wounds.

Wound infections generally begin with colonization of the skin surface and proliferation of organisms on the surface, often with extension into hair follicles followed by growth within the necrotic tissue. Growth within necrotic tissue is considered evidence of tissue infection, however, and is potentially more dangerous than growth on the surface of necrotic skin. Even when quantitative cultures show more than 10^5 bacteria per gram of tissue, when careful histologic study shows that the organisms are limited to the skin surface or the superficial necrotic tissue, the risk of sepsis appears to be low. Such growth on or in necrotic tissue, however, sets the stage for invasion of viable tissue. The finding of clusters of bacteria or fungi within viable tissue implies a serious risk of sepsis and further tissue invasion. Bacterial invasion of viable tissue is readily apparent by histologic study of appropriate tissue samples (Fig. 44.1). Invasive fungal infection presents a somewhat different pattern in that there is often a wavefront of necrosis that accompanies fungal invasion (Fig. 44.2). Thus, the presence of fungal hyphae extending to a boundary between necrotic and viable tissue is considered evidence of fungal invasion of viable tissue. On this basis, infections identified within burn wounds are reported as surface colonization; invasion of necrotic tissue, which may be superficial or deep; and invasion of viable tissue. The responsible surgeon is called immediately when invasion of viable tissue is found. If the level of clinical suspicion is high, cryosectioning techniques can be useful. We use a tape transfer device to facilitate handling of these specimens, since cryosections of adipose tissue and necrotic tissue adhere poorly to slides. The results are confirmed with routine sections on the following day. Diagnosis of viral infection of the skin is achieved most efficiently by sampling freshly opened vesicular lesions or the bases of recently ruptured vesicles and molecular testing by polymerase chain reaction (PCR).

When septicemia occurs, there is a generalized reaction, which often includes hypotension, tachycardia, increased

hyperthermia or hypothermia, and poor perfusion of the intestines and other viscera.[15] Coagulopathy is also an important complication of sepsis.[16] In addition, after bacteria have gained entrance to the general circulation, tissue infection may develop at distant sites. This is most likely to occur in the lungs. One recent case demonstrated clearly the route of dissemination of fatal burn wound sepsis. The patient was admitted in a clinically septic condition 2 weeks after sustaining a large burn and died despite aggressive therapy. At the time of autopsy, there were many areas of bacterial proliferation within the burn wound, invasion of viable tissue deep to the burn eschar, and thrombosis of blood vessels invaded by bacteria at the margin of the necrotic zone. Bacteria were especially numerous within the smooth muscle of veins in the dermis, suggestive of biofilm formation. Septic emboli with fibrous organization were seen in pulmonary artery branches in all lobes of the lungs. There were foci of necrosis throughout the lungs in which bacterial proliferation was visible within the walls of arteries, and these necrotic areas were surrounded by massive pulmonary hemorrhage and edema. Very little acute inflammatory reaction was seen around the many foci of bland necrosis in the lungs. A direct hematogenous route of spread of infection from the skin to the lungs seemed clear in this case. This pattern is similar to that of ecthyma gangrenosum of the skin, which is also characterized by bland necrosis thought to be caused by ischemia.[17,18] A similar angioinvasive pattern of pulmonary infection can be seen with generalized infection caused by *Aspergillus* spp. or similar filamentous fungi. On the other hand, airway obstruction is known to predispose to pneumonia acquired through the airways by preventing normal clearance of bacteria from the airways and by providing a favorable medium for bacterial growth. Multiple foci of airway obstruction are almost always seen at autopsy in burn patients.[19] In another recent case, although pneumonia was not present, there was invasion of antibiotic-resistant *Pseudomonas* spp. directly into the wall of a bronchus (Fig. 44.3). Although many serious infections in burn patients are caused by endogenous flora and many derive from wound infections present at the time of admission, nosocomial infection is a constant hazard.[20,21] The problem of burn wound sepsis is amenable to therapy. The strategy of excision of the potentially infected burn wound as early as possible, together with judicious administration of effective antibiotics, can reduce the number of deaths caused by infection. After the institution of early excision and grafting of burn patients in our institution, the incidence of burn wound sepsis as a cause of death declined dramatically, but the problem of sepsis persists. Organisms resistant to all available antibiotics are seen in burn patients with increasing frequency, and development of new antibiotics has not kept pace.[22] Patients who are referred for therapy more than 1 week after burn injury often have extensive invasive wound infection and sepsis caused by antibiotic-resistant organisms. Other microorganisms also can cause life-threatening infections in burn patients. *Fungal infection* is a continuing problem in patients with large burns.[23] Diagnosis of specific fungal infections by histopathology is difficult because important morphologic features that allow identification in culture do not occur in tissues, and fungi may display unexpected structural features in injured tissues. Pigmented fungal species generally do not show invasive behavior, and saprophytic species can mimic Zygomycetes. In one recent case of apparent systemic fungal infection, invasive and systemic dissemination of a pseudofungus of the genus *Oomycetes* was demonstrated.[24] Molecular methods (reverse transcriptase PCR) were used to identify the organism in this case. Zygomycetes have recently been recognized as dangerous burn wound pathogens.[25] It seems likely that the increased availability of molecular diagnostic testing of infectious agents may lead to recognition of additional previously unrecognized causes of invasive infection in burn patients as well as allowing more precise and rapid diagnosis of infection. Viral infections may also complicate burns. We have also experienced cases in which acquisition or reactivation of herpes virus infections led to major tissue injury. The risks of infection of a victim of a large burn are somewhat similar to those of an immunosuppressed transplant patient. Recent studies have illustrated the usefulness of the study of autopsy tissue in generating hypotheses to be tested in the laboratory.[26,27]

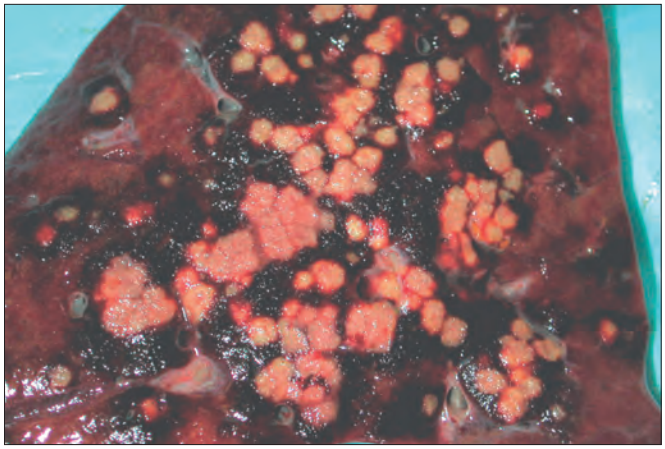

Fig. 44.3 Photograph showing a slice of the upper lobe of the lung taken at autopsy from a patient who showed clinical signs of sepsis when he developed disseminated infection after multiple wound cultures of open wounds yielded multiple antibiotic-resistant *Pseudomonas* spp.

COAGULOPATHY

The burn wound has procoagulant effects and may induce coagulation throughout the circulation (disseminated intravascular coagulation [DIC]).[28,29] Tissue necrosis can lead to coagulopathy. Generation of thrombin within the circulation leads to generation of fibrin peptides and stimulates acute inflammatory reactions, including increased vascular permeability and upregulation of adhesion molecules on neutrophils and endothelial cells (Fig. 44.4).[30] Generation of fibrin degradation products may interfere with normal thrombosis, and thrombocytopenia can develop.[31] Activation of the kinin system can stimulate further abnormal vascular permeability and hypotension.[32] Consumption of coagulation factors can lead to abnormal bleeding, which can cause extensive tissue injury secondarily. It is important to note that the acute-phase response to burn injury includes increased synthesis of fibrinogen

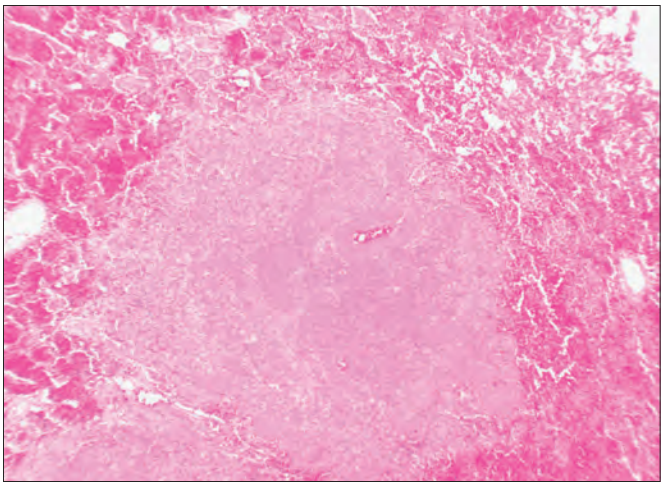

Fig. 44.4 Micrograph, taken at low magnification, showing a small round pale area of necrotic lung tissue in which no nuclei are staining, surrounded by a zone of congestion and hemorrhage, with very little acute inflammatory reaction. Hematoxylin and eosin stain.

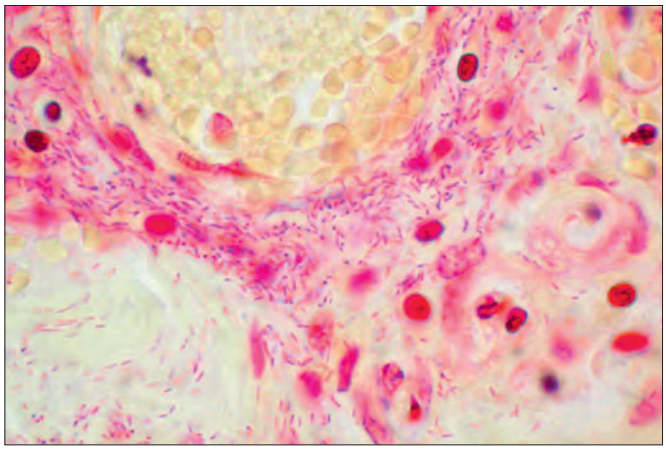

Fig. 44.5 High-magnification micrograph showing short Gram-negative rods growing profusely within the wall of a small pulmonary artery branch. Brown–Hopps tissue Gram stain.

and factor VIII. During the first 3–10 days after burn injury, patients often have greater than normal clotting activity. When DIC occurs, coagulation factors, including antithrombin, are depleted.[33,34] When DIC occurs in the patient's terminal course, microscopic fibrin thrombi are seen in many organs at the time of autopsy, most commonly in the lungs, the skin, the kidneys, and the gastrointestinal (GI) tract.[13,35]

Review of Organ Systems Affected by Burns

INTEGUMENTARY SYSTEM

The skin is the site of initial injury in burn patients, and many of the events that lead to dysfunction or failure of other organs begin in the skin. Thermal injury rapidly produces irreversible injury and cell death in all tissues in the skin. In many cases, a burn wound excised within 48 hours of injury shows that the entire dermis and all of the hair follicles are necrotic, but much of the subcutaneous adipose tissue remains viable. It appears that the greater insulating capacity of adipose tissue protects it. In some cases, however, necrosis extends deep into the subcutaneous tissue. Frequently a bandlike infiltrate of degenerating polymorphonuclear neutrophils is seen in histologic sections in the midst of a totally necrotic dermis. This suggests that the boundary between necrotic and viable tissue may have extended deeper after the initial burn injury and its inflammatory response. There is experimental evidence that burn wounds often evolve from an initial level of necrosis to a deeper level, even from second to third degree, as a result of poor perfusion of the tissue immediately deep to the initial burn injury.[36] This process of vascular stasis deep to the burn is undoubtedly due in part to the rapid loss of intravascular fluid from the damaged capillaries and venules just below the necrotic burn wound. In addition, there is evidence that neutrophils contribute to this process of burn wound extension (Fig. 44.5).[37]

A fortunately rare complication involving the skin of patients with large burns is the development of squamous cell carcinoma during the late phase of recovery. This so-called "Marjolin ulcer" shows extensive local invasion but generally can be controlled with adequate local excision.[38–40]

RESPIRATORY SYSTEM

Respiratory failure, defined as the inability to maintain adequate oxygen saturation while 100% oxygen is given via ventilator, is the immediate cause of death in some burn patients. The causes and mechanisms of respiratory failure are multiple and will be addressed separately, although often more than one mechanism operates. Direct thermal injury to the trachea and bronchi probably does not occur, except in patients exposed to large amounts of steam. In addition to the problems listed below, patients may develop problems related to the airways such as pneumothorax or interstitial emphysema, aspiration of gastric contents, pulmonary embolism, and nonspecific pulmonary edema related to increased venous pressure. Lesions of the lungs, which may be multiple, are often found at autopsy in burn patients.[41]

Diffuse alveolar damage, the histopathologic correlate of acute respiratory distress syndrome, affects the pulmonary parenchyma in all lobes, although it is often patchy in distribution, and begins with exudation of protein-rich fluid into alveolar spaces. This exudate is a consequence of damage to or increased permeability of both capillary endothelial cells and the epithelial type I cells of the alveolar lining. Within hours, the exudates form hyaline membranes, which are a histologic hallmark of this disease process (Fig. 44.6). Within a few days, the exudate begins to undergo organization by spindle-shaped fibroblasts within alveolar spaces (Fig. 44.7), and collagenous fibrosis develops, which obliterates alveoli and greatly thickens the septa between alveoli and extends between capillaries and the alveolar surface. Macrophages accumulate within alveoli, and alveolar epithelial type II cells multiply. In the

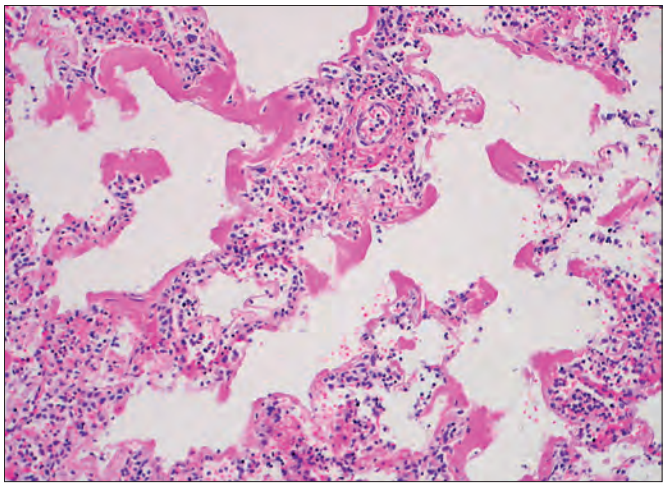

Fig. 44.6 Section of lung tissue showing bright pink, homogeneous hyaline membranes attached to alveolar walls and septa of alveolar ducts. This is from a 2-year-old patient who died 8 days after a large scald burn. This represents the exudative phase of diffuse alveolar damage, which may be seen in the absence of smoke inhalation injury. Hematoxylin and eosin stain.

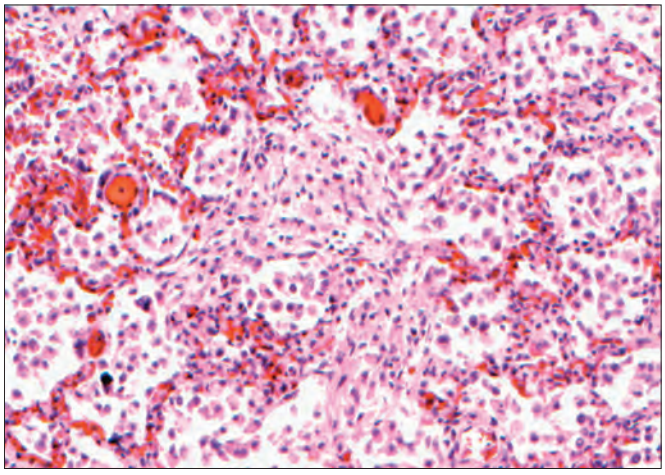

Fig. 44.7 Micrograph showing numerous elongated cells resembling fibroblasts occupying alveolar spaces and secreting connective tissue matrix. This abnormality represents the proliferative phase of diffuse alveolar damage. This patient died 1 month after a large flame burn and had clinical evidence of smoke inhalation injury and acute respiratory distress syndrome. Hematoxylin and eosin stain.

late stages, there is severe interstitial fibrosis. Multiple pathogenetic mechanisms are involved for this process, and it is not yet clear which of these are most significant in patients with burn injury.[42,43] The burn injury stimulates activation of complement, which could stimulate vascular leakage in the pulmonary bed. These and many other peptides are thought to activate circulating neutrophils, which produce secondary injury to the vascular and epithelial membranes in the lung.[44,45] Conversion of xanthine dehydrogenase to xanthine oxidase in the burn wound can cause release of superoxide into the venous circulation, stimulating endothelial injury and oxidative stress in the lung.[7] The neutrophils reacting to the burn wound undergo an oxidative burst, with release of superoxide into the circulation. This process is greatly enhanced if the patient's course is complicated by ischemic injury to muscle compartments, limbs, or other organs. Lipid peroxidation is a recognized consequence of burn injury. Superoxide can also react with nitric oxide, produced in the wound or the lung, to form peroxynitrite, a highly toxic substance.[46] Thrombin peptides, released during thrombosis of blood vessels in the wound, can also activate neutrophils and stimulate endothelial cells to express adhesion molecules.[47] The kinin system can be activated during thermal injury, with its systemic consequences. When patients develop sepsis, additional pulmonary damage may be produced by release of proinflammatory cytokines and augmentation of the processes that lead to inflammatory injury of the lung.[13,48] Neuropeptides, including substance P and calcitonin gene-related peptide (CGRP), may have a role in increasing vascular leakage in the airways.[49,50] Finally, the presence of oxygen in high concentration can itself lead to injury manifest as diffuse alveolar damage.[51–53] Despite this plethora of mechanisms that can lead to pulmonary injury in burn patients, many patients with massive burn injury do not develop clinically apparent respiratory difficulty. The conditions that seem to be most strongly associated with this form of pulmonary injury are delayed fluid resuscitation, limb ischemia, and sepsis. A recent publication noted that although diffuse alveolar damage has been found less frequently than infection as a cause of death at autopsy in recent years, the histologic changes of diffuse alveolar damage are frequently identified at the time of autopsy.[54]

Smoke inhalation injury commonly complicates burns that occur in burning buildings. The toxic effects of products of combustion directly injure tissues in the airways and lead to lung injury after a phase characterized by airway inflammation and exudation. These patients are recognized during bronchoscopy by observing hyperemia of the tracheobronchial mucosa and small particles of carbonaceous soot within the airways. Associated findings include facial burns and singed nasal hairs. These patients usually do not require ventilator therapy for several days but are at high risk of developing respiratory failure, which responds poorly to ventilator therapy and may prove fatal even when the burn injury is small. The mortality rate of burn injury has been found to be greatly increased when inhalation injury also is present.[55–59] Experimental studies in sheep and dogs have partially clarified the mechanisms of smoke inhalation injury.[60–63] In animals, the immediate reactions to inhalation of toxic smoke include detachment of numerous ciliated columnar cells from the tracheobronchial epithelium, massive secretion of mucus by secretory cells, and a more than 10-fold increase in tracheobronchial blood flow.[64–66] Within a few hours, an intense acute inflammatory reaction develops in the airways, with exudation of numerous neutrophils and release of protein-rich fluid that may coagulate within airways, forming occlusive "casts" (Fig. 44.8). After 48 hours, the exudate of neutrophils fills many terminal bronchioles and begins to extend into the lung parenchyma (Fig. 44.9). Studies using markers of upper airway mucus, including Alcian blue staining and immunostaining for Muc5B, demonstrate the presence of this material in small peripheral airways and alveoli, showing that the obstructive material moves from larger to smaller, more

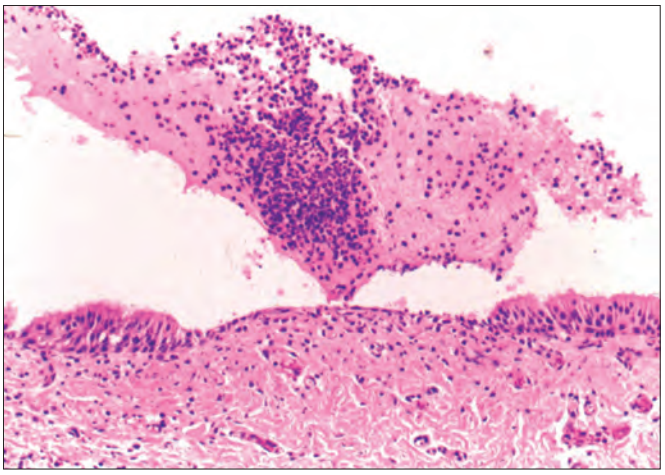

Fig. 44.8 Micrograph of a sheep trachea sampled 3 hours after experimental smoke inhalation injury by insufflation of cooled cotton smoke under anesthesia. Numerous polymorphonuclear neutrophils appear to be flowing into the tracheal lumen from a gap in the epithelial lining. Hematoxylin and eosin stain.

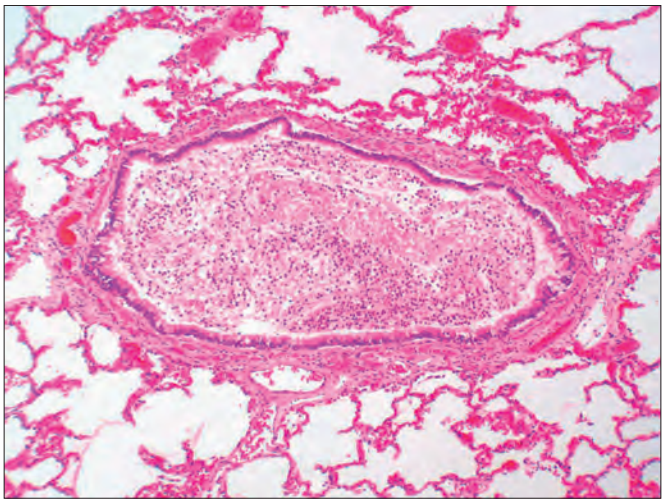

Fig. 44.10 Micrograph showing a bronchiole in human lung tissue obtained at autopsy 7 days after a large flame burn. The lumen is almost completely obstructed by a mixture of fibrin, mucus, and neutrophils. Hematoxylin and eosin stain.

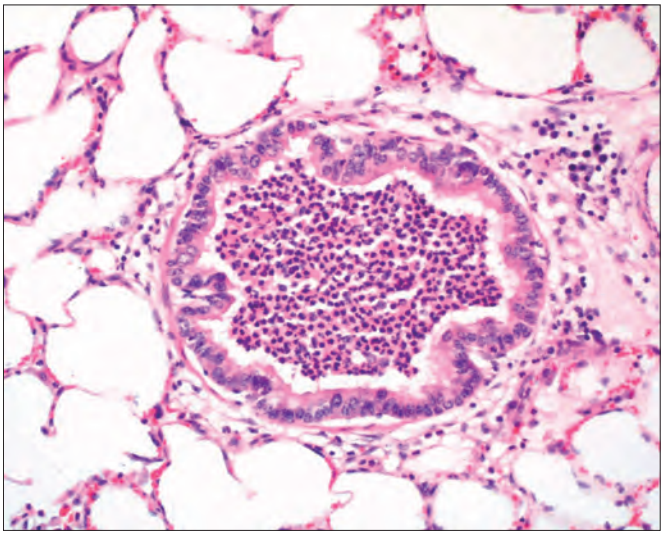

Fig. 44.9 Micrograph showing polymorphonuclear neutrophils filling the lumen of a small bronchiole in a sheep 48 hours after experimental smoke inhalation injury. Hematoxylin and eosin stain.

peripheral airways.[26] This inflammatory reaction resolves in the experimental animal, and the epithelium slowly regenerates. However, autopsy evidence suggests that exudation of neutrophils and protein into the airways resolves poorly in humans and may persist for weeks (Fig. 44.10). The loss of airway epithelium, which may be extensive, does not regenerate for long periods. Perhaps because of failure of the mucociliary escalator, mucus can be seen to accumulate around terminal bronchioles focally.[19] Failure of mucociliary clearance would be expected to increase the risk of pneumonia in burn patients. Multiple mechanisms may be responsible for the respiratory disease evoked by inhalation of toxic smoke.[67] Factors that may be likely to lead to selective damage to the airways include local release of neuropeptides by afferent C-fibers in the airways and activation of vagal reflexes and activation of proinflammatory processes in reaction to injury to the airway mucosa, particularly local production of interleukin (IL)-8.[68–71] Local production of nitric oxide and other reactive nitrogen species has significant deleterious effects in this form of acute lung injury, according to large animal experiments.[72,73] Local activation of thrombin during the formation of fibrin clots and local production of endothelin-1 may further enhance the inflammatory reaction in the airways.[74,75] Experimental studies in sheep have demonstrated that activation of poly-adenosyl-ribose polymerase (PARP) contributes to lung injury after burn and smoke inhalation injury.[76] Obstruction of small bronchi and bronchioles is thought to lead to failure of ventilation of multiple small segments of lung tissue, and inappropriate vasodilation in these poorly ventilated segments caused by the vascular effects of nitric oxide may well contribute to the failure of adequate oxygenation.[26] Treatment with nebulized heparin or tissue plasminogen activator has been found to reduce the degree of airway injury in the ovine model, demonstrating the importance of fibrin polymerization in this model.[77,78] Segmental atelectasis and prominent vasodilation in focal areas are features of smoke inhalation injury seen in experimental animals and in patients examined at autopsy after burn injury and smoke inhalation injury. Obstruction of bronchi and bronchioles by mucus, fibrin, and cell debris contributes to respiratory malfunction in experimental animals, and similar obstructive material is seen in human lung tissue at autopsy.[19,26,62,67,79] A recent review of more than 40 years' experience at the Shriners Burns Hospital in Galveston found that although clinical evidence of smoke inhalation injury was present in only 14% of patients admitted for recent burns, such evidence was recorded in 66% of the patients who died. Although autopsy cases in which death is attributable to smoke inhalation injury without infection have become uncommon, histologic evidence of diffuse alveolar damage is still commonly seen in lung tissue sampled at autopsy.[54]

CARDIOVASCULAR SYSTEM

Despite the tachycardia and increased output common to patients with burn injury, structural lesions of the heart have been uncommon in our autopsy series, which represents a pediatric population. However, cardiac hypertrophy is a consistent finding.[80] Cardiac dilation and clinical evidence of poor myocardial contractility develop in some patients after burn injury. Bacterial endocarditis occurs in occasional patients with sepsis complicating burn injury. Nonbacterial thrombotic endocarditis (marantic endocarditis) has also been seen and may also give rise to embolic complications (Fig. 44.11). When the endocardial region of the left ventricle is examined at autopsy, small foci of necrosis associated with local hemorrhage are often observed (Fig. 44.12). Contraction band necrosis in these foci is sometimes the only evidence of myocardial injury. These lesions may represent poor perfusion of a tissue with high metabolic demands during terminal episodes of hypotension. In some cases, they may represent the effects of endogenous or exogenous adrenergic agents.[81,82] This mode of injury is potentially preventable in burn patients.

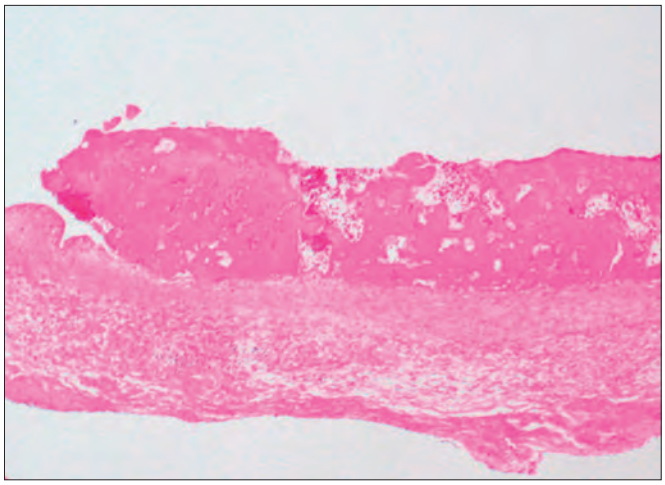

Fig. 44.11 Micrograph of a hematoxylin and eosin-stained cardiac valve showing a deposit of fibrin on the tricuspid valve of a patient who died of sepsis and had nonbacterial thrombotic (marantic) endocarditis diagnosed at autopsy. Gram stains did not reveal any bacteria.

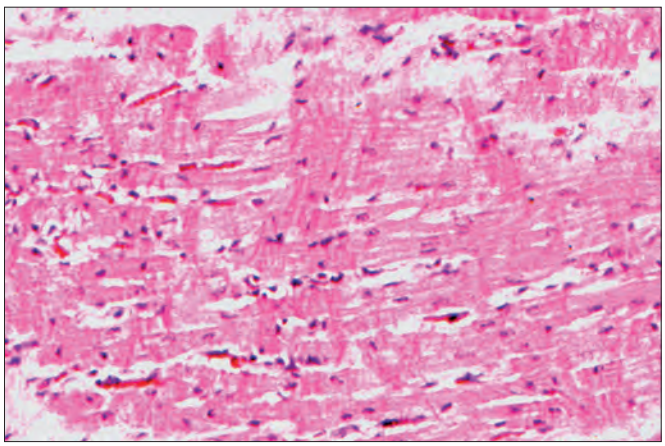

Fig. 44.12 High-magnification micrograph of heart tissue showing the presence of multiple contraction bands in cardiac myocytes, seen as refractile dark red bands running across muscle fibers. This is an early irreversible change that is seen early after ischemic injury causes lethal cell injury, especially when the tissue is reperfused with blood. It can also be seen in the setting of β-adrenergic toxicity. Hematoxylin and eosin stain.

URINARY SYSTEM

Patients with extensive burn injury, if resuscitated adequately during the first few hours, may have normal renal function throughout their hospital courses. However, when the initial fluid resuscitation was not optimal or when patients develop episodes of sepsis, acute renal failure may develop. In such cases the autopsy may reveal acute tubular necrosis.[41,83] Clinical renal failure was an independent factor associated with increased mortality rate in the analysis of prognostic factors in patients with greater than 80% total body surface burns in our institution.[84] Patients with renal failure seem to be at especially high risk for the infectious complications of burn injury.

DIGESTIVE SYSTEM AND HEPATOBILIARY TRACT

The association of duodenal ulcers with burn injury, described by Curling, is a classic lesion that still occurs in patients with burn injury, although its incidence is low, probably as a result of routine treatment of burn patients with inhibitors of gastric acid secretion.[85] Local mucosal necrosis and hemorrhage or erosion, an early manifestation of this process, are seen in some cases.

The intestinal tract is especially susceptible to ischemic and hypoxic injury, and lesions related to poor perfusion are often found at the time of autopsy. Decreased blood flow in the splanchnic circulation is a well-established physiologic consequence of endotoxemia.[14,86] Thus, sepsis is associated with an increased risk of intestinal injury. Hypoxic or ischemic injury of the intestinal epithelium can lead to translocation of intestinal flora into the mesenteric lymphatic circulation and into the portal venous circulation.[87,88] Alterations in the bacterial ecology of the gut can favor the escape of bacteria from the intestine.[89] Thus, hypotension and hypoxia can also be causes of sepsis. In our autopsy experience, abscesses or foci of tissue infection in the intestinal tract were uncommon. The intestinal lesion most commonly seen at autopsy is transverse streaks of hemorrhage in the small intestine in a "ladder" pattern, associated with focal necrosis of folds of mucosa. This is called superficial hemorrhagic necrosis (Fig. 44.13).[90] Perforation of the intestinal tract is an uncommon occurrence in patients with burn injury. Occasional patients develop pseudomembranous colitis or "typhlitis," typically a consequence of infection by toxin-producing *Clostridium difficile* (Fig. 44.14). This complication can be minimized by screening for the toxin in the stool. Rarely, ischemic injury in the intestinal tract is sufficient to yield zones of transmural necrosis.

The liver is enlarged in most autopsies of children who succumb to burn injury, often to double or triple its normal weight. Such massive hepatomegaly can compromise ventilation.[91] Steatosis is often found at autopsy (Fig. 44.15).

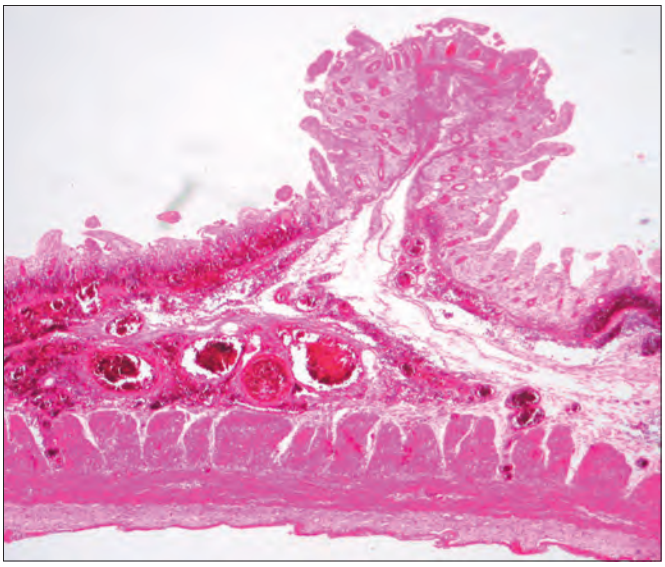

Fig. 44.13 Low-power micrograph showing a transverse mucosal fold in the jejunum of a patient who was septic and hypotensive for several days before death. Whereas the mucosal fold at the top is necrotic and shows no nuclear staining, the remainder of the intestinal mucosa and wall are intact but show submucosal hemorrhage. Hematoxylin and eosin stain.

Fig. 44.14 Photograph showing dark green to black discoloration of patches elevated above the surrounding mucosa in the cecum of a patient who had intestinal distension and occult blood in the stools. This is a typical appearance of pseudomembranous colitis. Hematoxylin and eosin stain.

The degree of steatosis is often mild, however, even in the presence of massive hepatomegaly. Analysis of the lipid content of liver obtained at autopsy documented the presence of excess lipid but showed that its quantity was far too small to account for the increase in weight of the liver.[92] Congestion of the liver is also frequently seen at autopsy, often with centrilobular necrosis, which may be a consequence of reduced splanchnic blood flow in patients with sepsis and elevated venous pressure. Intracellular cholestasis is commonly observed in patients with burn injury. The basis for this abnormality is not clear, although multiple physiologic derangements could be expected to lead to cholestasis.[93,94]

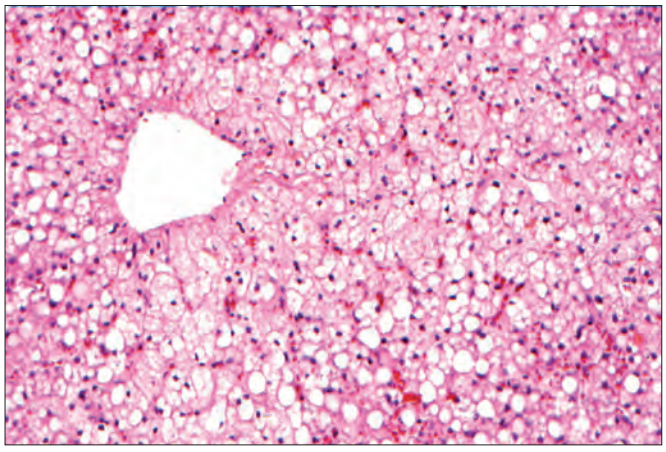

Fig. 44.15 Micrograph showing liver tissue in which almost every cell contains one or several large pale vacuoles that are the sites where lipid was stored within hepatocytes. Steatosis or fatty metamorphosis is consistently seen in the liver at autopsy but may not account for the increase in size and mass of the liver. This patient was 6 years old and lived for 1 month after injury. His liver was 2.2 times the normal weight. Hematoxylin and eosin stain.

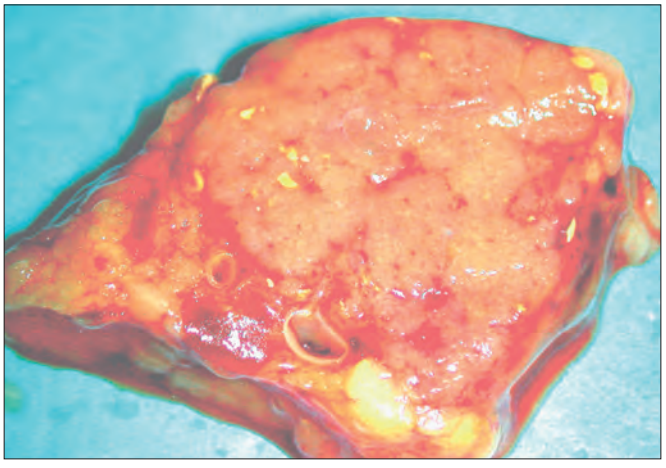

Fig. 44.16 A cross-section of the pancreas obtained at autopsy. The patient died after a long course of sepsis. The bright yellow flecks represent fat necrosis with saponification of fatty acids liberated by pancreatic lipases, and patchy hemorrhage is visible within and around the gland.

Acute pancreatitis is found at autopsy in a sizable minority of cases of fatal burns. Often necrosis and hemorrhage appear out of proportion to the extent of acute inflammation. The pancreas is particularly vulnerable to the reduced splanchnic blood flow that accompanies sepsis (Fig. 44.16). Increased clinical suspicion of pancreatitis has led to assessment of circulating amylase and lipase. On this basis, clinical pancreatitis is not rare in our patient population but is often transient.

LYMPHOID SYSTEM

Depletion of lymphocytes from lymphoid tissues throughout the body is a consistent feature seen at autopsy in patients with burn injuries. The abnormalities were well described by Linares in 1978.[95] The thymus is consistently

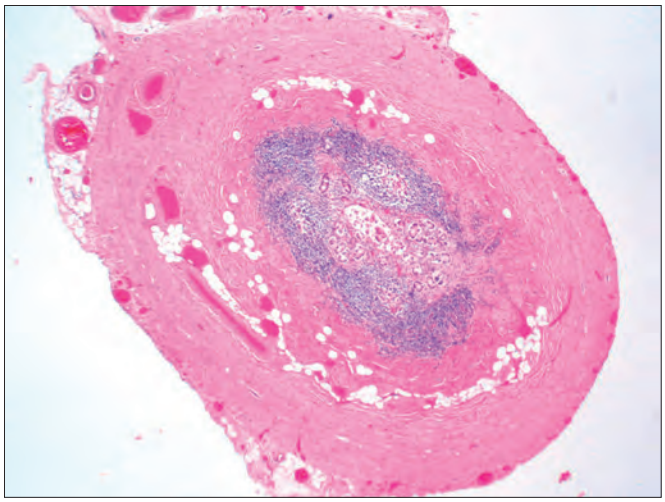

Fig. 44.17 Low-magnification micrograph showing a cross-section of the appendix. There is striking depletion of the amount of blue-staining lymphoid tissue that normally makes up the bulk of the surface of a section of the appendix. Hematoxylin and eosin stain.

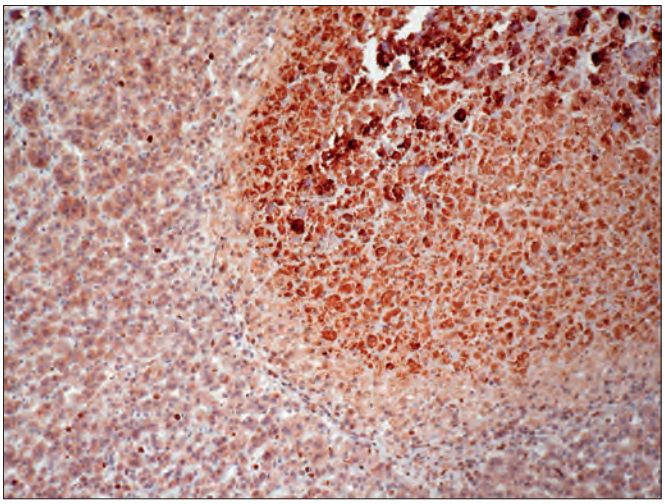

Fig. 44.18 Micrograph that is an immunohistochemical stain for herpes simplex virus type II of the adrenal cortex of a child who had extensive skin infection and injury caused by reactivation of a neonatal herpes infection. The dark brown material is reaction product that was not seen when the antibody was omitted. Multiple small necrotic lesions were seen in the liver and adrenal glands.

very small, even in young children. The lymph nodes often lack germinal centers and may be strikingly depleted of lymphocytes. Sinus histiocytosis is often present, and pyroninophilic cells resembling plasma cells are often prominent in the portions of the node normally occupied by B cells. The splenic white pulp is deficient, sometimes strikingly so. The GI lymphoid tissue of the terminal ileum is generally atrophic, despite its normal prominence in children, and the appendix often shows a striking lack of normal lymphoid tissue in its wall (Fig. 44.17). These abnormalities of lymphoid tissue correlate with the deficient immune response typical of patients with extensive burn injury. To some extent, they may represent the effects of high levels of endogenous glucocorticoids in burn patients.

ENDOCRINE SYSTEM

Excessive secretion of glucocorticoids and of epinephrine by the adrenal gland is characteristic of the prolonged hypermetabolic response to burns. Morphologic evidence of lipid depletion of the adrenal cortex has not been seen in our experience. In one interesting case, reactivation of neonatal infection with herpes simplex virus type II occurred in a young child with a large burn, leading to extensive skin injury and graft loss. Focal necrotic lesions were found in the adrenal cortex that were labeled by an immunostain for herpes simplex, indicating that dissemination of the infection had occurred (Fig. 44.18).

MUSCULOSKELETAL SYSTEM

Lesions of skeletal muscle are uncommon in burn patients but are ominous when they occur. Occasionally, direct thermal or electrical injury extends into deep muscle, and at times, this injury can be so severe that adequate debridement is not practical. When invasive bacterial or fungal infection extends into muscle, again, it may not be feasible to treat adequately by excision of the infected tissue, and the infection may be resistant to antibiotic therapy and likely to disseminate. Atrophy of skeletal muscle occurs as part of the catabolic state of burn patients and represents a challenge for those involved in rehabilitative efforts.

CENTRAL NERVOUS SYSTEM

When the brain and spinal cord are examined carefully at autopsy, abnormalities can be found in the great majority of patients who die after burn injury. The commonest lesion is degeneration or loss of neurons in the portions of the cortex most susceptible to hypoxic and ischemic injury. These lesions can be a result of hypovolemia during resuscitation, shock developing as part of the syndrome of sepsis, or as a consequence of respiratory failure. Of course, extensive hypoxic brain injury may occur in patients who are asphyxiated during the initial burn injury. Some patients, especially those who require CPR at the scene of injury, develop massive cerebral edema and brain death several days after the initial injury, reflecting development of massive cerebral edema in response to extensive hypoxic–ischemic injury in the brain. Severe hypoxic brain injury also can occur in burn patients who are deprived of oxygen during the progress of a house fire or who are poisoned by carbon monoxide at the scene of the burn. Direct thermal injury to the brain occurs occasionally in young children; can be detected by radiologic imaging studies; and is represented at autopsy by small foci of tissue necrosis on the cortical surface, surrounded by hyperemia.

The Burn Autopsy

As long as patients develop complications of burn injury that are difficult to manage, especially when the pathogenesis of these complications remains uncertain, careful postmortem examination of patients who do not survive will continue to contribute to patient care. The major medical

problems that complicate burn injury are summarized in the next few paragraphs. There is no disease with more complex clinical and physiopathologic derangements than an extensive burn. Observations made at the time of autopsy often clarify the nature of the problems that have led to the patient's demise. Sometimes the findings lead to suggestions for changes in procedure that may lead to improved patient safety. Very often a review of recent deaths effectively reminds the staff of the importance of measures to prevent wound infection. Often a causal sequence of events can be reconstructed by including the clinical evidence, including cultures with sensitivity testing and metabolic profiling, and the autopsy findings. Infectious processes, for example, often can be traced from their sites of origin, in the skin or elsewhere, to the fatal conclusion. Dangers caused by the emergence of highly resistant bacterial strains can be traced. The autopsy should always be approached from the point of view of using both clinical and autopsy evidence to better understand the reactions of the patient to the burn injury and to the treatments provided. In other words, the burn autopsy can provide not only an appropriate morphologic analysis but also a dynamic interpretation of the pathogenesis of the disease processes of importance in an individual patient. When approached in this way, investigation of patient deaths becomes a valuable learning experience for all those who participate.[96] Often, unexpected lesions are found that were likely to have been significant in the patient's course. Of course, the circumstances of burn injury may have legal implications.[97] Documentation of the patient's injuries and careful interpretation of the hospital course can provide factual evidence when only supposition would be available otherwise. Several recent publications have confirmed the continuing usefulness of autopsies, especially in the setting of burn trauma.[98–102] We advocate a policy of carrying out complete autopsies on all patients who die after burn injury whenever possible in collaboration with the local medical examiner or coroner.

45 Molecular and Cellular Basis of Hypertrophic Scarring

PETER KWAN, ALEXIS DESMOULIÈRE, and EDWARD E. TREDGET

Introduction

Clinically postburn hypertrophic scars (HTS) are elevated, erythematous, pruritic, and inelastic.[1] In addition to poor cosmesis, these scars typically form contractures resulting in dysfunction and discomfort, leading to significant morbidity for burn patients (Fig. 45.1). HTS is fundamentally different from normal skin and mature scar in several key ways: (1) the extracellular matrix (ECM) of HTS is significantly altered in both composition and architecture, (2) the behavior of keratinocytes and fibroblasts present in HTS is profibrotic compared to mature scar, and (3) many profibrotic cytokines are upregulated and their expression prolonged. Generally, HTS undergoes some remodeling and maturation over time, and this may account for the variability in descriptions of HTS. Many features of HTS are shared by other fibroproliferative disorders, including renal fibrosis, pulmonary fibrosis, and scleroderma.[2] Thus understanding the pathophysiology of HTS applies to other areas of medicine, and developments in treating various fibroproliferative diseases can directly affect scar management. Since an exhaustive discussion of every nuance of abnormal wound healing is impossible, we focus on aspects of HTS formation highlighting well understood pathways or novel developments. It is our hope that a deeper understanding of abnormal wound healing pathophysiology and fibrosis will lead to nonsurgical treatments that improve life not only for burn patients, but for the many patients suffering fibrotic diseases.

Extracellular Matrix

ECM in healing wounds is laid down by fibroblasts and subsequently remodeled as the scar matures. The ECM in HTS displays significant differences from mature scar and normal skin, most notably in the arrangement and composition of collagen bundles and in the relative proportions of several proteoglycans.[3] Owing to the interaction of fibroblasts and ECM, these differences not only result from abnormal fibroblast behavior but also contribute to it.[4]

COLLAGEN

Collagen is the major constituent of ECM, providing a scaffold for cells and mechanical strength to tissues. In HTS the quantity of collagen per unit surface area is increased;[5] however the relative proportion of collagen in HTS is decreased compared to normal skin, owing to much greater increases in proteoglycans and glycoproteins.[3] In normal skin the majority of collagen is type I (80%) with smaller amounts of type III (10–15%) and type V (minimal), resulting in thick, regular collagen fibril bundles running parallel to the skin surface.[6] In contrast, HTS is composed of greatly increased amounts of type III (33%)[7] and type V (10%)[8] collagen, which drastically alters collagen fibrils, making them thinner[6] and disorganized.[9] In normal wound healing, type III collagen appears early then gradually disappears as the scar is remodeled and matures,[10] but this does not occur in HTS, where persistently high levels reflect biological immaturity.[11]

Classic histologic descriptions of HTS highlight "whorls" and "nodules" of poorly organized collagen encapsulated in more normal-appearing collagen fibrils,[6] as seen in Fig. 45.6. However not only are collagen fibril composition and morphology altered in HTS, but interfibrillar spacing is also irregular and greatly increased.[12] This space is filled with proteoglycans and glycoproteins whose composition is markedly different from normal skin and mature scar.

PROTEOGLYCANS AND GLYCOPROTEINS

Proteoglycans are responsible for physical properties of skin such as turgor, resilience, and resistance to compression, resulting from their interaction with collagen. Proteoglycans also modulate the activities of multiple growth factors and cytokines. Glycoproteins, such as fibronectin, are generally involved in cell–matrix adhesion and influence cell behavior via this mechanism. Together proteoglycans and glycoproteins are major constituents of skin, both physically and functionally.

Proteoglycans are formed by a protein core, often with repeating units such as leucine in decorin, and glycosaminoglycan side chains.[13] These side chains are ionized and hydrophilic and thus mainly responsible for tissue water retention.[14] Early studies of HTS demonstrated elevated glycosaminoglycan levels,[15] which are responsible for the hyperhydrated state of HTS that leads to its classically increased turgor. These levels of glycosaminoglycan are not uniformly elevated. Instead certain proteoglycans are downregulated and others upregulated, with unique implications for HTS.

Decorin is a prototypical small, leucine-rich proteoglycan (SLRP) produced in abundance in normal skin and mature scar but reduced by 75% in HTS.[3] Originally named for "decorating" collagen fibrils, decorin affects wound healing via several distinct and complementary pathways. Decorin binds to collagen fibrils, controlling their diameter, morphology,[16] and interfibrillar distance.[17] In decorin knockout mice collagen fibrils are irregular in morphology and have highly variable diameters.[18] Decorin binds to and

Fig. 45.1 Hypertrophic scarring in a 34-year-old white man, 8 months following a 60% total body surface area burn involving the face, upper extremities, and hands. (From Scott PG, Ghahary A, Chambers MM, Tredget EE. Biological basis of hypertrophic scarring. In: Malhotra SK, ed., *Advances in Structural Biology*, vol. 3. Greenwich, CT: JAI Press, 1994: 157–202.)

inactivates the profibrotic cytokines transforming growth factor-β (TGF-β)[19] and platelet-derived growth factor (PDGF).[20] The effects of this inactivation are most readily visible in fibroblast-populated collagen lattices where decorin significantly reduces contraction by normal and HTS fibroblasts.[21,22] Decorin also binds to and antagonistically downregulates several cell surface receptor tyrosine kinases: epidermal growth factor receptor (EGFR),[23] hepatocyte growth factor receptor (HGFR),[24] and insulin-like growth factor 1 receptor (IGF1R),[25] which reduces cellular proliferation and migration. Decorin production increases significantly as scars mature.[26] In a mouse model of diabetes, renal fibrosis and nephropathy developed significantly faster in decorin knockout than in wild-type mice.[27] Similarly upregulating decorin production via an adenoviral vector in mouse models of bleomycin-induced pulmonary fibrosis reduced fibrosis.[28]

In contrast to decorin downregulation, two other proteoglycans, biglycan and versican, are significantly upregulated in HTS. Biglycan is 57% similar to decorin in amino acid sequence but with two dermatan sulfate chains and is believed to have originated as a gene duplication of decorin.[29] Despite these similarities, biglycan and decorin have significantly different functions in vivo. Biglycan is minimally present in normal skin but significantly upregulated in fibrosis, yet it does not compensate for the lack of decorin.[29,30] Versican is also significantly upregulated in HTS, up to six times higher than in normal skin,[3] where it is normally confined to the proliferating epidermis.[31] As a large proteoglycan with 12–30 glycosaminoglycans

chains, versican is most likely responsible for the increased hydration and turgor leading to the increased volume of HTS.[5]

The most common glycoprotein in ECM is fibronectin, which has effects on cell–matrix interaction via its interaction with integrins. Although the role of fibronectin in HTS is unclear, its upregulation in HTS,[32] influence on the assembly of other ECM proteins, and interaction with cellular integrins[33] suggest that it, too, plays a role in fibroblast behavior and HTS formation.

Cellular Contributions to Hypertrophic Scar

HYPERTROPHIC SCAR FIBROBLASTS

Fibroblasts are the cells primarily responsible for ECM production and remodeling in wound healing. Numerous studies have demonstrated that dermal fibroblasts can be divided into distinct subpopulations—superficial (papillary) and deep (reticular)—based on both physical location and phenotype.[34–36] When characteristics of superficial dermal, deep dermal, and HTS fibroblasts are compared, as in Table 45.1, it becomes clear that HTS fibroblasts most closely resemble deep dermal fibroblasts.[36] These in vitro results correlate directly with a clinically relevant dermal scratch model developed by Dunkin and colleagues.[37] In this model a linear skin wound is created with depth that increases along its length from no injury to full-thickness penetration. This results in regeneration in the superficial portion (depth ≤0.56 mm) with minimal scar; whereas HTS formation occurs in the deeper portion of the wound.[37] Combining these basic science and clinical observations with the tendency of HTS to form following deep partial- to full-thickness burns suggests two possible theories of HTS formation: (1) selective proliferation of deep dermal fibroblasts after fibrogenic cytokine stimulation, or (2) destruction of superficial dermal fibroblasts by thermal injury, leaving only deep dermal fibroblasts to repopulate the wound.[38] Both theories are consistent with an experimental model in which human skin was grafted onto the backs of nude mice and subsequently injured. In this model, deep dermal fibroblasts closed wounds and superficial dermal fibroblasts then remodeled them.[39] It is possible that in deep burns superficial fibroblasts are not present to initiate this remodeling process, leaving the healing wound in a hyperactive state (Fig. 45.2).

Table 45.1 Superficial and Deep Dermal Fibroblasts Compared to Hypertrophic Scar Fibroblasts

	Superficial Dermal Fibroblasts	Deep Dermal Fibroblasts	Hypertrophic Scar Fibroblasts
Collagen production	↓	↑	↑
Collagenase production	↑	↓	↓
Decorin production	↑	↓	↓
TGF-β production	↓	↑	↑
CTGF production	↓	↑	↑
Keratinocyte proliferation	↑	↓	↓
Capillary formation	↑	↓	↓

ROLE OF MYOFIBROBLASTS IN NORMAL AND PATHOLOGICAL SITUATIONS

Myofibroblasts are cells that have acquired a phenotype intermediate between fibroblasts and smooth muscle cells. Presently it is accepted that myofibroblast modulation of fibroblastic cells begins with the appearance of precursor proto-myofibroblasts whose stress fibers contain only β- and γ-cytoplasmic actins. These proto-myofibroblasts acquire de novo contractile bundles whose stress fibers generate sufficient forces to pull cells forward to populate tissue spaces in a migration process and to pre-remodel the ECM. Proto-myofibroblasts evolve, but not necessarily always, into the differentiated myofibroblast.[40] Fully differentiated myofibroblasts express α-smooth muscle actin (α-SMA), the actin isoform present in typical contractile vascular smooth muscle cells (Fig. 45.3). The presence of α-SMA is directly related to the contractile activity of myofibroblasts. A direct correlation has been demonstrated both in vitro and in vivo between the level of α-SMA expression and myofibroblast contraction.[41,42] Myofibroblasts also exhibit some similarities with pericytes.[43] In physiological conditions, after healing, myofibroblasts undergo apoptosis,[44] and only a few fibroblasts are left to ensure renewal of the ECM.

Among the soluble factors, TGF-β1 is a potent inducer of myofibroblast differentiation.[45,46] TGF-β1 action on myofibroblast differentiation is only possible in the presence of ED-A fibronectin, which underlines the fact that ECM components play an important role in soluble factor activity.[47] Granulocyte–macrophage colony-stimulating factor stimulates macrophage proliferation and myofibroblast differentiation, thereby promoting granulation tissue formation.[48,49] Endothelin has also a positive effect on differentiation and activation of myofibroblasts. This peptide also induces myofibroblast contraction and migration.[50] More recently it has been shown that granulation tissue formation is modified by chemical denervation.[51] This peripheral nervous system involvement in tissue repair has likewise been shown in the liver; in this organ, in an experimental model of fibrosis

Fig. 45.2 Injury below a critical depth in skin leads to scarring. (From Kwan P, Hori K, Ding J, Tredget EE. Scar and contracture: biological principles. *Hand Clin.* 2009;25[4]: 11–528.)

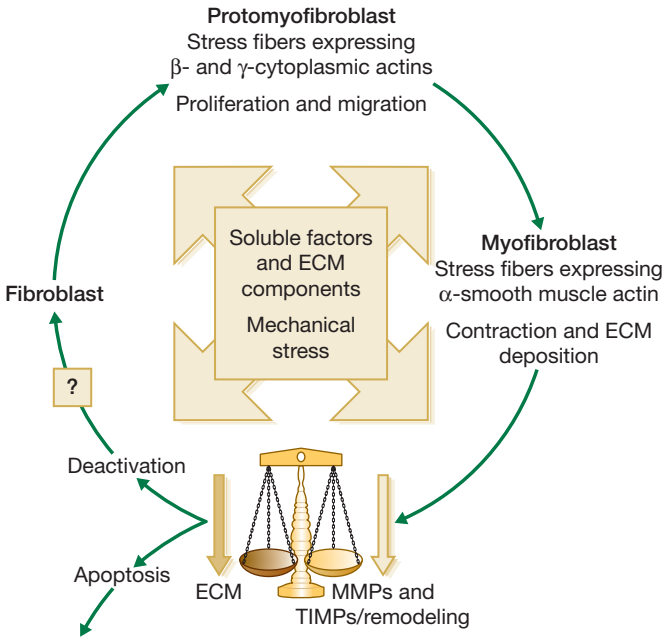

Fig. 45.3 Schematic illustration showing the evolution of the (myo) fibroblast phenotype. The myofibroblast modulation of fibroblastic cells begins with the appearance of the proto-myofibroblast, whose stress fibers contain only β- and γ-cytoplasmic actins and evolves, but not necessarily always, into the appearance of the differentiated myofibroblast, the most common variant of this cell, with stress fibers containing α-smooth muscle actin. Myofibroblasts present a well-developed rough endoplasmic reticulum and are responsible for (excessive) deposition of extracellular matrix (ECM); they also secrete matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) and are involved in granulation tissue remodeling. Soluble factors, particularly transforming growth factor-β1, associated with ECM components (e.g., fibronectin ED-A), play important roles during myofibroblast differentiation. Mechanical stress is also importantly involved in myofibroblast differentiation. The myofibroblast can undergo apoptosis; the deactivation leading to a quiescent phenotype has not been clearly demonstrated at least in vivo. (From Desmoulière A.)

using carbon tetrachloride treatment, chemical denervation significantly reduces matrix deposition and myofibroblast differentiation.[52]

ROLE OF MECHANICAL STRESS AND MYOFIBROBLASTS

Myofibroblast cells, because of their contractile properties and privileged relationships with ECM, can modify their activity depending on the mechanical environment. It has been shown, in gingival fibroblasts, that α-SMA expression induced by TGF-β1 is regulated by the compliance of collagen gels on or in which they are cultured.[53] The direct effects of mechanical stress on fibroblasts can be easily shown in culture using stressed fibroblast-populated collagen lattices (Fig. 45.4). Moreover, myofibroblast differentiation features, such as stress fibers, ED-A fibronectin, or α-SMA expression, appear earlier in granulation tissue subjected to increased mechanical tension by splinting of the full-thickness wound with a plastic frame than in normally healing wounds.[42] It has also been shown that fibroblasts cultured on substrates of variable stiffness present different phenotypes. Cultured fibroblasts do not express stress fibers on soft surfaces, but, when the stiffness of the substrate increases, a sudden change in cell morphology occurs and stress fibers appear.[54,55] Shear forces exerted by fluid flow are also able to induce TGF-β1 production and differentiation of fibroblasts cultured in collagen gels in the absence of other external stimuli, such as cytokine treatment.[56] Intercellular mechanical coupling of stress fibers via adherens junctions improves contraction of collagen gels by myofibroblasts.[57] By assessing spontaneous intracellular Ca^{2+} oscillations, Follonier et al. have shown that intracellular Ca^{2+} oscillations are coordinated between contacting myofibroblasts via adherens junctions, but randomly between fibroblasts and noncontacting cells.[58] They propose the following model of mechanical coupling for myofibroblasts: individual cell contraction is transmitted via adherens junctions and leads to opening of mechanosensitive ion channels in adjacent cells. The resulting Ca^{2+} influx induces a contraction that can feed back on the first cell and/or stimulate other contacting cells, working like a syncytium. This mechanism could improve the remodeling of cell-dense tissue by coordinating the activity of myofibroblasts.[59]

PATHOLOGICAL REPAIR (HYPERTROPHIC SCARS AND KELOIDS)

Pathological wound healing can result from impaired remodeling of the granulation tissue leading to abnormal cutaneous repair in hypertrophic or keloid scars (Fig. 45.5). Keloid and HTS differ in their expression of α-SMA; indeed, in keloids, no α-SMA is observed, although proto-myofibroblasts could account for large amounts of extracellular matrix but are unable to contract, whereas numerous myofibroblasts express this protein in HTS, thus explaining the fact that contracture often appears specifically in HTS.[38,60] Thus the use of α-SMA to differentiate HTS and keloids has been proposed.[61] The presence of contractile myofibroblasts in HTS is responsible for the formation of contractures that interfere with function and may require extensive reconstructive surgery (Fig. 45.6). Moreover, keloids contain thick collagen fibers, whereas HTS contain thin fibers organized in nodules.[60,62] It emphasizes that the different processes involved in collagen maturation together with the effects of the matrix metalloproteinase (MMP)/tissue inhibitor of MMP (TIMP) system play an important role in excessive scar formation. The expression of lysyl hydroxylase-2b (LH-2b), a splice variant of LH-2, an enzyme involved in the cross-linking of the collagen fibrils, has been linked to fibrotic development occurring in pathologic situations.[63] Animal models mimicking this specific expression of LH-2b are available and could be used to test new antiscarring therapies based on the inhibition of LH-2b.[64] In these lesions, the normal healing process cannot be achieved and granulation tissue continues to grow owing to an abnormal and excessive secretion of growth factors and/or lack of molecules inducing apoptosis or ECM remodeling. Interestingly HTS have an excess of microvessels, most of which are partially or totally occluded due to a functional regression of endothelial cells induced by (myo)fibroblast hyperactivity.[65] In excessive scarring, a focal upregulation of p53 expression, which probably inhibits apoptosis, has been observed. ECM modifications also seem to be an important factor in induction of the apoptotic process. In vivo, covering granulation tissue by

Fig. 45.4 Myofibroblast evolution in collagen gels. When myofibroblasts previously cultured in plastic dishes are incorporated in a floating collagen gel, a high proportion rapidly undergo apoptosis (arrows). In contrast, when incorporated in an attached collagen gel, they show a typical elongated morphology, express high amounts of α-smooth muscle actin, and proliferate. (From Coulomb B, Inserm U970, Université Paris Descartes, France and Desmoulière A, unpublished data.)

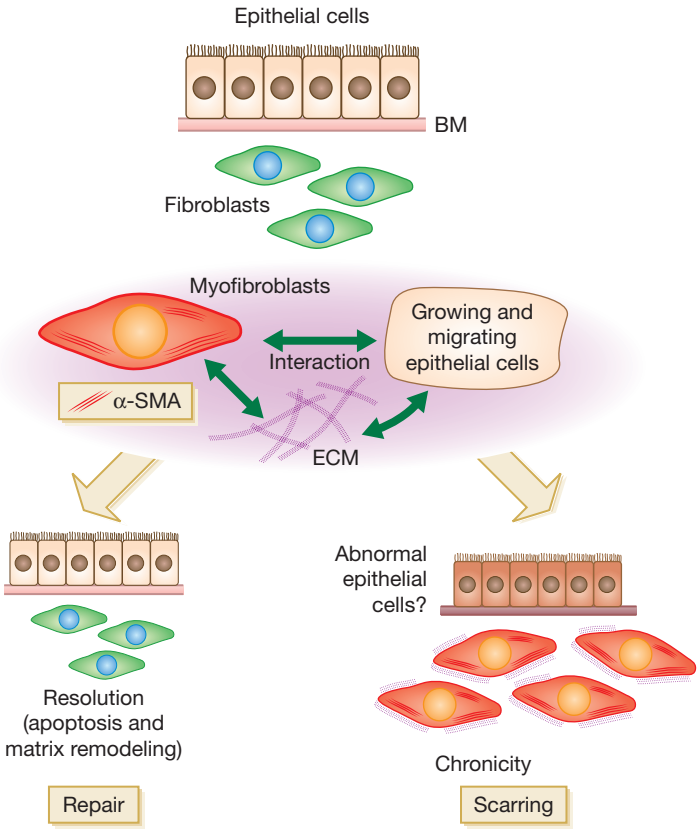

Fig. 45.5 Processes leading to normal repair or pathological scarring. In normal tissue repair, myofibroblasts disappear by apoptosis during the transition between granulation tissue and scar. In pathological situations, myofibroblasts proliferate and participate in the excessive deposition of extracellular matrix. In all these situations, not only interaction between fibroblasts/myofibroblasts and extracellular matrix, but also the dialogue between epithelial cells and mesenchymal cells play a major role. BM: basement membrane; SMA: smooth muscle actin; ECM: extracellular matrix. (Modified from Sarrazy et al. Wound repair and regeneration: mechanisms of pathological scarring: role of myofibroblasts and current developments. *Wound Repair Regen.* 2011;19[1]: s10–s15.)

a vascularized skin flap induces an upregulation of MMP together with a decrease in TIMP, leading to a rapid loss of granulation tissue cells by apoptosis.[66] In vitro, the matrix environment can modulate fibroblast apoptosis. Furthermore, in HTS, the mechanical forces obtained by compression of the scar are able to restore the classic organization observed in normal wounds and trigger the disappearance of myofibroblasts by apoptosis.[67] Thus mechanical stress can maintain myofibroblast differentiation. It has been shown that mechanical loading early in the proliferative phase of wound healing produces HTS by inhibiting cellular apoptosis.[68] In contrast, it is suggested that mechanical challenge could be a clinically relevant strategy to improve ischemic and chronic wound healing by supporting myofibroblast formation.[69] Interestingly oncogenic-Ras-transformed human fibroblasts lose growth factor selectivity and cell matrix density-dependent inhibition of migration.[70] In the liver and certain other organs, stiffness appears to result from matrix cross-linking and possibly other unknown variables in addition to matrix quantity, suggesting that increased stiffness may play an important role in initiating the early stages of fibrosis.[71] The epithelium could also be involved in the development of excessive scarring.[72] Hakvoort et al. have shown that, in HTS, keratinocytes expressed an activated $CD36^+$ phenotype.[73] They suggest that HTS formation is not only due to dermal dysfunction, but is also the result of a perturbation affecting dermal–epidermal interactions involving neurohormonal factors. Indeed, a "neurogenic inflammation hypothesis" has been suggested.[74] Mechanical stress stimulates mechanosensitive nociceptors in skin sensory fibers, which release neuropeptides involved in vessel modifications and fibroblast activation.

ORIGIN OF (MYO)FIBROBLASTS

It is now accepted that myofibroblasts can originate from various cell types, as illustrated in Fig. 45.7. The majority of these cells originate from local recruitment of connective tissue fibroblasts. For example, in skin, dermal fibroblasts located in the edges of the wound can acquire a myofibroblast phenotype and participate in tissue repair.[75,76] In diffuse cutaneous systemic sclerosis, microvascular pericytes constitute a cellular link between microvascular damage and fibrosis by transdifferentiating into myofibroblasts.[77] In the liver, the role of hepatic perisinusoidal hepatic stellate cells has been widely studied, and their key role during fibrogenesis has been clearly demonstrated.[78] Recently it has also been shown that portal fibroblasts are involved in the formation of portal septa.[79] Vascular smooth muscle cells residing in the walls of portal vein branches and portal arteries have been implicated in fibrosis observed in chronic schistosomiasis.[80] In the kidney, both mesangial cells and interstitial fibroblasts of the medulla can acquire a myofibroblast phenotype and participate in ECM deposition after damage.[81,82] Moreover the involvement in tissue repair of local mesenchymal stem cells is becoming better understood. These progenitor cells have been described in the dermal sheath that surrounds the outside of the hair follicle facing the epithelial stem cells, constituting a niche of stem cells. They are involved in the regeneration of the dermal papilla and can also become wound healing (myo) fibroblasts after an injury.[83] This concept of a cell association able to reconstitute the different organ cell populations and constituting a niche of stem cells is currently discussed in diverse organs, notably the liver, in the periportal zone containing Hering's canals.[84,85] Recent data have shown the implication of circulating cells, called fibrocytes, in the tissue repair process[88] tissue repair process, another type of circulating cell originating from bone marrow participates in tissue repair. These mesenchymal stem cells are bone marrow-derived nonhematopoietic precursor cells[89,90] that contribute to the maintenance and regeneration of connective tissues through engraftment. Indeed, they have the capacity to engraft into several organs and to differentiate into wound-healing myofibroblasts. However, recently it has been suggested that fibroblasts/myofibroblasts that participate in cutaneous wound healing are not derived from circulating progenitor cells.[91] Finally, epithelial- and endothelial-to-mesenchymal transition (EMT), a process by which differentiated (or malignant) epithelial cells and endothelial cells undergo a phenotypic conversion that gives rise to the matrix-producing fibroblasts and myofibroblasts, is increasingly recognized as an integral part of tissue fibrogenesis after injury, particularly in the kidney[92]

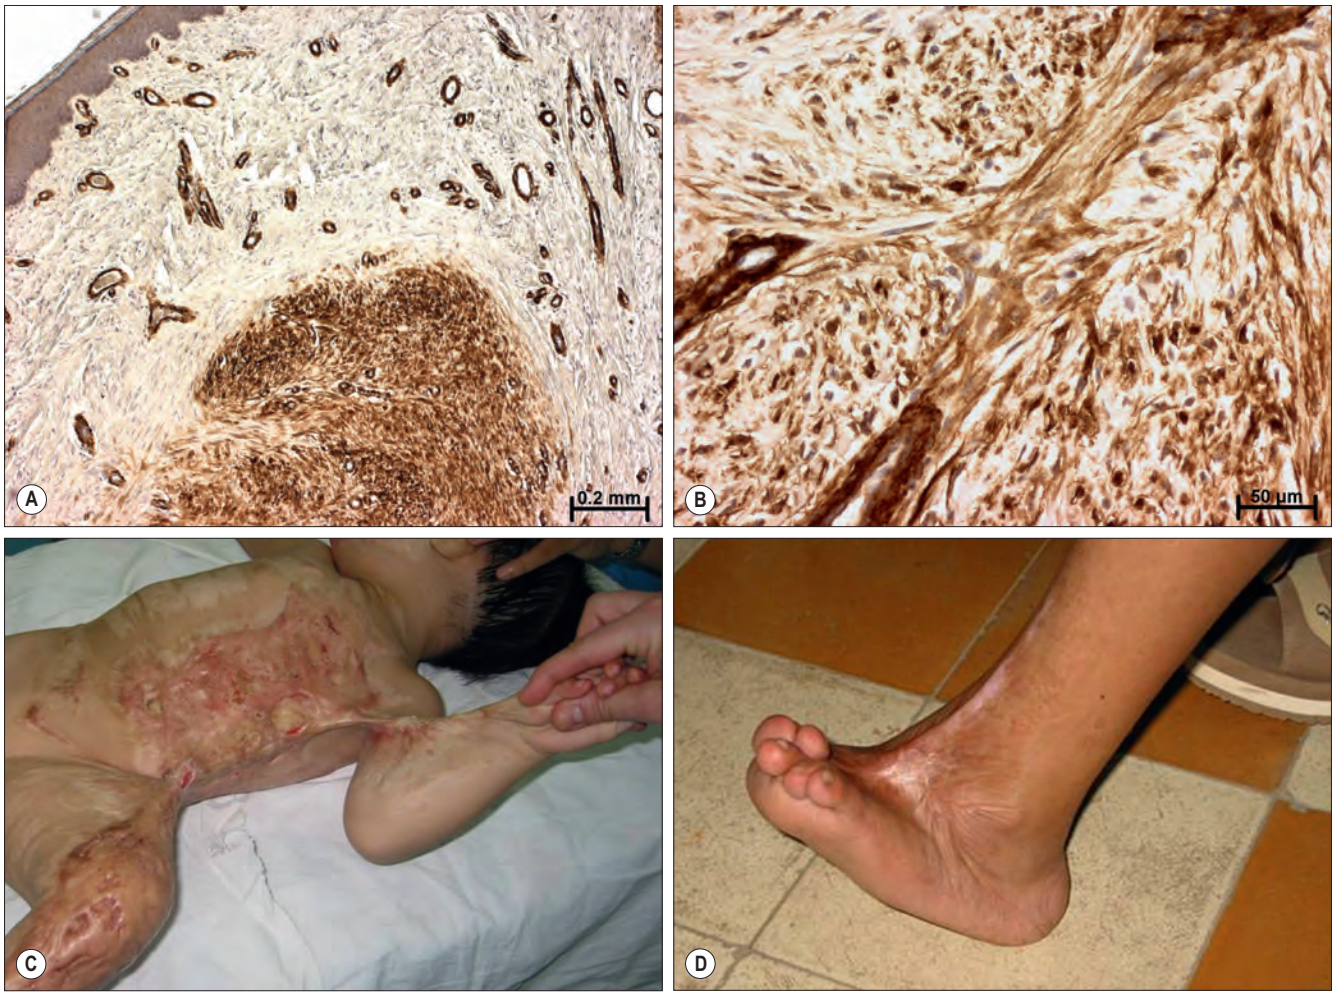

Fig. 45.6 Myofibroblasts in hypertrophic scars. In hypertrophic scar nodules myofibroblasts express large amounts of α-smooth muscle actin (A,B, immunohistochemistry for α-smooth muscle actin) and develop huge contractile activity in scars after burn injury (C,D) (From Desmoulière A; C,D are from Casoli P, Plastic Surgery and Burns Unit, University Hospital of Bordeaux, France.)

and during stroma reaction formation. However the degree to which this process contributes to fibrosis and stroma reaction in the skin remains a matter of intense debate and is likely to be context dependent. Altogether mesenchymal stem cells, fibrocytes, bone marrow-derived cells, and cells derived from EMT may represent alternative sources of myofibroblasts when local fibroblasts are not able to respond. These diverse cell types probably contribute to the appearance of myofibroblast subpopulations whose phenotype can be modulated by their interactions with neighboring cells and ECM.[93,94]

THE ROLE OF FIBROCYTES IN HYPERTROPHIC SCAR

Fibrocytes are a bloodborne, $CD14^+$ monocyte subpopulation[86] that mediate wound healing, first identified in 1994 by Bucala et al. in mouse wound chambers.[95] Although originally defined as collagen$^+$/vimentin$^+$/$CD34^+$ cells, other accepted markers include combinations of collagen$^+$ and $CD45^+$ or $LSP1^+$ markers.[87,96] Fibrocytes have been found in normal wound healing[86] and also in a wide variety of fibrotic diseases, including pulmonary fibrosis,[97] renal fibrosis,[98] and hypertrophic burn scars.[87] Fibrocytes traffic to wounds via a secondary lymphoid chemokine gradient, and differentiate under the influence of T cells and TGF-β.[86] It has been noted that $CD4^+$ T cells producing TGF-β are present in high levels in burn wounds,[99] where fibrocyte levels in burn patients are also increased.[100] In contrast, Pilling et al. demonstrated that fibrocyte differentiation is blocked by serum amyloid P (SAP), a constitutive plasma protein related to C-reactive protein, by using SAP to inhibit fibrocytes in a mouse bleomycin-induced pulmonary fibrosis model.[101] It appears that fibrocytes contribute to ECM formation and fibrosis through two mechanisms. Exposure to profibrotic cytokines causes fibrocytes to secrete collagen and differentiate into myofibroblasts via Smad2/3 and SAPK/JNK MAPK pathway activation.[102] Fibrocytes also modulate the activity of local fibroblasts in burn wounds via secretion of TGF-β and connective tissue growth factor (CTGF)[103] and may serve as a crucial link between healing wounds and the immune system. Like leukocytes, fibrocytes can act as antigen-presenting cells to prime naïve T cells[104] and also express Toll-like receptors, allowing them to function as part of the innate immune system.[105] Fibrocytes also induce revascularization of wounds through MMP-9 secretion, which degrades ECM and promotes endothelial invasion and the production of vascular endothelial growth

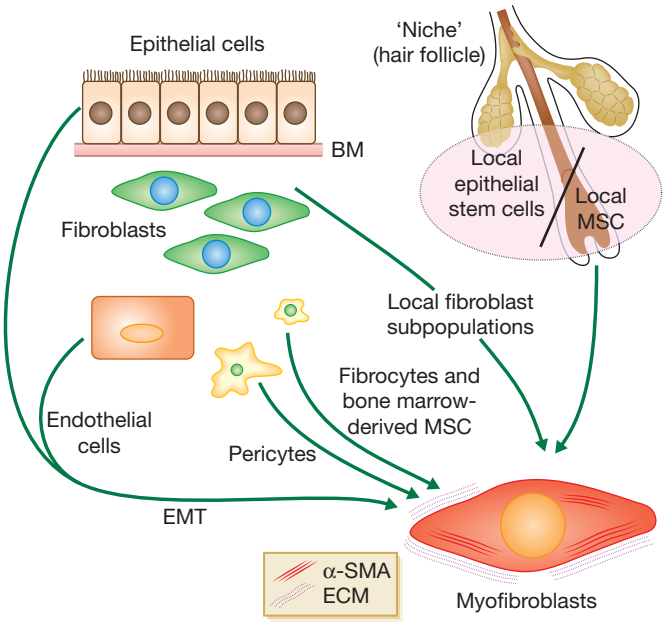

Fig. 45.7 Schematic illustration showing the different origins of the myofibroblast cells. Various cell types can acquire a myofibroblast phenotype; these diverse origins lead to distinct myofibroblast subpopulations. Circulating fibrocytes and bone marrow-derived mesenchymal stem cells (MSCs) are important sources of myofibroblasts when the dermis, source of local fibroblasts, is destroyed (second- and third-degree burns). A local source can also be local stem cells (both epithelial stem cells and MSCs forming a niche located at the level of hair follicles). The hypothesis suggesting that a major source of fibrosis- and tumor-associated myofibroblasts is through transdifferentiation from nonmalignant epithelial cells, from epithelial-derived carcinoma cells or from endothelial cells through epithelial- and endothelial-to-mesenchymal transition (EMT), requires further studies. SMA: smooth muscle actin; ECM: extracellular matrix. (From Desmoulière A.)

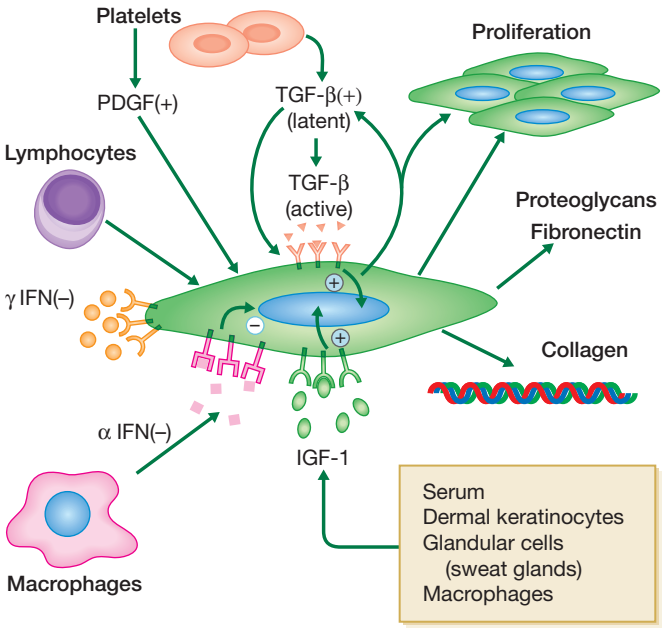

Fig. 45.8 Balance of pro- and antifibrotic cytokines in wound healing. The fibrogenic and antifibrogenic factors that modulate fibroblast function during wound healing. (From Tredget EE, Nedelec B, Scott PG, Ghahary A, Hypertrophic scars, keloids and molecular basis for therapy. *Surg Clin N Am*. 1997;77:701–730.)

factor.[106] Our understanding of fibrocytes as profibrotic mediators of wound healing continues to evolve, with several recent descriptions of alternate fibrocyte subpopulations[107] and the ability to reprogram fibrocytes into an antifibrotic phenotype.[108] Although this appears to complicate the fibrocyte picture, it does highlight the importance of systemic responses to wound healing and suggests that the initial cytokine signals that bone marrow-derived cells receive as they leave the circulation can have a significant impact on their role in HTS formation.

HYPERTROPHIC SCAR KERATINOCYTES

Keratinocytes are an important component of wound healing. Classically the remodeling phase of wound healing begins once reepithelialization of the wound is complete,[109] and wounds taking longer than 2 weeks to reepithelialize are more likely to form HTS.[110] Keratinocytes regulate fibroblast activity and vice versa,[109] suggesting that they play key roles in normal wound healing and HTS formation.[111] Experiments with keratinocyte-conditioned media in skin-equivalent models show that keratinocytes downregulate fibroblast production of the profibrotic cytokines TGF-β and CTGF.[112] Normally keratinocytes increase fibroblast proliferation but simultaneously reduce collagen production[113] and increase collagen breakdown by upregulating MMP-1 via factors such as stratifin.[114] In contrast, keratinocytes from HTS promote increased fibrosis in normal dermal fibroblasts,[72] display an activated phenotype similar to early wound-healing keratinocytes,[115] and have higher proliferation rates in the basal layer many months after reepithelialization is complete.[116] This may be due, in part, to elevated PDGF production by HTS keratinocytes.[117] This suggests that normal keratinocytes promote normal wound healing and abnormal keratinocytes promote HTS formation. It is also possible that HTS fibroblasts alter the normal wound-healing keratinocyte phenotype to a HTS phenotype, and these HTS keratinocytes in turn reinforce the HTS fibroblast phenotype. Thus therapies for HTS must address not only wound fibroblasts but also wound keratinocytes.

The Role of Cytokines in Hypertrophic Scar

Cytokines serve as signals for communication between cells, in paracrine signaling, and for cells to signal themselves in autocrine signaling. While the number of cytokines, and hence the diversity of signals, is immense, there are several key cytokines whose prototypic role in fibrosis and HTS has been extensively studied and whose actions account for a wide variety of fibroses. The roles of these cytokines are illustrated in Fig. 45.8.

TGF-β

TGF-β is one of the most studied profibrotic cytokines and belongs to a large superfamily of related proteins regulating processes as diverse as embryonic development, chemotaxis,

cell cycle, homeostasis, and wound healing. When produced by cells, TGF-β is secreted in an inactive form bound to latent TGF-β-binding protein. This bond is subsequently cleaved by enzymes in the milieu of healing wounds, including several matrix metalloproteinases (MMP-2, MMP-9) and plasmin (present in blood). Mammals produce three known isoforms: TGF-β_1, TGF-β_2, and TGF-β_3.[118] These are produced by many cells involved in wound healing, including degranulating platelets, macrophages, T lymphocytes, endothelial cells, fibroblasts, and keratinocytes.[119] The actions of TGF-β_1 and -β_2 are mediated by the intracellular Smad pathway and have directly profibrotic actions on mesenchymal cells.[120] TGF-β is upregulated locally in wounds and systemically in the blood of burn patients with HTS.[121] HTS fibroblasts produce greater amounts of TGF-β than normal fibroblasts[122] and regenerative fetal fibroblasts.[123] In fact, normally regenerative fetal fibroblasts can be induced to form scar following TGF-β exposure.[123] TGF-β has direct effects on the ECM by upregulating collagen production[124] and downregulating decorin production[125] by fibroblasts. This decrease in dermal decorin is profibrotic because decorin binds to TGF-β in the ECM, blocking its activity.[126] TGF-β promotes not only the transformation of fibroblasts into myofibroblasts[46] but also the transdifferentiation of epithelial cells into mesenchymal cells,[127] and it reduces apoptosis in the healing wound.[128] In this context, TGF-β is a highly profibrotic cytokine playing a unique role in HTS initiation. Interestingly, it has been suggested that the isoform TGF-β_3 acts as an antifibrotic cytokine. Clinical trials of TGF-β_3 have shown promise in improving wound healing,[129] and it is noteworthy that TGF-β_3, which is upregulated in the remodeling phase of wound healing, reduces ECM deposition.[130] Many effects of other cytokines in wound healing can be directly related to activation by or interaction with TGF-β.

CTGF/CCN2

Connective tissue growth factor (CTGF or CCN2) is a prototypic member of the CCN family of cytokines. The CCN family motif consists of four linked regions: an IGF-binding domain, a von Willebrand type C domain, a thrombospondin-1 domain, and a cysteine knot heparin-binding domain.[131] This configuration and multiple studies suggest that CTGF does not act simply as a growth factor, but rather as an important cofactor for TGF-β and as an interface between cells and the ECM by binding to cellular integrins and matrix proteoglycans.[132] Independent stimulation by TGF-β or CTGF alone induces only transient fibrotic upregulation in fibroblasts, whereas co-stimulation by both cytokines leads to prolonged fibrosis,[133] and in chronic fibrosis CTGF remains elevated after TGF-β returns to basal levels.[134] Thus one can surmise that TGF-β serves to initiate fibrosis and CTGF serves to continue the process as a downstream mediator of TGF-β.[124] In keeping with this hypothesis, CTGF is upregulated in HTS, scleroderma,[135] and other fibrotic diseases.[136] TGF-β induces CTGF through the Ras/MEK/ERK pathway, and blocking this activation with iloprost (a synthetic prostacyclin PGI_2 analog) reduces fibrosis.[137] Other methods of targeting CTGF, such as anti-CTGF antibodies and CTGF siRNA, have also proved effective in reducing fibrosis.[138]

PLATELET-DERIVED GROWTH FACTOR

PDGF is delivered to wounds by platelets from injured capillary vessels and is also produced by local fibroblasts.[139] There are four isoforms of PDGF: A, B, C, and D, which form dimers to activate two structurally related tyrosine kinase receptors[140] leading to fibroblast proliferation and actin filament reorganization that induces a transformation into myofibroblasts.[45] PDGF also increases ECM production and inhibits myofibroblast apoptosis.[141] PDGF activity contributes to pulmonary fibrosis, hepatic fibrosis, renal fibrosis, and scleroderma.[142] PDGF has been shown to upregulate TGF-β receptors in scleroderma fibroblasts,[139] and its multiple effects are magnified in HTS and keloid fibroblasts.[143] Recent research into the causes of nephrogenic systemic fibrosis, a disorder of dermal fibrosis occurring after gadolinium contrast administration in patients with impaired renal function, shows that blocking PDGF receptors using antibodies inhibits the proliferative effects of gadolinium on fibroblasts.[144] Other researchers have shown that blocking PDGF action using tyrosine kinase inhibitors reduces fibrosis in murine models of radiation-induced pulmonary fibrosis[145] and scleroderma.[146] Thus although PDGF is an independently profibrotic cytokine, it also serves to reinforce and magnify the effects of TGF-β, and blocking its activity can reduce fibrosis.

INSULIN-LIKE GROWTH FACTOR 1

Insulin-like growth factor 1 (IGF-1) was originally described in chondrocytes, where it regulates glycosaminoglycan production.[147] IGF-1 is a mitogen for fibroblasts[148] and endothelial cells,[149] and it induces collagen production in pulmonary[150] and dermal[151] fibroblasts. IGF-1 upregulates TGF-β gene transcription in fibroblasts, accounting for observed similarities in their profibrotic actions.[151] It has been shown that IGF-1 also downregulates collagenase mRNA levels and activity in dermal fibroblasts.[152] This increase in collagen production and decrease in breakdown shift the balance of ECM remodeling toward fibrosis. IGF-1 is upregulated in a number of fibrotic conditions, including post-burn HTS,[153] scleroderma, pulmonary fibrosis, and hepatic fibrosis.[5] Interestingly in unwounded skin IGF-1 is produced exclusively in epidermal sweat and sebaceous glands and is thus sequestered from dermal fibroblasts.[153] One may hypothesize that when these structures are disrupted, as in burns and other wounds, dermal fibroblasts are then directly exposed to IGF-1. Prolonged inflammation and delayed re-epithelialization would increase the duration of fibroblast stimulation with IGF-1 and could help explain the formation of HTS. Although IGF-1 is certainly not the only cause of HTS, its relationship to TGF-β and its unique distribution in skin suggest a key role in the pathogenesis of abnormal scarring.

INTERFERONS

HTS is not simply the result of overexpression of profibrotic signals, but also results from a disturbance in the delicate balance between pro- and antifibrotic cytokines. The interferons (IFN) are cytokines classically produced by immune cells to activate the host defense system.[154] IFNs

can be divided into type I (IFN-α and IFN-β produced by leukocytes and fibroblasts, respectively) and type II (IFN-γ produced by activated T lymphocytes).[154] Of these, the two antifibrotic cytokines whose roles in wound healing and HTS have been best studied are IFN-α_{2b} and IFN-γ. Treatment of fibroblasts with these IFNs inhibits cell proliferation and also downregulates collagen,[155] fibronectin,[155] and TGF-β production.[121] IFN-α_{2b} also upregulates collagenase production and reduces TIMP-1,[156] making it a good candidate to promote scar remodeling.[121] IFN-α_{2b} reduces in vitro collagen lattice contraction rates[157] and in vivo wound contraction in guinea pigs.[158] IFN-α_{2b} also reduces myofibroblast populations and increases the numbers of apoptotic fibroblasts in later stages of wound healing,[158] a finding also demonstrated in several other cell types.[159,160] A prospective clinical trial of IFN-α_{2b} in post-burn HTS patients demonstrated reductions in scar volume, normalized TGF-β levels, and reduced scar angiogenesis.[121] It is suggested that abnormal scar results, at least in part, from reduced levels of endogenous IFN in burn patients. An examination of the peripheral blood mononuclear cells (PBMCs) of patients forming keloids after trauma compared to those with normal scarring showed decreased production of IFN-α and IFN-γ,[161] which is consistent with this hypothesis. Therefore an understanding of IFNs highlights the important balance between pro- and antifibrotic cytokines and suggests possible therapeutic treatments for HTS.

The Immune System Regulates Wound Healing

Mast cells, neutrophils, and macrophages have long been recognized as playing important roles in the inflammatory phase of wound healing.[162] Macrophages produce classic immune cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor-α (TNF-α), which stimulate keratinocytes and fibroblasts,[45] and classic profibrotic cytokines TGF-β, PDGF, and IGF-1.[163] Recently the importance of the immune response type rather than degree of inflammation in determining the risk of HTS formation has been recognized. HTS are highly infiltrated by lymphocytes,[6] of which activated $CD4^+$ T-helper (T_H) cells are an important subgroup.[99] These T_H cells can be generally classified as one of at least four groups: T_H1, T_H2, T_H17, and T-regulatory cells, based on cytokine production patterns.[164] Of these, the T_H1–T_H2 axis in wound healing and burn patients is the most studied. T_H1 cells produce IFN-γ, IL-2, and TNF-β and are involved in cell-mediated immunity, whereas T_H2 cells produce IL-4, IL-5, and IL-10 and are involved in antibody-mediated

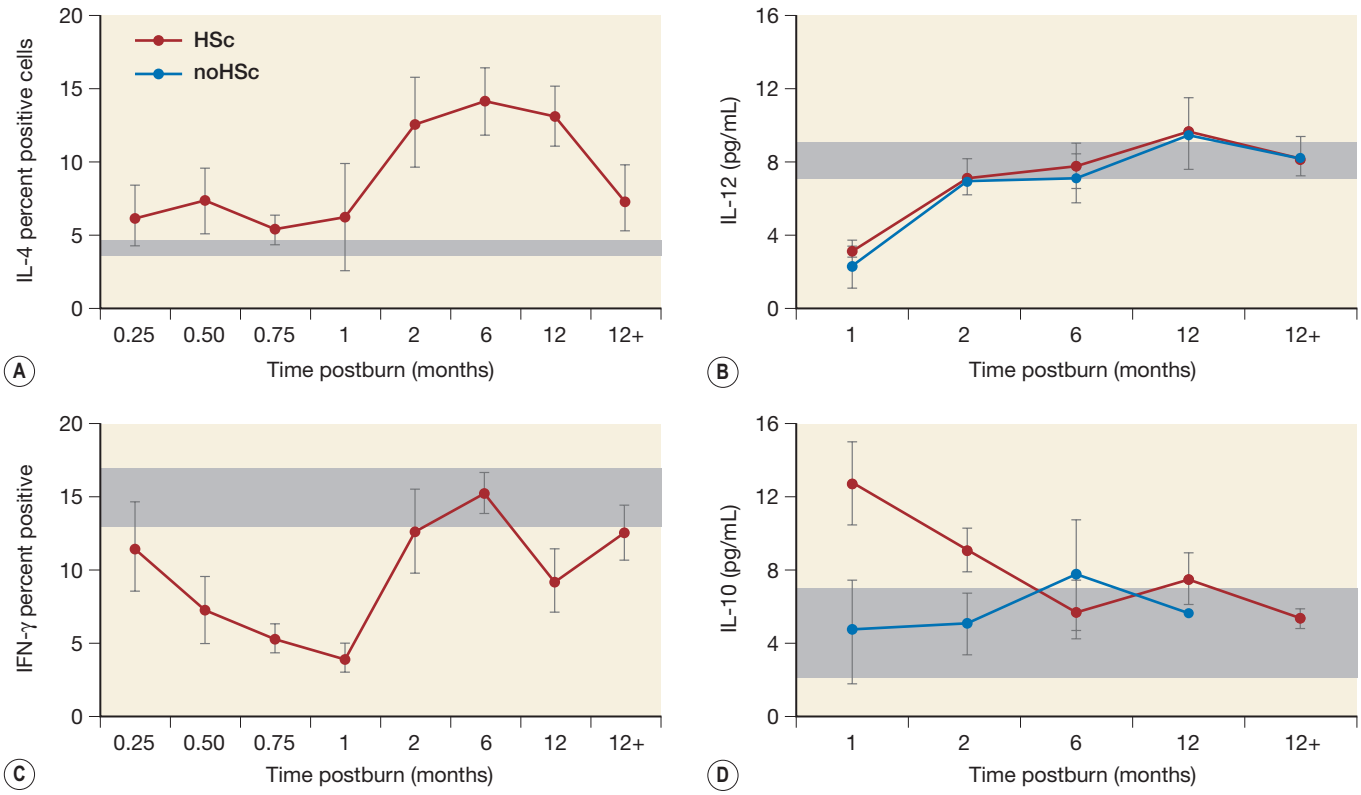

Fig. 45.9 Cytokine production in burn patients. Cytokine production by lymphocytes from burn patients as a function of time after injury. The percentages of lymphocytes producing IFN-γ (A) or IL-4 (C) were estimated by flow cytometry analysis of cells stained for intracellular cytokines using fluorescent-labeled antibodies (n = 22). Panels B and D show the time course of IL-12 (B) and IL-10 (D) production by peripheral blood mononuclear cells (PBMCs) cultured from burn patients who developed hypertrophic scar (HSc) and those who did not (noHSc), measured by enzyme-linked immunosorbent assay (ELISA: n = 16). The values measured for cells from normal human volunteers are shown in the shaded boxes (mean ± SD). (From Tredget EE, Nedelec B, Ghahary A. Hypertrophic scar, keloids and contracture: The cellular and molecular basis for therapy. *Surg Clin N Am*. 1997;77(3):701–730.)

immunity.[165] Interestingly these cytokine profiles are involved not only in specific immune responses, but are also anti- or profibrotic.[166] The T_H2 cytokine IL-10 stimulates activated naïve T_H cells to secrete TGF-β, and this is more pronounced in IFN-γ (T_H1) knockout mice and reduced in IL-4 (T_H2) knockout mice.[167] In a burn mouse model T_H2 cytokines (IL-5) were upregulated and T_H1 cytokines (IFN-γ and IL-2) were coordinately downregulated.[168] A similar T_H2 type response is seen in human burn patients using stimulated PBMC from those with burns of 25% or more total body surface area (TBSA),[169] a finding confirmed by another study in burn and major trauma patients.[170] The severity of fibrosis in animal models has also been linked to the type of T_H-cell response. In a model of liver fibrosis BALB/c mice developed a T_H2 response to chemically induced liver injury and displayed more severe fibrosis than did C57BL/6 mice, which developed a T_H1 response. This effect was abrogated by administration of IL-4 antibodies or IFN-γ, which induced a T_H1 response in the BALB/c mice.[171] A longitudinal study of recovering burn patients demonstrated a predominant T_H2 response to burn injury, as demonstrated by increased IL-4 and IL-10 levels from PBMC and in scar tissue (Fig. 45.9). Interestingly this response was significantly higher in burn patients who went on to develop HTS than in those who developed normal scars, whereas those patients developing normal scar had higher levels of IFN-γ-producing PBMC.[172] Recently it was found that IFN-α blocks T_H2 development and inhibits cytokine secretion by committed T_H2 cells.[164] This suggests that IFN-α_{2b} has effects not only on fibroblasts, as discussed previously, but also the T_H2 cells that modulate them.

Conclusion

HTS is a fibrotic disorder resulting from derangement of the normal wound-healing process and shares many common features with other fibrotic diseases. As discussed, HTS is markedly different from normal skin and mature scar in terms of the structure and composition of ECM, active cellular phenotypes, and cytokine messages displayed. This results in a mass of disorganized connective tissue with thin, irregular collagen bundles in whorls and nodules instead of thick, organized fibers parallel to the surface. The concomitant decrease in decorin and increase in other proteoglycans not only contributes to this disorganized ECM but also allows profibrotic signals to propagate in the dermis. The fibrotic, hypercellular nature of HTS both contributes to and results from elevated profibrotic (e.g., TGF-β, CTGF) and decreased antifibrotic (IFN-γ) cytokine levels. The resulting local HTS fibroblast is modulated by systemic fibrocytes and T_H cells, which migrate to the wound. The resulting pathogenesis of HTS is complex, with many aspects that serve to reinforce the fibrotic process. Although this complexity makes elucidating the mechanisms of HTS formation difficult, it also provides multiple targets for medical therapy. It is our hope that this will provide therapies to improve the quality of life for both burn patients and others with fibroproliferative conditions.

46 Pathophysiology of the Burn Scar

HAL K. HAWKINS, JAYSON JAY, and CELESTE C. FINNERTY

Introduction

PREHISTORIC AND HISTORIC PERSPECTIVES

Wounds due to combat, hunting injuries, accidents, and thermal injuries have been the leading causes of death in humans for millennia, whereas prolonged survival of large full-thickness wounds is a recent phenomenon. Complex biological responses to cutaneous injury have evolved over time without evolutionary pressure to evolve appropriate healing responses to large wounds. There are records of human attempts to improve wound healing in ancient texts from Mesopotamia and Egypt. Guido Majno has explored what can be learned from archeology and paleontology regarding wounds and their treatment in ancient times and provides an accurate description of the wound healing process in lay terms.[1] In the development of modern medicine, the advances in wound treatment advocated by Ambroise Pare (1520–1590) stand out, together with the antisepsis campaign of Joseph Lister (1827–1912) and the development of antibiotics and other modern methods of treatment described in this book.

INCISIONAL WOUNDS WITH PRIMARY CLOSURE

The essential components of wound healing are easily understood. They are: (1) activation of tissue repair in the wound by fibroblasts and small blood vessels and an inflammatory response initiated by vascular leakage and (2) entry into the wound of circulating polymorphonuclear neutrophils, lymphocytes, and macrophages.[2] When a sharp incision is closed while still sterile, minimal vascular leakage and inflammation occur, and the predominant reaction to injury occurs in the fibroblasts present in the dermis and subcutaneous tissue. These resting connective tissue cells are rapidly activated to secrete collagen, which quickly bridges the small remaining gap to restore the resistance of the skin to tearing. Vascular continuity is restored by budding and remodeling of blood vessels, and the basal keratinocytes of the epidermis divide briefly to restore the complete structure of the epidermal barrier. All that remains to indicate the site of injury is a linear ribbon of dense collagen with little flexibility that marks the site of the incision, as well as small scars that mark the suture sites. This process of incisional wound healing was well described in humans by Ross and colleagues.[3,4]

DELAYED WOUND CLOSURE "BY SECOND INTENTION" AND WOUND CONTRACTION

If the epidermis and dermis are incised or removed and the edges of the wound remain separated, then the resultant inflammatory and reparative events are prolonged and more prominent. Extensive leakage of blood plasma by damaged small blood vessels maintains an outward flow that serves to keep the wound clean but causes deposition of coagulated fibrin and other desiccated proteins on the wound surface. Conversion of fibrinogen into fibrin fills the gap in the epidermis and provides a gelatinous matrix capable of sustaining migrating cells. Thrombin stimulates expression of interleukin-6 (IL-6) in connective tissue cells.[5] Degranulation of platelets releases platelet-derived growth factor (PDGF) and other proinflammatory cytokines.[6] Fibrin degradation releases peptides that stimulate fibroblast proliferation and secretion, division of vascular endothelial cells, and production of cytokines by other cells.[7–9] Dermal fibroblasts, together with circulating stem cells, divide rapidly in the wound bed and secrete large quantities of collagen and proteoglycans, with predominance of type III collagen.[10,11] Simultaneously the endothelial cells of small blood vessels proliferate rapidly and form numerous small capillary loops that extend upward toward the surface. Together these cells form a mass of granulation tissue that covers the wound. These activities of fibroblasts and endothelial cells are stimulated by cytokines and other peptides, largely secreted by monocytes and lymphoid cells that infiltrate the wound bed. Certain proteins and peptides that are normally present in blood plasma also stimulate and enable formation of the wound matrix, notably fibronectin and vitronectin.[12–14] Polymorphonuclear neutrophils also enter the wound bed in large numbers where they phagocytize and kill bacteria and fungi that gained entry to the dermis and subcutis through the open wound. Next the fibroblasts develop interconnections among themselves and produce and assemble the contractile machinery of actin and myosin within the cytoplasm of each cell.[15] These interconnected myofibroblasts contract to shrink the size of the open wound, pulling adjacent intact skin to cover the wound bed. Wound contraction is most dramatic in experimental wounds of rodents; however the effects of wound contracture in applying tension to surrounding tissues can be seen in humans as well. Simultaneously with these processes, the basal keratinocytes of the cut edges of the epidermis proliferate and change to a migratory and secretory phenotype and begin to invade the wound bed between the granulation tissue layer and the scab of dried proteins on the surface.[16] Once they make contact to seal the center of the wound, the migrating keratinocytes change phenotype again and restore the normal laminated structure of the epidermis and produce a new basal lamina.[17,18] Melanocytes also migrate during healing of large wounds and establish a degree of pigmentation in the healed wound that approximates the pigmentation of the uninjured skin. It

should be noted that only the epidermis regenerates to resemble the normal epidermis. Hair follicles, sweat glands, and other epidermal appendages do not regenerate. Thus the part of the wound that was not closed by contracture remains dry, hairless, and flat. Furthermore the restored dermis in a fully healed scar is composed of collagen type I fibers running in straight lines adjacent to one another and parallel to the surface, providing strength (though somewhat less than the native skin) but far less elasticity and flexibility than the connective tissue of the normal dermis.

FIRST-DEGREE OR SUPERFICIAL INJURY OF SKIN

Superficial burn wounds are those in which part or all of the epidermis is lost, but the epidermal basal lamina remains intact and the dermis is uninjured. In these areas, only epidermal regeneration is required, hair follicles and sweat glands remain intact, and healing can occur with little or no disfigurement.[19]

SECOND-DEGREE OR PARTIAL-THICKNESS INJURY

In partial-thickness wounds, the entire epidermis and the upper part of the dermis become necrotic. If left intact, the presence of a large quantity of devitalized tissue requires prolonged activity of macrophages to clear the necrotic debris. Granulation tissue forms underneath the necrotic dermal tissue, and epidermal migration occurs under the eschar formed by dead tissue, leading to restoration of the epidermis and production of dermal connective tissue in the form of a thin scar. The deep portions of the hair follicles remain viable, and the keratinocytes lining the hair follicles become migratory and undergo mitosis behind the migrating cells, eventually covering the surface with new epidermis derived from the hair follicle.[16,20] In severe cases, loss of hair follicles may lead to insufficient regenerative activity to cover the surface.[21–23] Multipotent stem cells within the hair follicles generate cells that can multiply, migrate, and regenerate the surface epidermis.[24] The stem cell population that was first identified is slowly cycling, expresses the conventional stem cell surface marker CD34, and resides in the bulge region of the follicle near the attachment of the arrector pili muscle.[25,26] More recently, additional stem cell populations have been identified that reside in the isthmus region and the hair germ region of the follicle and express distinct markers.[27–29] Much is being learned about the function of these stem cells by studying knockout and overexpressing mice. The changes in follicular stem cells during healing of burn wounds, however, remain to be described.

One new aspect of hair follicle biology that is of great interest for burn surgeons is the delineation of the role of the dermal papilla, the tiny cluster of mesenchymal cells within the hair bulb.[30] Fetal development of hair follicles depends on interaction between epithelial cells of the epidermis and mesenchymal cells. The mesenchymal cells of the dermal papilla, which can be amplified in culture using keratinocyte-conditioned medium, can induce formation of hair follicles from interfollicular skin. Formation of new hair follicles, complete with hair, has been induced in hairless nipple skin of the mouse and in the renal capsule.[31,32] Since one of the major problems in long-term care of burn patients is alopecia, the possibility that hair follicles could be induced to regenerate is very appealing.[33]

THIRD-DEGREE OR FULL-THICKNESS INJURY

In full-thickness burns, thermal injury extends deep enough to destroy all of the hair follicles that have the capacity to regenerate the epidermis and some of the upper subcutaneous tissue may also become necrotic. In this case regeneration of the epidermis from hair follicles is not possible, and the wound can develop an epidermal covering only slowly as the epidermis lateral to the wound spreads out over the entire wound surface.[2] During this time, the necrotic tissue in the wound bed is at risk of infection, and extensive activity of tissue macrophages is required to eventually remove it.

Biology of Wound Healing

CHANGES IN VASCULAR PERMEABILITY

In order to review current understanding of the processes important in wound healing, each will be considered separately. Changes in local blood vessels are the earliest component of the wound's response to injury and are essential for the succeeding steps. Plasma exudation is due to increased permeability of venules to proteins, largely due to local release of histamine and vascular endothelial growth factor (VEGF) from mast cells and substance P from local sensory nerve endings. With burn injury, there is an added component of plasma leakage that occurs for several hours throughout the body in response to unknown stimuli. Of course, both plasma and red blood cells enter the wound through broken or necrotic blood vessels. Infection triggers further plasma exudation by constantly stimulating and prolonging the vascular phase of acute inflammation. Additionally the newly formed capillaries of granulation tissue allow passage of plasma proteins and fluid until they mature. Certain plasma proteins, notably fibronectin and vitronectin, are important in stimulating reparative responses in the wound.

GRANULATION TISSUE AND THE PROLIFERATIVE PHASE OF WOUND HEALING

Massive proliferation of fibroblasts and vascular endothelial cells is characteristic of the early phase of wound healing. These cells, and the fine fibrils of collagen and the gel provided by mucopolysaccharides and proteoglycans, make up the granulation tissue that is a major feature of all wounds that remain open. The most important of many peptides that stimulate fibroblast growth appear to be transforming growth factor-β (TGF-β) and basic fibroblast growth factor (bFGF/FGF2), whereas the most important peptide that stimulates growth of endothelial cells appears to be VEGF.[34–39] In order for wound contraction to occur, fibroblasts form networks within the dermis that allow the wound to contract. Interactions between the extracellular matrix and the cellular cytoskeleton are important in controlling cellular differentiation and function.[40–42] When

wound healing is abnormal and hypertrophic scars (HTS) develop, this process of interlinking fibroblasts to form a meshwork that supports tension parallel to the surface is disrupted since nodules of collagen result that do not flatten out normally.

INFLUX OF CIRCULATING CELLS

Many circulating cells actively migrate into wound beds and play roles in defense against bacteria and fungi, clearance of devitalized tissue components, and stimulation of later phases of healing of the dermis and epidermis. Based on experiments with partially selective ablation of individual cell types, the cells most important in stimulating and maintaining tissue repair appear to be the T lymphocytes and monocytes.[43] Monocytes, which differentiate into tissue macrophages, are responsible for synthesis and release of many of the cytokines important in wound healing, as are connective tissue cells and epithelial cells. Mast cell abundance increases in the healing wound, and mediators secreted by the mast cells recruit neutrophils and other circulating inflammatory cells to the wound. At the same time, mast cells induce an inflammatory response in the healing tissue by acting on keratinocytes. In addition, circulating stem cells enter healing wounds, where they can differentiate to form fibroblasts and other connective tissue cells needed to restore tissue integrity.[44,45]

MIGRATION OF KERATINOCYTES TO COVER THE WOUND (EPIBOLY)

When the epidermis is transected, changes take place rapidly in the basal cells of the epidermis adjacent to the wound. The process of epidermal regeneration has been well studied by Stenn and his colleagues.[16,46,47] Altered basal keratinocytes send out thin sheets and undergo ameboid motion not over the wound bed, but under the nonviable eschar and/or scab, secreting a provisional matrix as they go.[48,49] Development of this migratory phenotype is stimulated by the plasma protein vitronectin and requires the presence of albumin as a cofactor.[16,47,50] Cell division occurs to support this migration, not among migratory cells, but among their precursors in the residual epidermis. Similar processes stimulate migration and replacement of epithelial cells from hair follicles in partial-thickness wounds. After a sheet of epithelial cells is established over the entire wound surface, they begin to divide and eventually create a multilayered stratified squamous epithelium with a granular layer and keratinization. Epidermal cells secrete substantial quantities of IL-1β and other cytokines.[51,52] The new proliferative epidermal basal cells also secrete a new basal lamina composed of laminin, type IV collagen, and bullous pemphigoid antigen; adhere tightly to that basal lamina; and develop attachments of type VII collagen between the basal lamina and the underlying fibers of type I collagen in the scarred dermis. Also, just after the newly formed epithelial layer completely covers the wound, the phenotype of the connective tissue cells in the matrix undergoes a series of changes and much less fibronectin is found in the wound matrix.[17] As noted earlier, in second-degree burns, epidermal cells from the hair follicles regenerate the epidermis on the surface.

COLLAGEN MATRIX FORMATION AND MATURATION

Scars gradually increase in their strength, as measured by their resistance to tearing, but never reach the strength of normal dermis. During this process, the delicate fibers of newly secreted collagens I and III are replaced by large collagen I fibers that are oriented parallel to each other and to the skin surface (Figs. 46.1 and 46.2). Maturation of collagen fibers is largely a chemical process of remodeling that involves covalent crosslinking of adjacent polypeptide chains. Collagen fibers normally form and are degraded continuously in normal skin and in scars, but the processes that control the rates of formation and degradation and the orientation of the mature fibers are not fully understood. Prolonged activation of the keratinocytes in the wounds leads to reduced regulation of fibroblast collagen production by the keratinocytes and prolonged inflammation, both of which contribute to fibrosis. At the same time, mast cells act to induce fibrosis through the release of histamine, tryptase, and chymase, which stimulate collagen production, procollagen synthesis, and procollagen cleavage, respectively.

CYTOKINES AND GROWTH FACTORS

Many short polypeptides, mostly cytokines and growth factors, are responsible for the changes in cells that lead to the stages of wound healing, including the transition from the inflammatory to the proliferative phases, and the formation and organization of a scar, or the maturation phase. Among the most important are TGF-β, bFGF, platelet-derived growth factor (PDGF), and VEGF.[53–60] Frequently the response of a particular cell type to a specific mediator depends not only on binding to the precise cell surface receptor, but also on simultaneous signals from other cellular receptors. Thus the network of peptide signaling is complex, and the range of possible cellular responses is large enough to allow generation of complex structures and considerable fine-tuning.[56,61] There are many opportunities for reparative processes to go wrong, to proceed in an unbalanced fashion, or to fail to complete an appropriate cycle of activation and regression.[62–64]

BIOPHYSICS OF THERMAL INJURY

Human skin cells die when their temperature is increased, largely because of the sensitivity of the cell surface membrane to disruption outside fairly narrow temperature limits. Flame, electrical, and contact burns often lead to pyrolysis and disruption and oxidation of some tissues as well. Among the various cell types present in the skin, some are likely to be more sensitive to temperature than others. The degree of temperature elevation at a given site in the skin also depends on the rate of heat transfer within the tissue. The thermal conductivity of the dermis is much greater than that of the subcutis since fat is a good insulator. Perhaps for this reason thermal injury often leads to necrosis of the entire dermis with little cell death in the subcutis, as seen in wound biopsies. Hair follicles in some sites typically extend well beyond the dermis into the adipose tissue of the upper subcutis, and eccrine sweat glands are also often present in the subcutaneous fat. Despite the

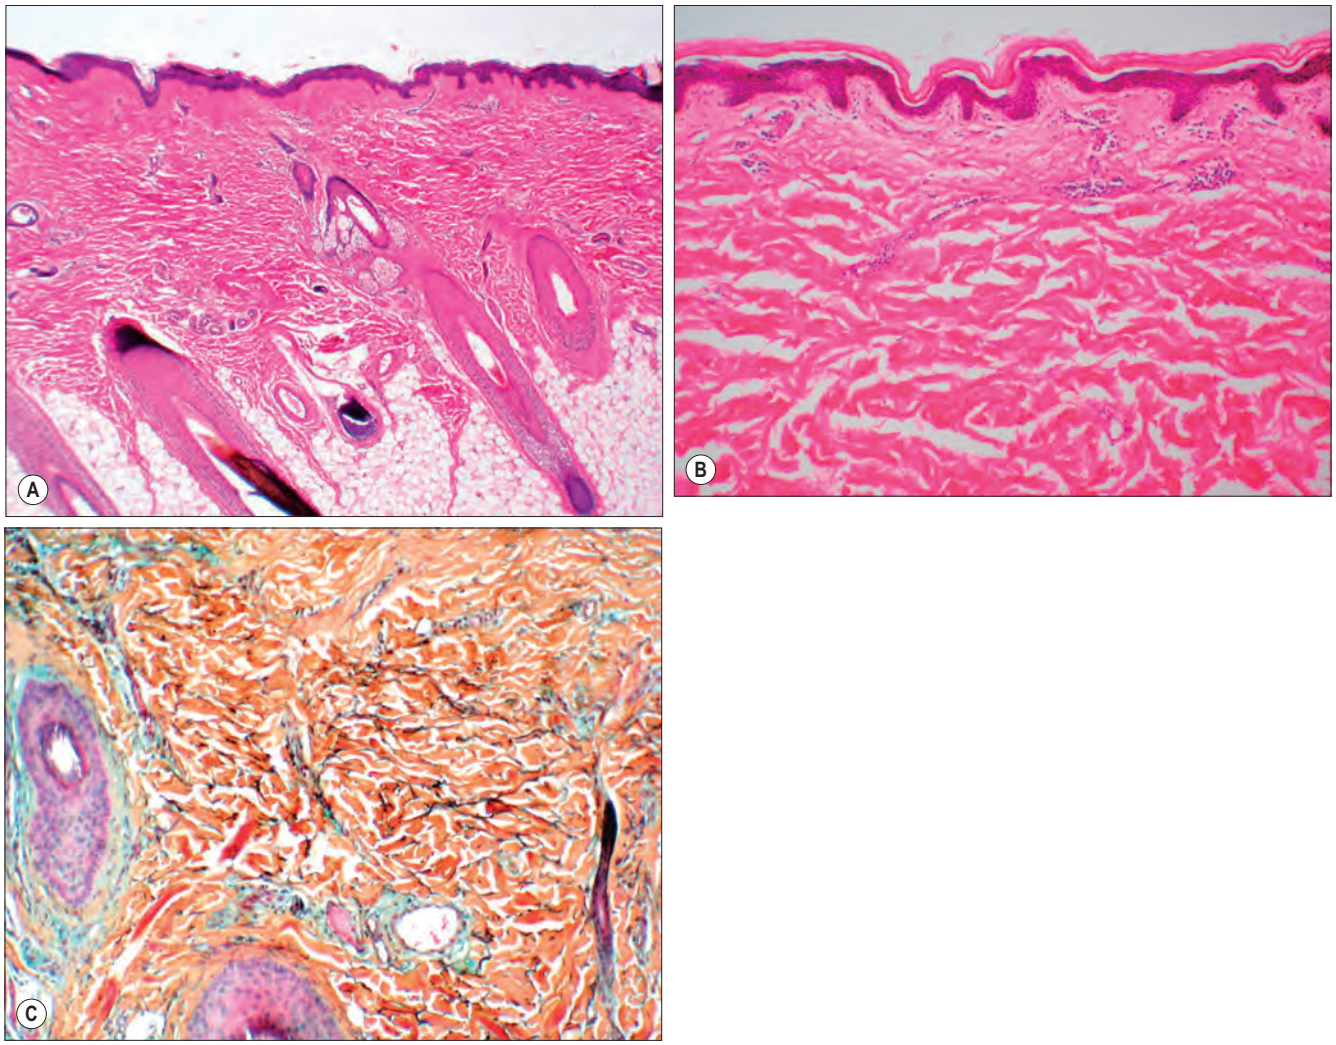

Fig. 46.1 Photomicrographs of normal skin, stained with hematoxylin and eosin. (A) The hair follicles often extend through the dermis into the subcutaneous adipose tissue. The epidermis forms irregular rete ridges at its base. (B) The reticular dermis of normal skin has an orderly arrangement of collagen fibers with no preferred orientation. (C) With the Movat pentachrome stain, normal collagen fibers stain yellow-orange, and delicate interconnecting black elastin fibers are present between collagen fibers.

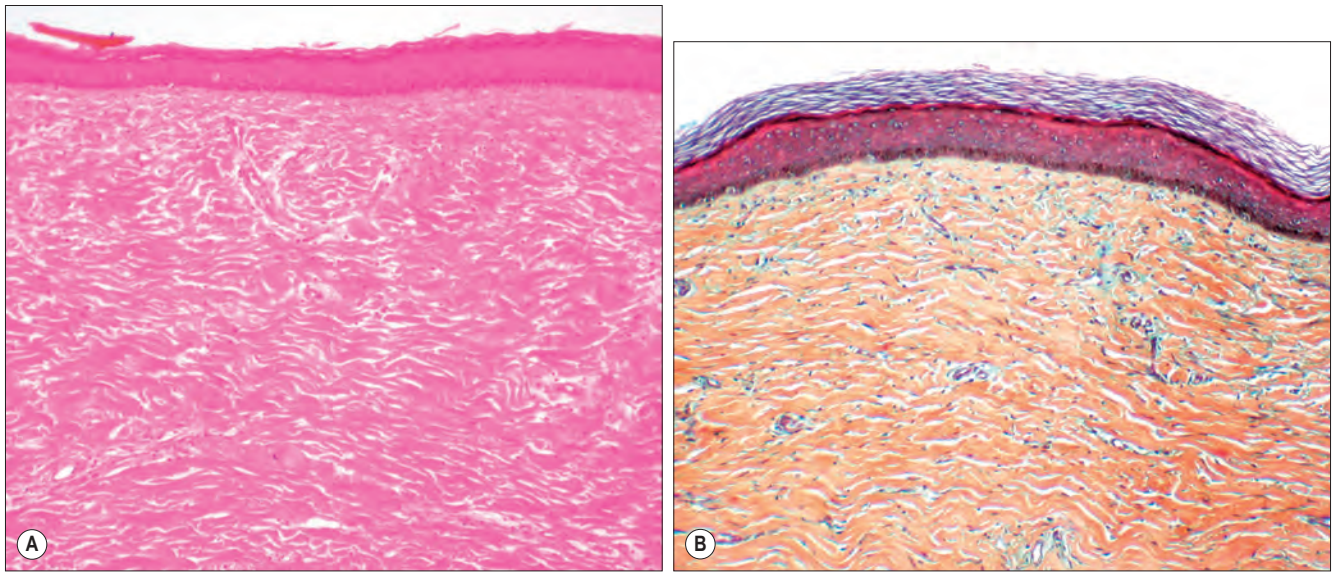

Fig. 46.2 (A) In a normal flat scar, the epidermis is flat and does not have any rete ridges and the dermis is replaced by collagen fibers that are oriented parallel to the skin surface. (B) A Movat pentachrome stain of a normal scar shows mature collagen fibers stained yellow-orange and does not demonstrate any elastin fibers.

presence of adipose tissue around follicles, regenerative capacity is frequently entirely destroyed by burns even though there is little or no apparent necrosis in the upper subcutis. In the most severe burns, however, the entire subcutis may become necrotic, and cell death may occur in the underlying fascia and skeletal muscle or even in underlying internal organs.

Factors That Alter Wound Healing

CHANGES IN BLOOD SUPPLY AND PERFUSION

The study of local blood supply by ultrasound led to the discovery that there is usually a zone of greatly increased blood flow below a burn wound, which is not surprising as part of a local inflammatory response to tissue injury. Above this zone of hyperemia is a zone of tissue ischemia, in which blood flow is less than normal. Remarkably, during the first 24 hours after a burn wound, the zone of ischemia typically becomes significantly deeper, indicating that ischemic injury of dermal tissues actually leads to a depth of tissue necrosis greater than that produced by the immediate thermal injury.[65] Experiments in animals have shown that neutrophils are involved in this progressive ischemic cell death in injured but viable tissue deep to a burn wound.[66] Altered blood flow may lead to vascular thrombosis in a burn wound, also contributing to the risk of ischemic tissue injury. In normal skin, there is a plexus of arteries and veins immediately below the dermis in the upper layer of subcutaneous adipose tissue. This subdermal plexus is at risk of thrombosis in deep partial-thickness burns and in full-thickness burns, and it is vulnerable to damage in the process of tangential wound excision, with further loss of blood supply to the wound.

COMPROMISED WOUND HEALING: REQUIREMENTS FOR OPTIMAL WOUND HEALING

Long clinical experience has demonstrated clearly that wound healing is greatly slowed and impaired when there is deficiency of essential ingredients for construction of the scar or of an adequate energy supply. Vitamin C deficiency and protein-calorie malnutrition are characterized by deficient wound healing, and provision of sufficient calories and reversal of the usual protein catabolism are major goals of general burn care. Vitamin D deficiency can impair wound healing, whereas vitamin D addition increases migration of fibroblasts and collagen production. Diabetic vasculopathy is associated with deficient wound healing, demonstrating the importance of an adequate microcirculation. Heart failure similarly compromises wound healing. Radiation, cigarette smoking, and hypoxemia also have been associated with delayed wound healing.[67] Advanced age is associated with increased mortality from large burns but does not in itself prevent good wound healing.[19,68]

BIOLOGIC RESPONSES TO WOUND EXCISION AND GRAFTING

The current standard of treatment in our institution is early excision of the burn wound, normally within 24 hours of admission, with removal of all necrotic tissue using either tangential excision to leave most of the subcutaneous fat or fascial excision which removes the entire subcutis. The wound is initially covered with meshed cadaver skin from the skin bank. Within a few days autografting is done using meshed partial-thickness grafts from unburned regions. Over the face and the hands, unmeshed sheet autografts are often used to obtain the best cosmetic result. The epidermis of the cadaveric homograft slowly degenerates, but the dermal matrix often is incorporated into the healing wound. The interstices of the autograft fill with granulation tissue derived partly from the underlying fibrous or adipose tissue and partly by migration of fibroblasts from the strands of autograft. The autograft's epidermis migrates over the granulation tissue matrix, under the fibrin layer, and reconstitutes the epidermis without any follicles or other epidermal appendages. The pattern of the meshed grafts is usually visible in the healed wound. The incorporation of dermal connective tissue elements from the donor site may enhance the pliability of the final scar. Occasionally epidermal inclusion cysts develop within grafted burn wounds, and they may rupture. These cysts could develop from residual hair roots that had lost their connection to the surface, from aberrant migration of epidermal cells during wound resurfacing, or from trapping of epidermis by expanding connective tissue. In addition, tiny bits of hair shaft are sometimes encountered in healing wounds, associated with a giant cell foreign body reaction, perhaps representing hairs left behind after necrosis of the hair follicles that originally produced them.

WOUND INFECTION

Bacterial infection frequently complicates wound healing. The risk is increased in burn patients since large amounts of necrotic cells and tissue are present in the wound and provide a good culture medium for bacteria. When infection occurs, the inflammatory component of wound healing is greatly amplified and the processes of conversion of granulation tissue to a dense scaffolding of collagen, wound contraction, and regeneration of the epidermis are all delayed. Frequently the wound suppurates. Some bacteria cause additional tissue necrosis, and some bacteria can invade into normal tissues, leading to hyperemia around the original wound and/or enlargement and deepening of the original wound. In response to the bacterial infection and the enhanced inflammatory reaction, the cytokine milieu of the wound is altered.[69–71] Grafts placed over wounds with residual infected tissue typically do not take, and when large numbers of bacteria are present deep in the wound bed there is always the hazard that the bacteria may enter the bloodstream, incite septicemia, and invade remote tissues. These processes, which were common in the era before antibiotics and before the practice of early wound excision became common, are now being seen again due to infection with highly antibiotic-resistant strains of bacteria, particularly *Pseudomonas* and *Acinetobacter*.

Hypertrophic Wound Healing

In most patients with large burns treated in our institution, healing of the burn wounds is complicated by development

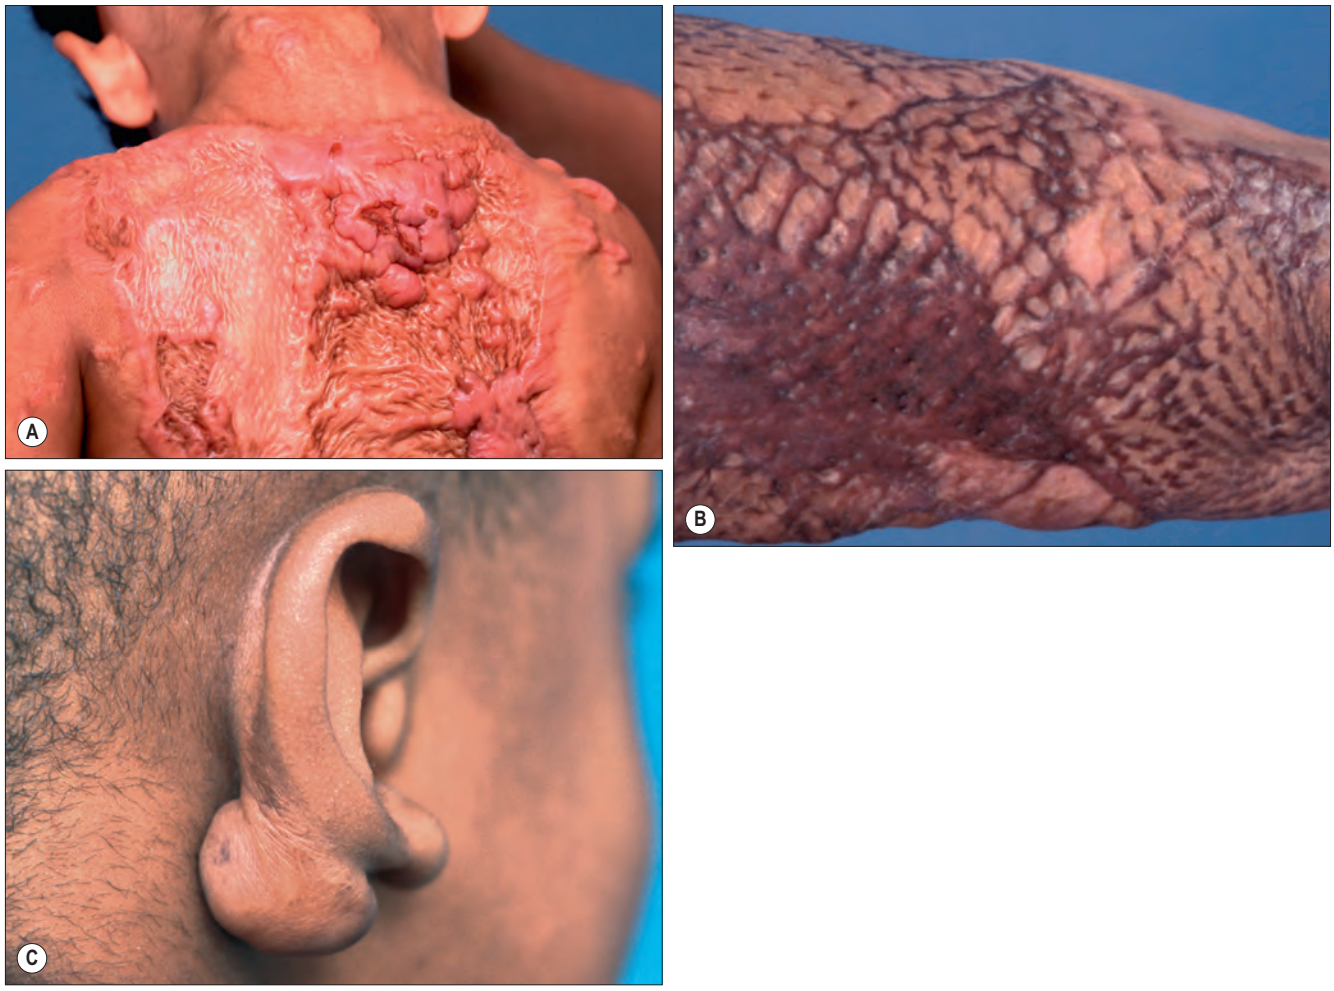

Fig. 46.3 Typical appearances of hypertrophic scars of burn patients. (A) The hypertrophic scar is raised above the surrounding normal skin, has sharp borders, and is very firm to the touch. This scar recurred after complete excision. (B) Hypertrophic scars often have patterns corresponding to meshed grafts and often are hyperpigmented, as shown here, or hypopigmented. (C) This round firm lesion developed from a minor burn on the patient's ear. It did not recur after excision.

of elevated, thick, firm, reddish scars that itch constantly. These hypertrophic cicatrices occur more commonly in wounds that had become infected or took longer than usual to become fully covered. They may cover large areas, but do not usually extend beyond the original burn wound. These abnormal wounds also are associated with more severe wound contraction. In the great majority of affected cases, these HTS enlarge for a period of months, then gradually regress over a period of a few years, eventually becoming flat scars with no further symptoms. In wounds that develop HTS, there are often abnormalities of skin pigmentation, either depigmentation or hyperpigmentation, that evolve over time (Fig. 46.3). The largest HTS impairing function are surgically excised, often with creation of Z-plasties or sheet grafting to release scar contractures or the use of lasers to ablate the scar. Generally new HTS do not develop again. There does not appear to be a link with ethnicity for this type of hypertrophic scarring, which occurs in about 75% of Caucasian, black, and Hispanic patients.[72]

Clearly this experience is quite different from that described in the literature with keloids, which frequently occur spontaneously or in response to puncture wounds or clean incisions that were closed primarily.[73–75] Keloids extend beyond the initial site of injury, respond poorly to medical therapy, persist for many years, and usually recur after surgical excision. There is often a positive family history of keloidal scarring, and keloids are 10–15 times more common in dark-skinned people of African ancestry than in northern Europeans and their descendants. Elaborate patterns of raised scars are a symbol of status in many African tribes, leading one to wonder whether this practice may have exerted selective pressure during human evolution.

HISTOLOGIC FEATURES OF HYPERTROPHIC SCARS

Numerous HTS have been examined histologically in our laboratory. The abnormal elevated scars consistently show several distinct differences from uncomplicated flat scars. The most striking is the presence of rounded whorls of immature collagen that consist of delicate collagen fibrils, mostly of type III collagen, small blood vessels, and plentiful acid mucopolysaccharide. These nodules are very sharply

demarcated from the surrounding scar tissue, which may be composed of similar material or may be composed of mature thick collagen fibers that are oriented parallel to each other and to the wound surface, typical of mature scars. Although the collagen fibers are clearly visible with routine H&E staining, they are most distinctly seen with the Movat stain, which stains mucopolysaccharides blue-green and mature collagen fibers yellow-orange. The nodules of HTS vary from 0.5 mm to more than 1 cm in diameter and can be spherical, ovoid, or cylindrical in shape. The abnormal dermal tissue is very firm and may reach a thickness of several centimeters. Both normal and HTS are characterized by lack of elastin, which is also visible using the Movat stain. However there are often residual elastin fibers in the deepest part of the dermis below zones of hypertrophic scarring, and sometimes there is a narrow zone of normal elastin fibers above the HTS, perhaps derived from the applied skin grafts. Occasionally small rounded nodules of HTS tissue are seen scattered between intact hair follicles. It is not unusual to see residual eccrine sweat glands in the adipose tissue beneath a large HTS, suggesting that these scars may originate in deep partial-thickness burns. These features are illustrated in Figs. 46.4 and 46.5. In addition, in a minority of HTS, an additional histologic feature is seen consisting of very broad, hypereosinophilic collagen fibers oriented parallel to each other but at varying angles with the skin surface. In some cases such broad, dense fibers dominate the wound. Generally they are surrounded by whorls of circularly oriented, immature collagen typical of HTS. These features are illustrated in Fig. 46.6. These are the features that have been described as typical of the histology of keloids. However, in our patient population, typical keloids are distinctly unusual, and there is no evidence to suggest that the patients with these thick, eosinophilic collagen fibers have a worse prognosis or a more delayed course of scar maturation than other patients with HTS. Thus, in our extensive experience with the histology of scars from large burns in children, the histologic features typical of keloids are seen as part of the spectrum of hypertrophic scarring.

The distinction between HTS and keloids was first made by Mancini and Quaife in 1962.[76–79] The features typical of HTS were further described by Linares, Kischer, and others.[80–83] The literature on HTS and keloids was thoroughly reviewed by Niessen[84] and Huang.[118]

Because the etiology and pathogenesis of HTS are different from that of keloids, we limit our discussion to HTS.

A number of differences distinguish between normal scars and HTS. HTS contain more type III collagen, fibronectin, and hyaluronic acid, all characteristic of the early phases of wound repair, than do normal flat scars. HTS are more vascular with higher cutaneous blood flow. HTS contain significantly more T cells and macrophages than normal scars. Larger numbers of mast cells have been found in HTS, and indeed a clinical history of atopy and higher levels of circulating IgE have been found in patients with HTS. Recently much larger numbers of epidermal Langerhans cells have been identified in association with HTS.[85,86]

Immunohistochemical staining has demonstrated additional striking differences between HTS and normal scars. Staining for α-smooth-muscle actin has consistently demonstrated this contractile protein within spindle cells in the characteristic collagen nodules of HTS. The sulfated proteoglycans of HTS are quite different from those of normal scars in that much less decorin is present, and versican is predominant in the rounded nodules. More VEGF immunostaining is seen in HTS. Larger numbers of small nerve fibers have been identified by immunostaining in HTS. These consistent findings may be providing important clues to the pathogenesis of hypertrophic scarring, but, at this time, they are difficult to incorporate into a single hypothesis. Although the lack of a suitable animal model and the scarcity of human tissue, in addition to the confusion surrounding the proper identification of hypertrophic scarring, have hampered research in this field, in recent years the study of the biology of HTS has been enabled by the

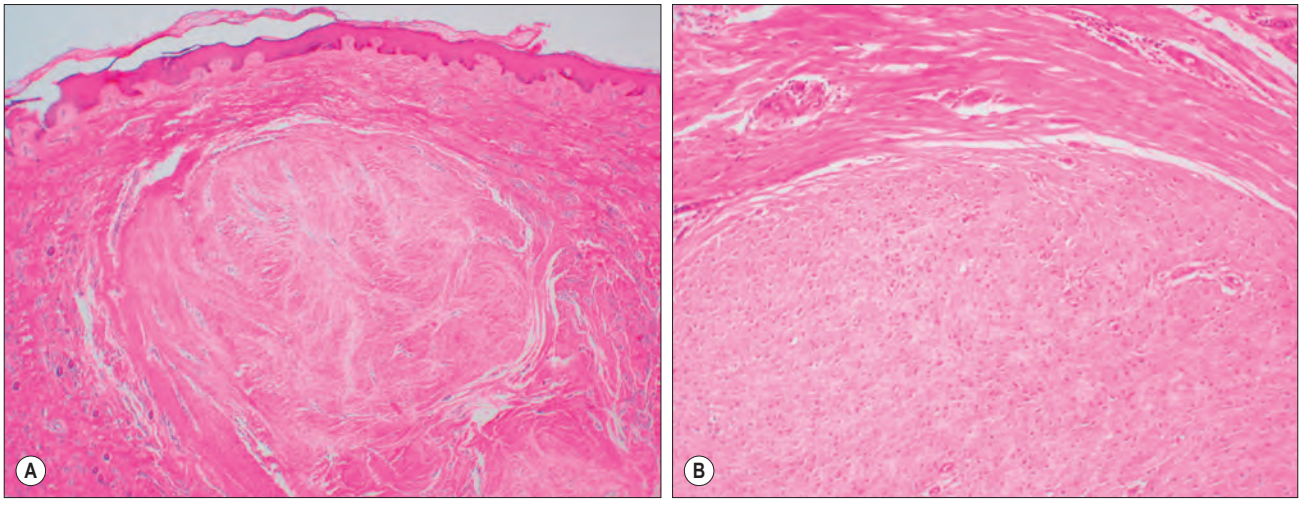

Fig. 46.4 Photomicrographs of hypertrophic scars. (A) Within the dermis there is a rounded nodule of collagen that has a sharp border and is distinct from the surrounding scar tissue. (B) The border of a collagenous nodule in a hypertrophic scar. In the surrounding scar tissue, collagen fibers are oriented parallel to the skin surface. Within the nodule, collagen fibers are very thin and are oriented circumferentially.

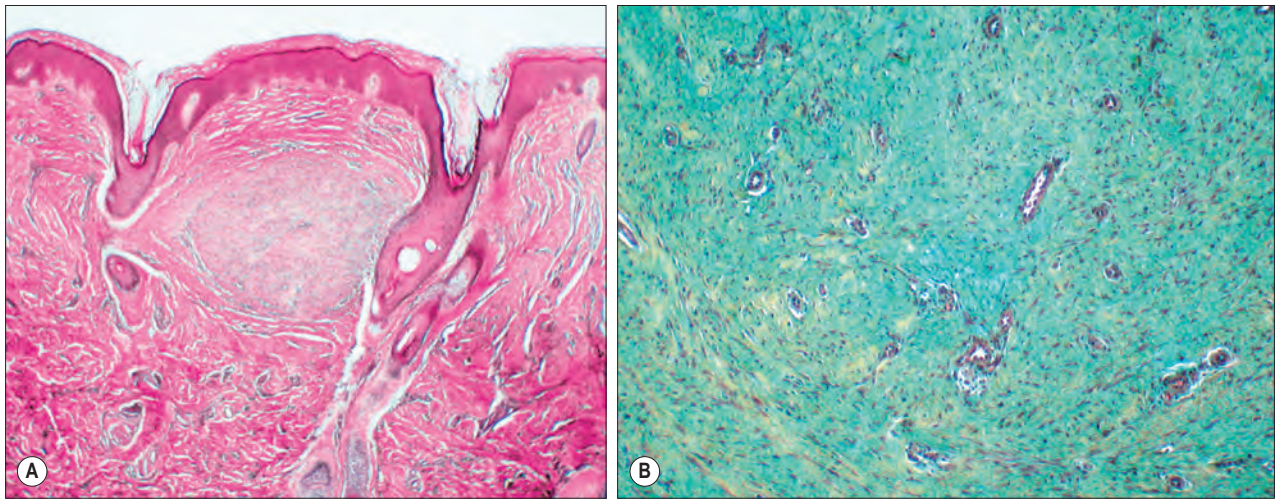

Fig. 46.5 (A) This Movat-stained slide shows a minimal hypertrophic scar consisting of a single round nodule between hair follicles. The nodule stains light green, in contrast to the yellow-orange color of the surrounding mature collagen fibers. The greenish color reflects a larger quantity of sulfated proteoglycans within the collagen nodule. (B) At higher magnification, numerous small blood vessels can be seen within a large, green-staining nodule from a hypertrophic scar.

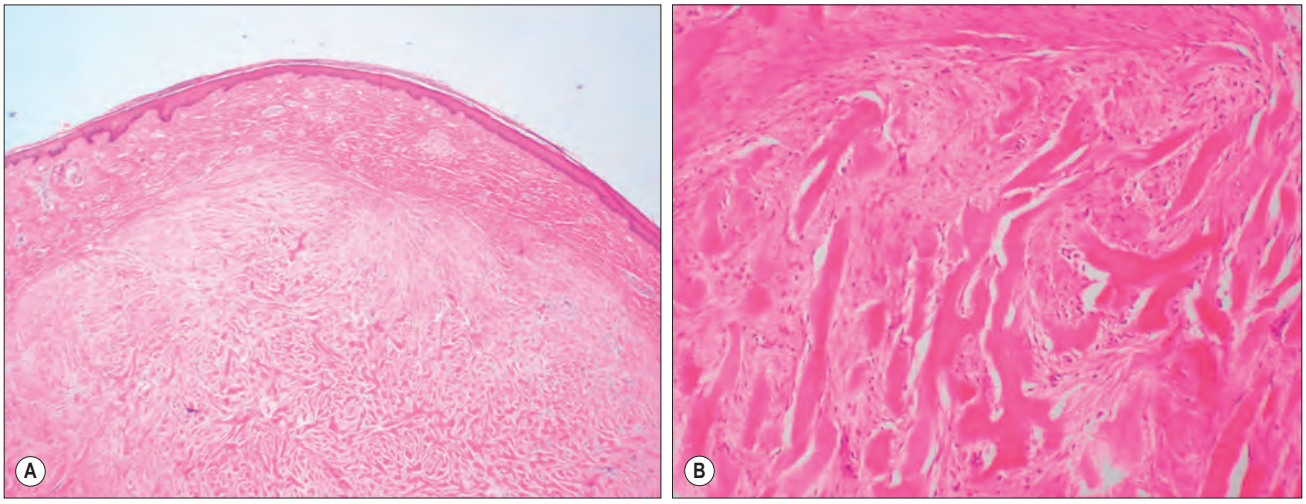

Fig. 46.6 (A) Some otherwise typical dermal nodules in hypertrophic scars contain very broad, hypereosinophilic collagen fibers similar to those typical of keloids. This specimen is from the patient shown in Fig. 46.3C. (B) The typical appearance of the thick, dense collagen fibers that stain intensely with eosin can be seen at higher magnification.

development of new experimental models. Adoption of cell culture models, culture of whole-tissue biopsies, use of immune-deficient mice, and establishment of hypertrophic scarring in the red Duroc pig have yielded important information on biologic processes underlying human hypertrophic scarring.

EXPERIMENTAL MODELS OF HYPERTROPHIC HEALING

The first animal model of keloids was described in 1959, based on immunization of experimental animals with autologous skin, followed by induction of wounds.[87] Extensive work has been done in which normal and abnormal human scar tissue have been implanted into the athymic nude mouse, which allows testing of potential therapies and modification of the biological milieu in vivo.[88–91] In this model, it is even possible to irradiate the mouse and transplant human bone marrow to study interactions between immune reactions involving human cells and the human skin grafts. Engrav and his colleagues developed a model in the female red Duroc pig that mimics many of the features of human hypertrophic scarring.[92–100] Recent studies by their group and others have elucidated molecular mechanisms underlying HTS development as well as the effects of antiscarring therapies at the molecular level.

PHENOTYPIC ABNORMALITIES OF HYPERTROPHIC SCAR FIBROBLASTS

There have been many studies of the functions and molecular biology of fibroblasts derived from HTS and keloids in tissue culture. It does appear from these studies that there is a significantly different phenotype of fibroblasts from HTS that persists in culture. HTS fibroblasts have been found consistently to secrete more TGF-β and collagen more rapidly than fibroblasts derived from normal skin or normal scars.[101] Furthermore the depth of residence of the fibroblast also determines the fibrotic phenotype, with deep dermal fibroblasts characterized by increased collagen secretion with reduced collagenase expression, slower proliferation, and an increase in α-smooth muscle actin expression when compared to superficial fibroblasts. Genomic analysis has been done in several laboratories on HTS fibroblasts, with identification of numerous differences in gene expression. In a genomic study from our institution, cultured fibroblasts from HTS showed a reduced response to IL-6 as compared to fibroblasts from adjacent normal skin, suggesting that decreased receptor activation might be a factor in hypertrophic scarring.[102]

GENE EXPRESSION IN HYPERTROPHIC SCARS

Studies of gene expression and regulatory pathways in HTS tissue have begun to provide much better understanding of both normal and hypertrophic wound healing. Initial studies of HTS gene expression using transcriptome analysis showed consistent differences in the expression of multiple collagen isoforms, growth factors, and metalloproteinases.[103] Similar studies demonstrated the similarities between human and porcine hypertrophic scarring.[104] In several experimental studies in animals, interventions have been applied that alter wound expression of important genes or signaling pathways, with substantial change in size of the resulting wound.[105–110] Studies in human patients have shown that variation in a gene's sequence can be associated with decreased severity of postburn hypertrophic scarring; although the role of CUB and Sushi multiple domains 1 (CSMD1) in hypertrophic scarring is not yet known, a potential modification of the TGF-β signaling pathway has been proposed. Although more research is needed, such studies promise possible therapeutic intervention in the processes that lead to hypertrophic scarring.

INTERPLAY OF SYSTEMIC AND LOCAL INFLAMMATORY RESPONSES

Both local and systemic cytokine expression impact the development of hypertrophic scarring. In burned children who do not develop HTS, active and total TGF-β1 levels in plasma increased during the first 2 weeks following the burn injury before dropping to levels below those found in nonburned patients. In burned children who later developed HTS, however, active and total TGF-β1 levels in plasma were diminished from the day of burn until at least 180 days later.[111] Augmented levels of systemic TGFβ1 have been correlated with increased circulating fibrocytes.[112] Although elevated systemic levels of TGF-β1 may be beneficial following a burn injury, prolonged expression locally within the burn wound may lead to hypertrophic scarring with increased fibrosis, downregulation of decorin, upregulation of versican, increased neovascularization, and decreased collagenase[113] The type of inflammatory response, in addition to the magnitude and location of the inflammation, play a role in hypertrophic scarring. Characterization of $CD4^+$ T-helper cells revealed that, following a burn, polarization of lymphocyte populations leads to a shift from a T_H1/antifibrotic phenotype to a T_H2/profibrotic response.[114] Decreased systemic expression of interferon-γ (IFN-γ) and IL-4 and increased IL-4-producing lymphocytes persist for a year following a burn injury.

PATHOGENIC CONCEPTS

Understanding of the biology of hypertrophic scarring has been hampered by multiple factors, including problems in gaining consensus on the definition of the lesion, the underuse of a suitable animal model, and the consequent inability to test hypotheses by altering the course of the disease. Multiple concepts of pathogenesis have been proposed, with some gaining wide acceptance while others have yet to be experimentally excluded. It does seem clear that development of an HTS represents an abnormality in regulation of the normal processes of wound healing, which may occur early, as Linares and Larson suggested.[72] Failure of the normal processes limiting collagen secretion and matrix formation is apparent in HTS. One might suppose that the normal processes by which tensions in the matrix signal cellular responses have become defective in HTS.[40,42] The roles of the mast cell and other inflammatory cells in scar development have become better defined; use of the mast cell stabilizers ketotifen and sodium cromoglycate demonstrates decreased fibrosis and wound contraction with inhibition of mast cell activity, indicating new targets for antiscarring therapies. Myofibroblasts are more prominent in immature and active HTS than in normal or mature scars and are thought to play a role in excessive wound contraction. Dermal fibroblasts within the HTS differentiate into myofibroblasts. The fibrous nodules of HTS might represent persistence and uncontrolled growth of a separate population of connective tissue cells perhaps related to the perifollicular cells that normally express versican. The formation of these nodules may represent abnormal epithelial–mesenchymal interactions; epidermal cells, such as Langerhans cells, and increased IL-4 with decreased IL-1α expression have been shown to influence dermal remodeling resulting in hypertrophic scarring. Since burn patients have higher circulating levels of glucocorticoids and IL-6 than do nonburned individuals, selection of cells resistant to the usual effects of these agents may occur following burn injury, leaving fibroblasts that are able to withstand the normal suppressive action on fibroblast proliferation. Metabolic differences, such as higher adenosine triphosphate (ATP) concentrations and greater oxygen consumption apparent within the hypertrophic scarring, may be the emphasis on metabolic differences. Finally, abnormal macromolecular expression by the covering epithelium may lead to abnormal development of the dermal scar or fail to suppress inappropriate fibroblast functions.[117] Clearly it continues to be important to develop and test many hypotheses until the problem of hypertrophic scarring is finally solved.

Conclusion

Healing of burn wounds requires activation of several host processes, including fibrin clotting and lysis, deposition of an immature connective tissue matrix and its reorganization into a mature scar, and epithelial outgrowth and interaction between the epidermis and the dermal matrix. In many burn patients, excessive scar tissue forms, with adverse consequences. Continued study of this problem will continue to be important until more effective modes of treatment are developed.

Introduction

The physical rehabilitation of patients who have sustained a burn injury is a serious undertaking and requires, among other disciplines, the involvement of physical therapy, occupational therapy, and exercise physiology in order to produce the best functional and cosmetic outcomes. Recent advances in medicine have significantly contributed to increased patient survival rates, and this necessitates faster, more comprehensive, and prolonged burn rehabilitation. With severe burn injuries, as perhaps with any other order of trauma, there is an urgent need for immediate and aggressive initiation of patient-specific rehabilitation programs. The distribution and depth of the burn injury clearly predict the patterns of deformity and joint contractures and mandate the establishment of therapeutic goals and the initiation of treatment as soon as possible. As stated previously, the more extensive the burn injury, the greater the rehabilitation challenge becomes. A seriously burned extremity in an otherwise modestly burned patient is much easier to restore to function than an extremity similarly burned in a patient with full-thickness burns involving multiple anatomical surfaces. In the case of seriously burned patients, the immediate and primary focus will always be preservation of life and wound coverage. Today, burn rehabilitation specialists intervene early on in the patient recovery process through the development and implementation of rehabilitation programs intended to maximize the potential of functional and cosmetic patient recovery.

The primary short-term rehabilitation goal is to preserve the patient's range of motion (ROM) and functional ability. Long-term rehabilitation goals include returning patients to independent living and teaching patients to compensate for any permanent functional loss suffered as a result of the burn injury while contributing toward acceptable cosmetic outcomes.

This chapter addresses the evaluation, positioning, splinting/orthotics, serial casting, prosthetics, scar management, exercise, performance of activities of daily living (ADL), and patient and caregiver education utilized in burn rehabilitation along the continuum of care.

Evaluation of the Burn Patient

Upon admission to the burn center, patients undergo a comprehensive evaluation by burn rehabilitation therapists (physical and/or occupational therapists) in order to assess their medical status and formulate a plan of care. It is crucial that therapists document the findings of their evaluation in the patient's medical record because these findings will serve as the baseline upon which progress will be determined. A good burn evaluation should include (1) the history of how the accident occurred; (2) an interview with the patient's caregiver to gather information regarding the patient's preinjury functional status and activity level; (3) documentation of the etiology, classification, and total body surface area (TBSA) of the burn injury; (4) documentation of associated injuries such as fractures, smoke inhalation injury, and exposed tendons and bone; (5) measurement of edema, ROM, strength, and sensation if appropriate; (6) assessment of ADL performance; (7) need for positioning of affected areas, including splinting; (8) development of short- and long-term treatment goals; and (9) development and documentation of a treatment plan. The patient's status should be reassessed on a regular basis and after each surgical procedure to update the plan of care as needed. Therapists should communicate the results of their evaluation and the treatment plan to the burn team and to the patients and their families.

Positioning and Splinting of the Burn Patient

In a study of burn survivor perceptions about rehabilitation, positioning and splinting routines were viewed positively and identified as useful in order to improve movement.[1] Positioning of the burned patient is fundamental to bringing about the best functional outcomes in burn rehabilitation.[2–4] Positioning programs should begin immediately upon admission to the burn center and continue throughout the rehabilitative process. The role of the burn rehabilitation therapist is invaluable in designing a patient-centered positioning program, one that reduces edema, enables wound care, facilitates joint alignment, minimizes the risk of peripheral neuropathy,[2,3] and counteracts all contractile forces without compromising function. In planning and implementing an effective patient-specific positioning program, the therapist should be aware of the patient's TBSA of burns, the depth of all injuries, respiratory status, and associated injuries such as exposed tendons/joints or fractures. Individualized positioning programs are monitored closely for any necessary adjustments depending on the patient's medical status. The quote that "the position of comfort is the position of deformity" applies to every burned patient who has sustained a serious injury. The risk

of deformity after burn injury is real, and burn scar contractures should be anticipated and dealt with proactively.[5,6]

Anti-deformity positioning can be achieved through multiple means: splinting, mechanical traction, cut-out foam troughs and mattresses, pillows, strapping mechanisms, serial casting, and, in some cases, through surgical application of pins. The burn therapist needs to be aware of physician-specific protocols and work closely with the entire burn team to design the most effective positioning program. Orthotics and splinting devices are vital in burn rehabilitation because they are utilized extensively to obtain appropriate positioning of the entire body and to counteract the contractile forces of scarring that lead to deformity. The application of positioning strategies is used to influence soft-tissue lengths to limit the loss of ROM due to scar formation and contraction.[2,3] No matter how the burn therapist approaches splinting (material choice, design, and application schedules), the goal is to achieve the best functional outcome at the completion of rehabilitation. When fabricating a splint or an orthosis, the burn therapist must be aware of the anatomy and kinesiology of the body surface to be splinted. Also, the therapist should be well aware of all mechanical principles of splinting as they relate to pressure, mechanical advantage, torque, rotational forces, first-class levers, friction, reciprocal parallel forces, and material strength.[7]

The general outcomes for the use of splints in a burn rehabilitation setting have been identified as protection of vulnerable structures, preservation of ROM, suppression of scar, and correction of soft-tissue contractures.[8] The goals for positioning and splinting will vary with the phase of burn rehabilitation. In the acute phase, the goal is edema control and pressure relief; in the intermediate phase, the aim is tissue elongation and graft protection; and, for long-term rehabilitation, the target is tissue elongation.[9] Positioning and splinting must be designed in a way to:

- Allow for edema reduction
- Maintain joint alignment
- Support, protect, and immobilize joints
- Maintain and/or increase ROM
- Maintain tissue elongation
- Remodel joint and tendon adhesions
- Promote wound healing
- Relieve pressure points
- Protect newly operated sites (grafts/flaps)
- Stabilize and/or position one or more joints, enabling other joints to function correctly
- Assist weak muscles to counteract the effects of gravity and assist in functional activity
- Strengthen weak muscles by exercising against springs or rubber bands.[7]

Devices should:

- Not cause pain
- Be designed with function in mind
- Be cosmetically appealing
- Be easy to apply and remove
- Be lightweight and low-profile
- Be constructed out of appropriate materials
- Allow for ventilation to prevent skin/wound maceration.[7]

Typical burn care positioning protocols describe the supine position in great detail. More emphasis is now being placed on the use of side-lying and prone positioning for patients with large burns who must be immobilized for extended periods due to newer grafting techniques that cover larger areas with fragile skin substitutes. When designing positioning programs, the joint angles are aligned in neutral postures and the supporting surfaces are modified to maximize the surface area to body contact while protecting bony prominences from compression.

Side-lying may be used on a rotating basis for patients at risk for sacral or scapular skin breakdown. In a preventive program, the rotation is right side to supine to left side. The order is then reversed on a 1- to 2-hour schedule. Full side-lying at 90 degrees from supine should not be allowed for any significant length of time due to excessive pressure over the greater trochanter. A more appropriate position for side-lying is approximately 30–40 degrees from the supine position, which distributes pressure more evenly between the head of the femur and the lateral portion of the sacrum.

The mechanics of a side-lying position can be accomplished using pillows or wedges made of foam or wood. The advantage of foam or wooden wedges is that they can be placed directly under the mattress with less manipulation of the patient. As the rotation schedule is completed, the wedge can either be removed for the supine position or transferred to the opposite side of the mattress to achieve side-lying on the opposite surface.

Prone positioning strategies are usually the position of last resort (Fig. 47.1) and are reserved for patients who are not successfully managed in supine or side-lying. For example, there may be nonhealing grafts or wounds in the rectal region that increase the risk of sepsis due to the introduction of fecal matter. Other candidates for this protocol include those with sacral pressure ulcers or posterior trunk grafts that are not healing.

The clinician faces a host of issues that must be considered when instituting a prone positioning program. The airway is always the first issue that must be considered when designing a prone position mattress. The supporting surface is cut from a solid open-cell foam mattress that is

Fig. 47.1 Patients may be positioned prone to protect posterior grafts from shearing.

placed on a wire mesh bed frame. Airway concerns are addressed first, and the patient is evaluated for mode of respiration. Nasal and tracheal intubation are issues to consider, but these are not contraindications for the prone position. A trough should be provided so that direct access can be obtained for routine airway care and if breaths are needed using an Ambu-bag. If the airway becomes compromised, the prone position should be abandoned immediately until proper respiration is established.

The facial opening should be cut in a manner that maximizes weight distribution without allowing the head to enter into the opening. Using this protocol places direct weight-bearing pressure on the brow ridge, zygomatic arches, and the anterior mandible. These structures should be monitored closely, and the patient should be educated that breakdown is likely to occur due to the limited subcutaneous tissue protecting the face. If burn scars are encroaching on the eyelids, then the corneas should be evaluated as well. Corneal abrasion can be avoided with due diligence and prevention of the foam from contacting the unprotected eye. Countersinking a gel cushion into the upper portion of the foam mattress can protect the forehead and brow ridge.

The sternum, pelvic region, and patellae are protected with the use of an air-cell mattress that is inserted into the mattress in a lengthwise manner. The air-cell segments are typically supplied in standard lengths and may not reach from the sternum to the ankles. If there is an unsupported area between the distal portion of the mattress and the dorsum of the foot, then the area can be supported with open-cell egg-crate-type foam. The feet are supported at the distal end of the mattress with a foam footboard. Extra precautions should be taken to evaluate the elevation of the great toe from the supporting bed frame.

In the prone position, all traditional joint alignment suggestions are maintained with the possible exception of the elbows. Shoulder mobility dictates the style of prone mattress that can be made for the individual burn patient. If the patient has greater than 115 degrees of abduction, then the mattress is modified to horizontally adduct and externally rotate the shoulder while flexing the elbow to allow for elevation of the hands. This minimizes edema in the hands and allows for greater function once the prone position is no longer needed. If the shoulders have limited abduction, then a "butterfly" cut is used to allow for horizontal adduction of the shoulder to protect the brachial plexus, with the hands remaining slightly dependent. This will result in some hand edema, which can be addressed with pressure wrapping (Coban glove) and active exercise.

HEAD

Acutely, in aiding with facial edema reduction, the head should be positioned by placing it in midline and elevating the head of the bed at 30–45 degrees if the patient's hips are not involved. In cases where the hips are burned, the entire bed may be elevated at the head with the use of shock blocks (wooden blocks, 12–16 inches, with recessed slots for bed legs) or the use of the reverse Trendelenburg position. These methods avoid positioning the hips in the flexed position that promotes contracture formation and deformity if persistent (Fig. 47.2).

Fig. 47.2 Wooden blocks are utilized to place the bed on an incline to help with edema reduction and prevent hip contractures.

In those cases where the ears are burned, they may be protected by strapping ear cups made of thermoplastic materials or foam.[10] An ear conformer may be constructed to prevent the rim of the ear from contracting toward the head. Internal ear canal splints may also be fabricated and serially adjusted as the circumference of the canal increases. In addition, if the ear is affected, a soft circular foam can be positioned posteriorly to the head to elevate the ears off the surface of the bed. A nasal obturator may be required to maintain the nostrils open. These obturators may be serially adjusted as the circumference of the nostril increases. Mouth splints are utilized for the prevention of oral microstomia. These devices are custom-made by the therapist, or they may be obtained commercially. Mouth splints may be fabricated static or dynamic for horizontal or vertical opening of the mouth.[11–15] In cases of severe microstomia, where compliance is an issue, an orthodontic commissure appliance that attaches to the teeth may be fabricated by an orthodontist.[16] The use of stacked tongue blades is an acceptable technique to aid in reversing oral microstomia. Ongoing research looks at the development of a microstomia device that circumferentially opens the mouth according to its anatomy (Fig. 47.3). In the post-acute phase, facial scar hypertrophy may require fabricating a high thermoplastic transparent mask, such as the Uvex and W-clear masks, or a silicone elastomer facemask.[17–19] A semi-rigid low thermoplastic opaque mask may also be fabricated depending on the state of scar maturation.

NECK

The neck is positioned in neutral or in slight extension of approximately 15 degrees without any rotation. The amount of neck extension must not be so great that traction on the chin causes the mouth to open. Positioning may be achieved with a short mattress supine, a rolled towel, or foam cushion placed behind the upper back on the scapular line. Pillows should be avoided in the cases of anterior neck burns because they may lead to flexion contractures. In the case of anterior neck burns, a conforming custom thermoplastic collar may be fabricated (Fig. 47.4).[20] For burns along the lateral surface of the neck and some long-term

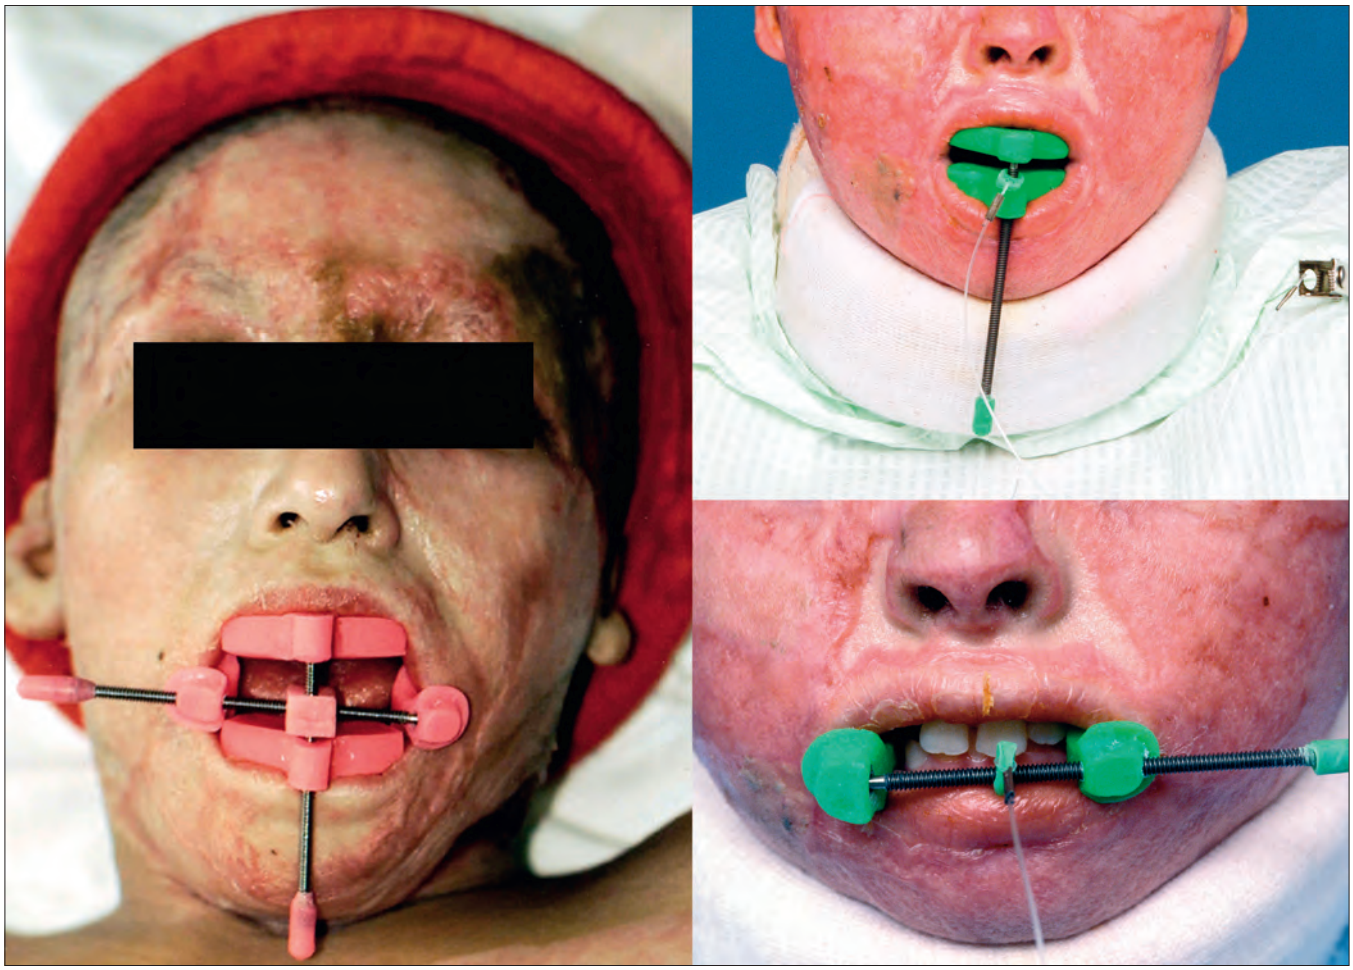

Fig. 47.3 Horizontal, vertical, and circumferential mouth-opening devices are utilized to correct oral microstomia.

Fig. 47.4 An anterior neck conformer helps prevent neck flexion contractures.

needs, a soft neck collar or a Watusi-type collar may also be fabricated as the patient's wounds heal and contractures or scars develop. The Watusi-type collar allows for isolated, direct pressure to a thicker scar band.[19,21,22] It has been observed that, in some cases, acute patients rotate or laterally flex their neck on one side, which may lead to a lateral neck contracture (torticollis). If the patient is to remain in bed for a while, a dynamic head strap mechanism may be fabricated to counteract the lateral neck contractile forces and bring the neck into the neutral position. For the prevention of torticollis, the therapist may fabricate a lateral neck splint that conforms to the patient's head, the lateral neck, and anterior/posterior shoulder (Fig. 47.5).

SPINE

Contracture resulting from unilateral or asymmetric burns of the neck, axilla, trunk, and groin will cause lateral curvature of the spine (scoliosis). The level and amplitude of curvature will vary with the site and severity of the contracture. In addition, pelvic obliquity accompanying asymmetric hip or knee flexion contracture will impose a lateral lumbar curve. As long as the patient is recumbent, lateral curvature can be prevented by maintaining straight

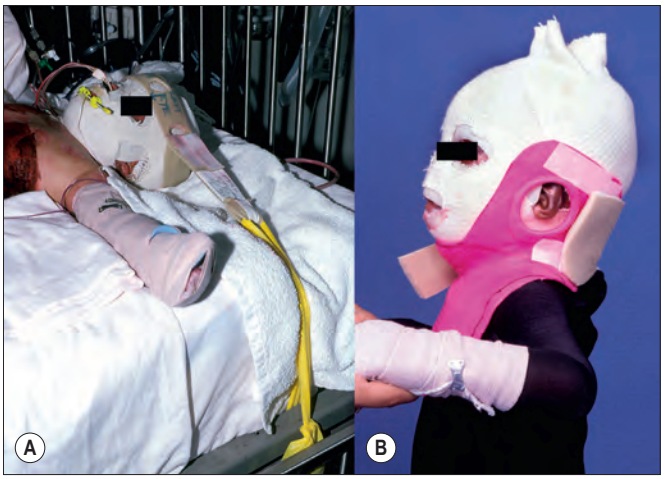

Fig. 47.5 **(A)** A dynamic head strap mechanism aids in positioning the neck in a neutral position during a prolonged ICU bed confinement. **(B)** A lateral neck splint is utilized to prevent lateral neck flexion contractures (torticollis).

Fig. 47.6 Scoliosis resulting from a left chest, abdomen, and left lateral trunk injury.

alignment of the trunk and neck (Fig. 47.6). However, the curve is often insidious in onset and will not be recognized until the patient begins to walk. Trunk list observed early in the ambulation period can be simply a transient accommodation to pain and wound tightness, but a persistent list may herald the development of scoliosis. Other subtle signs of spinal curvature are asymmetry of shoulder levels, scapular asymmetry, asymmetry of dependent upper extremity alignment to the trunk, and asymmetry of pelvic rim levels. A spinal mobilization exercise program is established with the patient once a curvature is identified; however, once there is an established asymmetric contracture it is difficult by therapeutic means to stretch it out, so it is probably better to deal surgically with a deforming scar early than to permit even minor scoliosis to persist.

SHOULDER GIRDLE/AXILLA

Acutely the upper extremity positioning program focuses on reducing edema through elevation. Failure to reduce

Fig. 47.7 Foam arm troughs are utilized for positioning the shoulders in bed.

edema in the first 48–72 hours can promote the development of a fixed deformity. Additionally, improper elevation techniques for the upper extremity may lead to soft-tissue calcification, increased bone density, and compressive neuropathies. The recommended position for the burned shoulder and axillary complex is 90 degrees abduction, 15–20 degrees horizontal adduction, and external rotation toward maximal. Abduction alone places the glenohumeral joint at risk for anterior subluxation, if the position is maintained for an extended period. Placement in horizontal adduction anatomically reduces the potential for tractioning of the brachial plexus or peripheral nerve compression. The glenohumeral joint is externally rotated in order to counteract anticipated deformities of internal rotation and adduction and to maintain balance of the soft tissues of the shoulder complex.

Positioning of the shoulder may be achieved with splints, silicone-filled pillows, bedside tables, foam arm troughs, metal abduction troughs, and thermoplastic slings suspended from a trapeze mechanism (Fig. 47.7).[23] Splinting of the shoulder joint becomes more intensive as scar maturation heightens the risk of contracture development. Airplane splints have been used for the resolution of axillary contractures and postoperatively to protect reconstructive procedures.[24–26] Upon closer inspection of the literature, a randomized controlled trial of adults with shoulder burn involvement compared splinting to no splinting with regard to functional outcomes and determined that shoulder splints did not improve clinical outcomes in the study population and that low adherence rates suggest splinting may be unacceptable to patients.[27] However, more recently, a pilot study of a newly designed multiaxis shoulder abduction splint concluded that the device resulted in a significant improvement in shoulder abduction angle compared to unsplinted patients.[28] The use of shoulder splints needs to be studied further to determine patient types, design principles, and timing of application.

In situations where deemed necessary, shoulder splints can be modified. To accommodate wound dressings and promote healing, a three-piece airplane splint may be fabricated (Fig. 47.8). Foam arm wedges may be substituted

Fig. 47.8 A three-piece airplane splint may be fabricated to accommodate wound dressings and promote healing while maintaining the shoulder abducted.

Fig. 47.9 A figure-of-eight axillary wrap provides a constant stretch of the axillary skin surfaces.

when the patient is in the bed postoperatively, when it is difficult to fabricate an airplane splint. Other adaptations may be required in the presence of amputations. Prefabricated airplane splints come equipped with mechanisms that allow for adjustments depending on available shoulder ROM.[19,20,22] A figure-of-eight axillary wrap may be utilized in conjunction with an airplane splint to provide compression for axillary contour and elongation of skin surfaces (Fig. 47.9). A descriptive study using the figure-of-eight sling after scar release and skin grafting indicated that the device is safe, comfortable, easy to use, and promotes compliant use by the patient; with at least as reliable results as the use of abduction splints.[29] For successful contracture management to the shoulder, the positioning program must be supplemented by exercise routines for ROM, strength, and endurance.

ELBOW/FOREARM

Acutely, elevation and extension is the desired position of the elbow. Severe burns involving the elbow may result in flexion contracture and threaten posterior exposure of the joint. Full extension is the protecting position for the elbow. If the joint is exposed posteriorly, extension may need to be rigidly maintained for several weeks. If the joint is not exposed, mobilization into increasing flexion range can begin very soon after the burn injury. The elbow is integral to the so-called delivery system for the hand, and elbow range to full or near-full flexion is more important for overall function than range to full or near-full extension.

Radial head rotation for pronation and supination is less often affected by the burn injury than is flexion and extension. The pronators and supinators are frequently injured in electrical accidents where bone heats, being a poor conductor, destroying the muscles closest to it. Forearm rotation is essential for accurate hand placement, and the rehabilitative program must address pronation and supination during functional tasks and skills training. Depending on the location and severity of the injury, the forearm may be positioned in neutral to slight supination. Static elbow splints may be soft or custom-fabricated of thermoplastic materials. An anterior elbow conformer may be fabricated over the burn dressing. Dynamic elbow extension or flexion splints may be utilized to provide prolonged, gentle, sustained stretch and aid in the correction of contractures.[30] Forearm dynamic pronation/supination splints may be custom-fabricated or obtained commercially for the correction of contractures.[19,20,22]

WRIST/HAND

A comprehensive team approach from initial evaluation through long-term follow-up is essential to maximize the functional outcomes for individuals with hand burns.[31] Treating therapists must have a thorough understanding of the effects of thermal injury on the anatomical structures of the wrist and hand. The presence of dorsal hand edema leads to intrinsic muscle ischemia and a resultant "intrinsic-minus" posture. The unsupported burned hand postures in wrist flexion, metacarpophalangeal (MCP) hyperextension, interphalangeal (IP) flexion, thumb adduction, and thumb IP flexion. The overall appearance is that of a claw deformity (Fig. 47.10A). Edema following a full-thickness burn to the dorsal hand imposes the positions of MCP hyperextension and IP flexion (Fig. 47.10B). Persistence of this position results in a claw hand deformity. The claw hand posture is primarily due to post-burn edema but may persist throughout the course of treatment due to scar contracture or in the presence of peripheral neuropathy. Among the digits, the second and fifth most easily drift into MCP hyperextension because each has a proper extensor tendon.

While superficial burns result in minor, transient edema, full-thickness injuries exhibit more severe and prolonged post-burn edema. Superficial hand burns should not be splinted in order to allow for frequent movement and the freedom to function independently.[2,3] In cases of severe thermal injury, it is important to monitor for signs and symptoms of vascular insufficiency or compartment syndrome. In treating the edematous burned hand, it is important to position the hand above the level of the heart at all times if it can be accomplished without compromising the neurovascular supply to the hand.[19,20,22]

Fig. 47.10 **(A)** Edema following a full-thickness burn of the dorsum of the hand: imposed metacarpophalangeal extension and interphalangeal flexion. **(B)** The deformity resulting from the persistence of this position is that of a claw hand.

Fig. 47.11 The intrinsic plus position hand splint (burn hand splint) positions the hand appropriately to prevent contractures and preserve function.

Acute positioning of the wrist and hand after burn injury is for edema control; immobilization/protection of tendons, joint structures, and/or skin grafts; and optimal positioning to maintain soft-tissue lengths and functional abilities. Within the first 24–72 hours, it is recommended that the wrist be splinted into extension, allowing the MCP joints of digits one through five to fall into flexion due to the normal tenodesis action of the wrist and hand. Wrist extension is essential to control digital position and prevent a claw hand deformity. The recommended functional position of the wrist is from 0–30 degrees of extension.

The burned wrist and hand should be positioned to oppose impending wound contracture. A review of the burn literature indicates some disagreement regarding positioning of the wrist and hand. A consensus panel of burn rehabilitation experts discussed splinting of the MCP joints in at least 70 degrees of flexion at night.[2] Another group of burn experts went a little further and described the position of choice as being wrist extension, MCP flexion greater than 60 degrees, and IP joint extension.[3] A third group, including surgeons, described the desired position as 20–30 degrees of wrist extension, approximately 80 degrees of MCP flexion, IP extension, and thumb in maximum abduction.[32] The authors of this text previously recommended that the optimal position for the burned hand is wrist 0–30 degrees extension, 70–80 degrees MCP flexion and IP joints in full extension (although some burn centers may advocate a slight amount of IP flexion, deeming the position to be "safe"). The thumb should be positioned in a combination of palmar and radial abduction, with the MCP/IP joints slightly flexed. An example of a modification to the burn hand splint that would improve the protection of grafted areas through the use of a "roll bar" is described in the literature.[33] What is clear is the need for controlled studies to determine the appropriate body positions to reduce deformity risks and to determine the most effective methods for the use of splinting for maintaining ROM or contracture management. All the described positions resemble the "intrinsic-plus" position and can be achieved through fabrication/fitting of a burn hand splint by a rehabilitation therapist (Fig. 47.11). The burn hand splint positions the hand appropriately to minimize soft-tissue contractures and preserve functional mobility. Involvement of the extensor tendon apparatus should be assumed and protected until viability of the system is known.[34] Continuous splinting is recommended to manage edema, exposed tendons, peripheral neuropathies, and uncooperative/unresponsive patients.

In the intermediate phase, positioning and splinting are used to prevent/correct deformities and protect surgically reconstructed sites. Splints may be fabricated dorsal, volar, or on the medial/lateral aspects. Contractures are a major complication of hand burns because they affect one's ability to perform ADLs.[5] Joint contractures have also been found to negatively impact quality of life in burn survivors, especially with regard to physical function, role limitations, pain, and vitality.[35] Dorsal hand burns are prone to contract into MCP hyperextension, IP flexion, and thumb adduction and should be splinted into MCP flexion, IP extension, and thumb palmar abduction. The most common post-burn upper extremity contractures are wrist flexion, index finger MCP hyperextension, index finger proximal IP flexion, and small finger MCP hyperextension/proximal IP flexion.[36] The cupped palm deformity is functionally detrimental because

Fig. 47.12 The cupped palm deformity limits the hand's ability to grasp objects normally.

Fig. 47.13 An example of a palmar extension splint to stretch a palmar contracture.

it makes it impossible to smoothly reach around objects (Fig. 47.12).

Burns to the volar surface of the forearm will predispose the patient to wrist flexion contracture, whereas burns to the dorsal surface will likely result in a wrist extension contracture. If the wrist ROM becomes limited in a specific direction, splinting the wrist in the opposite direction is indicated. The fifth digit is occasionally pulled into extreme abduction and hyperextension by scar contracture, muscle imbalance, or ulnar neuropathy. The thumb may become similarly displaced into adduction and retroposition. It is important to remember that the likelihood for MCP joint problems exists throughout scar maturation. Palmar hand burns are prone to MCP flexion and thumb opposition contractures and should be splinted into palmar extension and thumb radial abduction.

Static positioning with custom thermoplastic splints can be relatively efficient to implement in the clinical setting; however, a review of the literature indicates that there is no strong evidence for the use of static splinting in preventing scar contractures.[37] More recently, a group of surgeons and therapists collaborated to look at serial splintage of the upper limb after burn injury and found that the preoperative use of splints may lead to lesser surgical interventions, and minor contractures may be completely corrected.[38]

Two common faults are seen in custom splints that are designed to gain MCP flexion and to position the thumb in MCP flexion/radial abduction. If the distal transverse fold of the splint is not proximal to the MCPs of digits 2–5, the splint will impede rather than favor MCP flexion. If the thumb component of the splint applies volar pressure rather than medial pressure, the MCP will extend and the first metacarpal will become correspondingly more adducted. The first MCP joint should be maintained in slight flexion, and pressure from the splint should be applied just to the medial surface. Any degree of first metacarpal adduction contracture increases the likelihood that the proximal phalanx will be pushed into hyperextension and eventually into subluxation.

In the case of circumferential hand burns, a palmar extension splint is fabricated to prevent flexion contractures and a cupping deformity of the palm (Fig. 47.13). The burn hand splint and an extension splint may be alternated. A

Fig. 47.14 The "sandwich" hand splint prevents proximal interphalangeal (PIP) flexion contractures.

"sandwich" splint may be fabricated that includes a burn hand splint with a dorsal shell over the IP joints to prevent flexion of the digits. All splints may be secured with elastic bandage or with Velcro strapping components (Fig. 47.14).[39] Individual gutter splints are used to prevent flexion contractures, to restrict boutonnière and mallet finger deformities, and to protect exposed extensor tendons until wound closure. Recently, a group of hand therapists has combined the use of digital gutter splints built into a compression garment to improve adherence to wear schedules in a pediatric population.[40] C-bar splints are used to prevent adduction contracture of the first web space. Figure-of-eight splints are fit to correct or restrict swan neck deformities.

Dynamic splints are utilized to provide low-load prolonged stretch to counteract contractile forces and are recommended for the correction of scar contractures.[37] Dynamic splinting of the hand will focus on MCP extension/flexion splints, IP flexion/extension splints, and thumb abduction and may include prefabricated or spring-loaded splints (Fig. 47.15).[41] Patients may require dynamic splinting to assist muscles weakened by peripheral neuropathy.

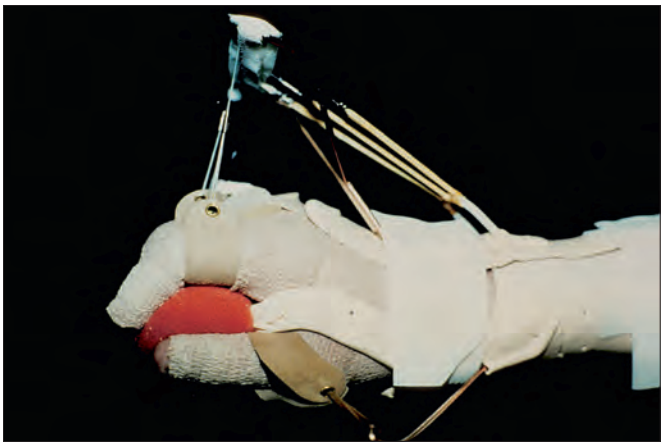

Fig. 47.15 A dynamic metacarpophalangeal (MCP) extension splint promotes functional use of the hand.

The therapist monitors dynamic splinting closely and makes frequent adjustments in order to provide effective tissue mobilization. Additionally, the fit of dynamic splints is checked frequently to ensure that the anatomical structures remain properly aligned.

Fig. 47.16 An anterior hip spica splint is utilized to prevent anterior hip flexion contractures.

HIP

When anterior burns extend from the abdomen to the thigh, hip flexion is the position of comfort. If the hip is fixed in any degree of flexion, posture will be modified. Bilateral symmetric contractures impose increased lumbar lordosis, knee flexion, or both. Asymmetric contracture will cause pelvic obliquity and scoliosis. In adults and older children, thighs are more likely to be held in adduction than in abduction, whereas in preambulatory infants the secondary component of the contracture is abduction. Thus, for the hips, the preventive position is full extension, 0-degrees rotation, and symmetric abduction of 15–20 degrees. If elevation of the upper body is needed for edema reduction, then the entire frame of the bed is elevated with the use of wooden shock blocks placed at the head of the bed or the bed is placed in reverse Trendelenburg with support of a padded footboard. Soft mattresses should be avoided because they may promote hip flexion. Hip positioning is accomplished with the use of abduction pillows and other strapping mechanisms that eliminate hip rotation. If the patient wears bilateral foot splints, then connector bars may be utilized on the splints to bring about the desired bilateral hip positioning stated earlier. Hip flexion contractures may be serially corrected with an anterior hip spica or with a three-point hip extension splint (Fig. 47.16).[19,20,22] Subtle hip flexion contractures can be easily overlooked when the patient stands, there being only a slight increase in lumbar lordosis or forward or lateral shift of the trunk. If established hip flexion contractures are not surgically corrected, body posture is likely to be permanently altered with scoliosis or exaggerated lordosis.

KNEE

Burn injury to the anterior or posterior surface of the lower extremity that crosses over the knee joint may result in knee flexion. Deep anterior burns may expose the joint, occasionally destroying the patellar tendon. Deep posterior burns result in bridging scar formation. The appropriate position for the knee is full extension to be maintained by splint or, in severe cases, skeletal traction until there is efficient quadriceps function and the patient is ambulatory. Thereafter, night splints must be used until scar contracture is no longer a threat. Knee splints may include a posterior custom-made thermoplastic knee conformer or a soft knee immobilizer.

Persisting bilateral knee flexion contractures will impose hip flexion. Persisting unilateral contractures may impose pelvic obliquity and scoliosis. As with the hip, posture alteration may be so subtle as to be overlooked. Correction of even a slight contracture should be a surgical priority, as should elimination of a soft bridging scar band that does not prevent complete willful knee extension but causes the patient habitually to hold the knee in slight flexion.

FOOT/ANKLE

Ankle equinus is the most frequently occurring deformity involving the foot. Initially, it is related more to gravity and failure to support the foot at neutral at the talotibial joint than to the early effect of the burn. Loss of deep and superficial peroneal nerve function will compound the problem by encouraging the foot to drift into inversion as well as equinus because of loss of dorsiflexion and eversion motors. In the end, the total deformity for the unsupported foot may be ankle equinus, hindfoot inversion, and forefoot varus and equinus. Ankle equinus quickly becomes a resistant deformity so that, within a few days or even hours, the foot can no longer be positioned at 90 degrees of dorsiflexion in the neutral ankle position. Eventually the contractures of scar, muscle, and capsular structures combine to fix the deformity.

Equinus deformity and the attending inversion and forefoot varus can be prevented by accurate and unyielding support of the foot in neutral alignment or slight dorsiflexion. If the patient must be nursed prone, the feet must be allowed to fall free from the mattress. Static splinting, if not performed correctly by an experienced therapist, is often unsuccessful because of the patient's desire and tendency to plantarflex strongly, displacing the splint and leading to ulcers of the heel, malleoli, toes, and where the splint edges touch the skin. A stable footboard may be effective if the feet are kept securely and totally against it. For large burns and particularly for circumferential burns of the lower extremities, skeletal suspension incorporating calcaneal traction will support the foot at neutral if the traction pin is placed in the calcaneus well behind the axis of ankle motion. A balanced traction system demands that the knees be supported in flexion with tibial pins at the level of the tibial tubercle. Calcaneal pins will not prevent forefoot equinus. If traction must be employed for several weeks, proximal-pull dorsal pins in the first or first and second metatarsals may be required for support of the forefoot. Transmetatarsal pins are useful as well when calcaneal traction alone is not sufficient to correct equinus.

Minor established equinus deformity can be corrected with a standing and walking program. At the outset, graduated heel lifts may be used to accommodate to the deformity. If the patient must be bed-confined, skeletal traction through the calcaneus may be the quickest and most efficient way to correct the deformity. Traction is effective even if scar contracture contributes to the deformity. Serial corrective casts or posterior splints alone are useful mainly for minor contractures. For the treatment of circumferential foot/ankle burns, anterior foot splints are also fabricated and their application is alternated with the posterior foot splints in preventing plantar or dorsal foot contractures.[19,20,22] The Multi Podus System foot splints may be utilized for the positioning of the burned foot/ankle because they relieve heel pressure and prevent pressure ulcers (Fig. 47.17). For fixed, unyielding deformity, scar release combined with tendo-Achillis lengthening with or without posterior capsulotomy is a standard surgical procedure that yields inconsistent results. The correction achieved is often just to neutral or to slight dorsiflexion. The Ilizarov technique has been used with generally satisfactory immediate results in severe cases.[42] No matter how correction is achieved, if there are no dorsiflexion motors and if the range of ankle motion is only a few degrees, ankle fusion may in the end yield the best functional result.

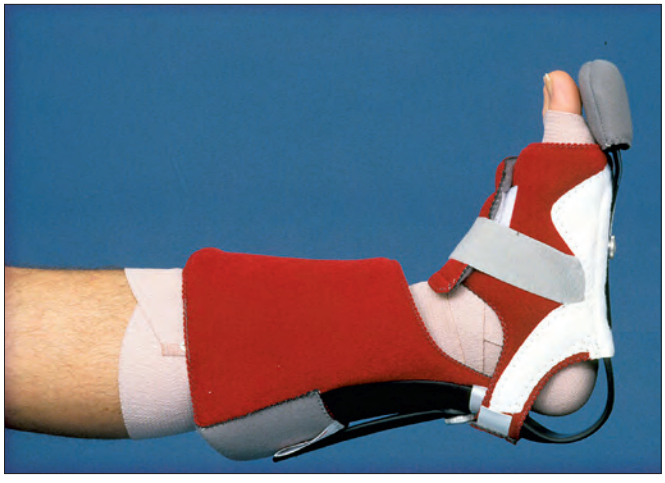

Fig. 47.17 The Multi Podus splint is utilized to position the burned foot appropriately and prevent heel and malleoli skin breakdown.

The most common intrinsic deformity of the foot is extreme extension of the toes due to dorsal scar contracture. This deformity is insidious in onset and is difficult to prevent because there is no type of nonskeletal splinting that will hold the toes flexed. In its extreme, the deformity includes dorsal metatarsophalangeal (MTP) subluxation, which may involve one or all toes depending on the location of the scar. The metatarsal heads become prominent on the plantar surface and walking may be painful. Correction of the deformity requires dorsal surgical release of the contracture, manual correction of the deformity, and, in severe cases, intrinsic or extrinsic pinning of the digit or digits in an overcorrected position (i.e., MTP and interphalangeal flexion). The deformity will commonly if not inevitably recur to some degree unless the patient, after the operation, is able to achieve active MTP flexion in all digits.

Dorsal scar contractures extending from leg to foot to toes may pull the foot into marked inversion if the scar is medial or into eversion if the scar is lateral. The fifth and first toes may be separately displaced by the same scar bands. These contractures must always be surgically corrected. Their persistence will lead to bone deformity in a growing child and will permanently adversely affect foot and ankle function. Even slight inversion, whether imposed by scar contracture or motor weakness, will increase pressure on the lateral border of the foot, leading to callus formation and a painful, inefficient gait. Occasionally the base of the fifth metatarsal is so offensive as to require partial surgical osteotomy.

When there is both anterior and posterior scar contracture, the talus will remain aligned with the calcaneus in a relatively plantar flexed position as the midfoot and forefoot are pulled into dorsiflexion. The result is so-called rocker bottom foot with the head of the talus being the principal weight-bearing feature. This deformity once established defies correction by usual surgical means because of the shortage of soft tissue and because vessels and nerves cannot be stretched to accommodate the corrected position. The Ilizarov technique may offer a partial solution to the problem. Removal of the head of the talus may give a reasonable weight-bearing surface. With chronic painful ulceration, amputation is the best treatment.[42]

Orthotic Treatment of the Lower Extremity

Multiple articles have been written about surgical interventions for burns to the feet in both adults and children.[43–46] The approach of the orthotist in treating the injured foot depends on the extent of the burn injury. Contracture deformities of the feet after burn injuries present a complex problem for all members of the burn rehabilitation team.[47] The options for management include orthopedic shoes with and without modifications, orthotic inserts, ankle–foot orthoses (AFOs), and heel lifts. Orthopedic shoes, which are the fundamental component of lower extremity orthotics, may be utilized with some modifications in correcting

deformities of the burned foot. Modifications of these shoes may include arch pads, molded foot thermoplastics, tongue pads, and metatarsal bars. The ideal shoes should distribute all forces to the foot appropriately, reduce pressure on sensitive or deformed structures, and encourage total surface weight-bearing along the plantar aspect of the foot. Inserts for plantar foot support, such as the University of California Biomechanical Laboratory (UCBL)-type, may be utilized as indicated.

During the preambulation stage, the patient may be fitted with those orthotic devices mentioned earlier; if properly utilized, they can position the ankle joint in a balanced position, assist in preventing or correcting plantar/dorsal contractures, and correct inversion/eversion of the foot.

Leg length discrepancies are seen frequently in the cases of severe lower-extremity burn injuries and should be addressed with a shoe lift. The ankle–foot complex is difficult to address, especially in the case of a severe thermal injury. In most cases, the resultant deformity is the equinovarus foot. Both conventional and thermoplastic systems may be designed to treat the equinovarus or equinovalgus foot. Such systems may include a metal AFO, polypropylene plastic posterior AFO (solid ankle or with an articulation), an AFO with stirrup attachment, or an AFO with stirrups and patellar tendon support. A dorsiflexion spring assist may be incorporated in the AFO to aid weak ankle motion. Different straps, such as a valgus correction strap, may be attached to the AFO for the correction of specific problems. Interface materials, such as silicone, Plastizote, and Aliplast, can be incorporated into an AFO to provide protection of the soft tissues, provide for total surface weight-bearing, and accommodate any anatomical anomalies that may be present (Fig. 47.18). In the event that a return of ROM is anticipated, an AFO could be fabricated that can be modified as the patient progresses. As described, the ankle joint is incorporated into the AFO; however, the device is left solid and articulated at a later date.

During more complicated cases, and depending on the anatomy and function of the lower extremities, a knee–ankle–foot orthosis, hip–knee–ankle–foot orthosis or a trunk–knee–ankle–foot orthosis may also be designed for the best functional outcome.[48]

Fig. 47.18 Specialized materials may be required to accommodate anatomical anomalies. Standard ankle–foot orthoses can be fabricated utilizing silicone materials to accommodate excessive scarring and limb loss.

SERIAL CASTING

Multiple authors have identified serial casting as a treatment option for burn scar contracture management.[5,49–54] Casting has been used in patients with burns for postoperative immobilization to promote graft adherence and to minimize scar contracture during the remodeling phase of healing.[54] Circumferential casting after skin grafting to the lower extremity has been an effective means of providing protection to the grafted area.[55] Serial casting has been used successfully on outpatients with burns when active ROM is limited due to scar tissue formation.[52] Dewey, Richard, and Parry described serial casting as an alternative to the use of orthotic devices for contracture management in the presence of burn scars.[9]

The literature has several examples of casting being used as an anticontracture device for the hand,[56–61] wrist,[54,60] elbow,[54,62] axilla,[63,64] knee,[54] and ankle.[53,54] In a retrospective study published in 2000, Richard, Miller, Staley et al. compared patients treated with a multimodal approach of scar massage, therapeutic exercises, and pressure therapy to those treated with a progressive approach that included static or dynamic splints and serial casting; the authors found significantly fewer days were required to correct the burn scar contractures in the progressive treatment group.[50]

Casting works based on the biomechanical principle of stress relaxation in much the same way as a static splint design does.[9] Similar to static splinting, serial casting is a rehabilitation approach used to increase elongation of scar tissue.[2] The application of a series of casts provides a low-force, long-duration stress that can cause a permanent, plastic deformation of connective tissue.[51] The goal of serial casting is gradual realignment of the collagen in a parallel and lengthened state by constant circumferential pressure.[53] Prolonged, gentle, sustained stretch provided by the cast aids in tissue elongation for the correction of contractures (Fig. 47.19). Burn scar under constant traction shows collagen formation in parallel alignment along the forces of stress.[65] Low-intensity force with prolonged duration of stretching can be applied to connective tissue whether it is scarred, contracted, or surgically shortened.[66]

A review of the literature indicates that serial casting is typically used when the patient is noncompliant, does not tolerate splints, there is persistent ROM limitation, or a skin graft site requires protection or immobilization.[51,53,54] Serial casting can be a relatively simple, fast, and painless intervention and provides an alternative to complex splinting when patient compliance is an issue (e.g., in pediatric patients or patients with decreased arousal). Bennett, Helm, Purdue, and Hunt casted 35 patients with scar contractures at an average of 161 days after burn injury and found that all had significant improvements in ROM, which raises the question of why serial casting is so often considered a last resort.[54]

Additionally, clinicians may be hesitant to apply a cast because of open wounds, despite the fact that serial casting has been advocated for protection of involved sites after skin

Fig. 47.19 Serial casting provides prolonged, gentle, sustained stretch and aids in tissue elongation and correction of contractures without pain.

grafting.[55] Ricks and Meagher evaluated cast application immediately after skin grafting in 36 patients with lower-extremity burns.[55] They found that the casted group had significantly fewer days from skin grafting to wound closure, a higher rate of graft adherence, and needed fewer surgical treatments for deficits in ROM. The use of serial casts is often advocated as a last-resort treatment when a patient does not respond to traditional therapy and is often used primarily in the long-term phase of recovery.[2]

The process of cast fabrication has been described for use in both the adult and pediatric patient populations.[51,55,56,59] A precasting assessment should include goniometric measurements, end-feel assessment of the involved joints to determine the structures involved, duration of limitation, skin or wound status, neurovascular status, functional needs, and cognition of all involved parties. The patient is educated on the position in which the cast will be applied, the expected duration of casting, and any restricted activities. Ridgway described the serial casting technique and sequence: (1) skin hygiene, (2) scar massage with moisturizer, (3) ROM exercises and assessment, (4) wound dressings, (5) application of a silicone insert, 6) extremity in figure-of-eight wrap or tubular bandage, (7) padding over bony prominences, and (8) one therapist to position and one therapist to fabricate cast.[53] Clinicians need to provide adequate pressure relief over bony prominences, however, to prevent skin breakdown. The clinician should only allow a minimal time lapse between cast removal and cast reapplication. Serial casting may be supplemented with static splinting of the adjacent joints.

Patients may require premedication and may also benefit from soft-tissue preconditioning (heating) for stretch prior to cast application. Precautions should be taken to ensure proper and evenly applied padding, including extra layers at the proximal and distal ends of the cast. The casting material should be rolled out and handled with an open hand as much as possible. Aggressive molding or overtight applications are to be avoided and can lead to compression neuropathies or vascular compromise. When cast materials harden, an exothermic reaction occurs causing the temperature within and beneath the cast material to rise, which leads to elevated temperatures and the risk of burn injuries. The greatest risk of thermal injury occurs when a thick cast using warm dip water is allowed to mature while resting on a pillow.[67] Excessively thick casts and a dip-water temperature of higher than 24°C should be avoided. Placing the limb on a pillow during the curing process of the cast puts the limb at risk for further injury and should be avoided.[68]

A variety of materials are available for the fabrication of casts. The most widely known would probably be plaster-of-Paris. Plaster is fast setting when reacting with lukewarm water. Plaster casts are inexpensive, strong, and easy to fabricate. However, they require longer drying times (24–48 hours), are prone to indentations and skin irritations, and are heavy. Other disadvantages of this technique include decreased water resistance and breakage if not constructed strongly enough. Plaster casts may be removed with a cast saw or moistened and removed with scissors.

Fiberglass casting material is an alternative to plaster-of-Paris. Fiberglass casting tape is fast setting when reacting with cool water. Fiberglass materials require a shorter drying time (15–30 minutes), are lightweight and durable, and offer resistance to dirt and water. Fiberglass casting methods are costlier than plaster. Because of fiberglass's abrasive properties, therapists must wear gloves when handling the materials during cast fabrication and removal. The patient's skin and clothing should be protected from contact with the fiberglass casting tape, as well as with fiberglass fibers during cast removal. Fiberglass casts require a cast saw for removal.

Recently, nonlatex polyester materials such as Delta-Cast have been utilized as alternatives to plaster and fiberglass. These materials, which resemble fiberglass, are very lightweight, flexible, and, because of their elastic properties, conform very well. These casts may be cut in a bivalve fashion so that they can be removed and reapplied after wound care, hygiene, and exercise.[69]

After cast fabrication is complete, the clinician should check the firmness of the cast, neurovascular status of the extremity, sharpness of cast edges, and any signs of the cast rubbing adjacent structures. When casting is completed, the patient should feel a gentle but not painful stretch. The first cast should be removed at approximately 24 hours; thereafter, depending on the patient's tolerance, it could be applied for up to 1 week at a time. In the literature, the reported frequency of cast change ranges from daily to every 10 days.[53,54,57,60,62,63] In cases of casting over open wounds, the cast should be removed every 1–2 days to avoid complications in wound healing.[53,55] The use of insert material for scar management under casts has been documented and found to be useful.[53] Serial casting is terminated when either normal ROM has been restored or no further functional gains are achieved.

According to a consensus summit of burn care professionals, the traditional thought processes regarding the use of serial casts with the burn patient need to be re-evaluated, casting regimens need to be standardized, and studies are needed to evaluate serial casting at various stages of burn recovery and the overall effectiveness of the modality for contracture management.[2]

Prosthetic Interventions

A prosthesis is a device used to replicate the function and appearance of a missing limb. Amputations among the burn patient population most often occur as a result of electrical insults but can also result from more severe thermal injuries as well. They have a significant physical and psychological consequence, which impacts quality of life.[70] Prosthetics are designed, fabricated, and fit by a certified prosthetist. Each device is individualized based on the needs of the patient. But, in general, the prosthesis should be comfortable to wear, easy to don/doff, lightweight, of durable construction, and be cosmetically appealing. The prosthetist and rehabilitation professional will consider the following when designing the prosthesis and its components: level of amputation, shape and contour of the residual limb, functional expectations, cognitive abilities, vocational requirements, hobbies/leisure pursuits, and financial resources. Standard prosthetic texts are useful in providing broad basic information and explanations of the many components available and their use.[71,72]

Patients who have sustained severe burns and subsequent amputations have complex, long-term impairments and face considerable functional deficits.

Severely burned patients tend to have sensorimotor limitations in the intact extremities that may affect their ability to utilize a prosthesis. Their limitations and strengths are important considerations when planning treatment. These patients may exhibit muscle weakness not usually seen at the same amputation levels in the nonburn patient. Areas of weakness should be noted and compensation, such as increasing joint stability through alignment or componentry, should be provided. Burned individuals may use their remaining functioning extremities differently than patients without total body involvement. Prosthetic rehabilitation should enhance adaptations and necessary compensatory methods. The challenge to the prosthetist is to design a device that is maximally useful to a person who may have multiple limitations. To be useful, a device must be as easy to use as possible. Simplicity often determines whether the device is successful or discarded.

Prostheses may be preparatory or definitive. Preparatory devices are those fitted while the residual limb is still maturing. A preparatory prosthesis is provided when reduction of stump volume is anticipated or when fitting over a bulky dressing is necessary. These devices are usually simple, passive devices that allow for early motion skills and weight-bearing through the affected limb. Some patients will continue to use their preparatory prosthesis for extended periods of time while other areas of the body are treated. Prior to definitive fitting, body weight, residual limb volume, and wear and use patterns should be stable in order to optimize the long-term result with the definitive prosthesis. The definitive prosthesis is fitted when the residual limb is fully mature. The use of a preparatory prosthesis is not mandatory, but the use of one will improve the fit and control of the definitive prosthesis and may, secondarily, reduce the amount of time needed for rehabilitation post-burn injury.

Prosthetic preparation in burn rehabilitation begins in the postsurgical phase. Early prosthetic treatment of an amputee includes splinting for the prevention of contracture. An upper extremity splint may extend past the distal end of the residual limb to match the length of the whole limb, thus assisting a patient in retaining the concept of length. Initially, therapists must address: promotion of wound healing; pain management, residual limb shaping, prevention of contractures, skin desensitization techniques (tapping, massage, scar mobilization, pressure application), edema control, and coping mechanisms for adjustment and grief. With early socket fitting, some skin problems will be encountered, but these are not usually of major significance. Silicone gel or urethane socket inserts have been used successfully for pressure relief to burn-scarred skin. As wound healing progresses, prosthetic training will begin to focus on care of the prosthetic device, don/doff methods, skin inspection routines, weight-bearing with the device, and progressive functional skills.

Just as upper extremities are different from lower extremities, so, too are upper- and lower-extremity prostheses. The minimum requirements for successful use of an upper-extremity prosthesis are trunk control to support an upright posture, sufficient upper body strength to selectively activate the control devices, and static and dynamic balance skills. The patient will need to be trained on specific body movements to develop control of the upper-extremity prosthesis. Glenohumeral flexion provides excellent power and reach for functional routines. It can be used to flex the elbow, activate the terminal device, and for activities away from the midline of the body. Scapular protraction is also trained for activation of the terminal device and facilitation of fine motor tasks at midline or close to the body. The other motions of glenohumeral depression/elevation, extension, and abduction are most frequently used to lock or unlock an elbow joint.

Different types of upper-extremity prostheses are available along a continuum from mostly passive or cosmetic to primarily functional. Most devices fall somewhere in the middle range between cosmesis and function. Cosmetic prostheses are difficult to keep clean, expensive, and ultimately sacrifice function for appearance. Functional prostheses fall into two categories. They can be designed to be body-powered (using cables) or externally powered (myoelectric or switch control). Body-powered prostheses are moderate in cost and weight, more durable, and offer higher sensory feedback. However, they require more gross limb movement and can be less cosmetically appealing. Externally powered prosthetic devices allow for more proximal function, greater strength for grasp/prehension, and improved cosmesis. Additionally, they may be heavy and expensive, offer less sensory feedback, and require more regular maintenance. Regardless of the type of prosthesis planned for, fitting of an upper-extremity body-powered prosthesis within 7–30 days correlates with higher acceptance and success rates.[73] Body-powered prostheses are most commonly used in burn rehabilitation, and Table 47.1 describes the components of upper-extremity prosthetic devices.[74,75]

The rehabilitation upper-extremity prosthetic goals should include stability of the shoulder girdle to allow prehension, overall ease of movement of the entire limb, energy-efficient use of the device, and the appearance of a normal upper extremity. Table 47.2 describes upper-extremity

Table 47.1 Prosthetic Components

Upper Extremity	Functions	Lower Extremity
Socket	Interface between prosthesis and residual limb Selective loading/pressure relief	Socket
Suspension	Holds prosthesis to residual limb Force transmission for function	Suspension
Control system: Usually movement of the shoulder or chest	Links movement of a body part to the prosthesis	Control system: Usually movement of the hip or knee
Interposed elbow joint	Performance of hand to midline Provides support during stance phase, smooth swing phase, and motion for sitting and kneeling	Interposed knee joint
Interposed wrist joint	Attaches socket to terminal device; orients terminal device in space	Shank (pylon)
Terminal device	Restores cosmetic appearance Replicates anatomic joints Replaces hand/ankle function Stable, weight-bearing surface Shock absorption	Prosthetic foot

Table 47.2 Types of Amputations and Prosthetic Needs

Types of Amputations		Prosthetic Needs
Upper extremity	Transphalangeal	Passive for cosmesis
	Transmetacarpal	Oppositional devices
	Transcarpal	Body-powered hand or hook
	Wrist disarticulation	Forearm socket, wrist component, and terminal device
	Transradial	
	Elbow disarticulation	Proximal arm socket, elbow hinge (passive, active, or externally powered), forearm lever arm, wrist component, and terminal device
	Transhumeral	
	Shoulder disarticulation	Harness system and transhumeral components
	Interscapulothoracic disarticulation	Harness system, shoulder socket and transhumeral components
Lower extremity	Transphalangeal	Toe-filler
	Toe disarticulation	Foot plate
	Ray amputation	Partial foot to tibial height prosthesis
	Transmetatarsal	
	Transtarsal	
	Syme	Socket to knee, low-profile foot
	Transtibial	Socket with foot and ankle
	Knee disarticulation	
	Transfemoral	Socket, knee joint, and ankle/foot complex
	Hip disarticulation	Socket is total contact shell, hip/knee joints, and ankle/foot complex
	Hemipelvectomy	

amputations by level and identifies the appropriate prosthetic device to address the patient's functional needs.[74,75]

The rehabilitation program for successful use of lower-extremity prosthetics begins with donning/doffing of the device, transfer skills, activities to build wearing tolerance, practice to reinforce balance reactions, and preambulation skills. Preparatory weight-bearing treatment for use of a lower-extremity prosthesis usually begins on a tilt table, progressing to standing and then ambulation in the parallel bars. The rehabilitation goals should address stability, ease of movement, energy efficiency, and the appearance of natural gait.[76] Table 47.1 outlines the common components of lower-extremity prostheses and their functions.

Lower-limb prosthetics require the following minimum requirements for successful use: upright trunk control, sufficient upper body strength, adequate lower-body stability and control, static and dynamic balance skills, and good postural alignment. Lower-extremity prosthetic fitting begins when the patient's wounds are well-healed and will tolerate pressure and weight-bearing. Lower-limb devices may be either preparatory or definitive. Table 47.2 details types of lower-extremity amputations by level and identifies the appropriate prosthetic and components.[74,75]

Two common sequelae of traumatic amputations are phantom sensation and phantom pain. *Phantom sensation* is the perceived sense that the amputated limb is still present. It is not typically characterized as painful by the patient. The patient may report feeling that the amputated limb has shrunk (telescoping). In contrast, *phantom pain* is the sensation of pain originating in the amputated part. Upon assessment, the pain may or may not be dermatomal in presentation. The patient may report constant burning, stinging, cramping, or a feeling of awkward positioning. Phantom pain is most intense acutely, gradually becomes intermittent, is worse at night, and is often exacerbated by stress/anxiety. From a therapy standpoint, phantom sensation may be managed by desensitization techniques, whereas phantom pain may be responsive to transcutaneous electrical nerve stimulation.

The overall process of prosthetic evaluation and fitting is described in Fig. 47.20. Satisfactory use of a prosthetic device in burn rehabilitation requires continuous dialogues among the patient, therapist, prosthetist, and surgeon. Return clinic visits should include consistent prosthetic re-evaluation. However, ultimately, the use of a prosthetic device depends largely on patient motivation.[74] Most prostheses can be expected to last at least 3–5 years with standard daily use. Children will need more frequent modifications or adjustments as they grow and develop.[77] In general, the simplest system that provides the most functional–cosmetic level is accepted by the amputee as the best choice.

Burn Scar Management

HISTORICAL REVIEW

The burn wound, like any other wound, heals by the formation of scar at the injured site to replace the destroyed tissues. Scar is defined as the fibrous tissue replacing normal tissues destroyed by injury or disease.[78] In the case of a burn injury, the scar, if not managed appropriately, has the potential of becoming thick and raised, resulting in scar hypertrophy. Hypertrophic scars are not cosmetically appealing, and, if they cross any joints, they may restrict movement and function. Pressure therapy for scar management is a very old and established component of a recovering burn patient's continuing rehabilitation program. Extensive historical notes on the earliest references to scarring are provided by Linares and colleagues, who attribute the first full medical description of scars to Petz in 1790.[18] They also state that the first medical reference to the use of pressure for treatment was written by Johnson in 1678 referring to the work of Ambroise Paré in the sixteenth century.[18] Other historical events noted by Linares et al. are the first known accounts of the use of pressure for treatment of children in 1859, use of elastic bandages in 1860, adhesive plaster for pressure in 1881, and use of traction to treat scars in 1902. Linares's review includes descriptions of Nason's work in 1942, in which he noted that ischemia produced by pressure arrests the overproduction of scar tissue, "where the imprint of the elastic of an undergarment or a belt may be seen—no keloid is present."[18] Another historical review by Ward[79] reveals that Blair in 1924 reported the positive influence of pressure on healing wounds. Nason's application of the "constant pressure" principle included developing a type of neck splint made of a piece of dental impression compound or a piece of heavy felt strapped tightly over the scar for 6–8 weeks and possibly longer. Later, various splints were developed utilizing pressure and immobilization.[80] In the 1960s, Silverstein and Larson observed the influence of pressure on fresh scars. Their observations led to the manufacture of custom pressure garments that revolutionized scar management in the 1970s and continue to be the most preferred method of managing scars to date.[18,79]

THE SCAR

As the burn wound closes, or after skin grafting operations take place, scars begin to form. Generally, the deeper the burn injury is, the higher the risk for the development of hypertrophic scars. Also, the longer a wound remains open, the higher the chances for hypertrophic scar formation.[80,81] As the wound begins the healing process, collagen fibers develop to bridge the wound surface, forming an immature (active) scar, which appears as a red, raised, and rigid mass.[82–85] Abston reported that pressure therapy while the scars were active led to flatter, softer, and more devascularized scars.[86] Burn scars may take up to 2 years or longer to mature. Factors contributing to the formation of hypertrophic scars may include wound infection, genetics, immunological factors, repeated harvesting of donor sites, altered ground substance, age, chronic inflammatory process, location of the injury, and tension.[87] Scar hypertrophy may be evident at 8–12 weeks after wound closure.[88]

SCAR ASSESSMENT

A thorough burn scar assessment should be carefully conducted by the burn therapist because the burn scar has serious implications on the final functional and cosmetic outcome at the completion of the rehabilitative process. Over the years, several scar assessment scales and individual scar assessment tools have been developed to quantify burn scars to determine the efficacy of scar management interventions. These scar assessment scales and tools are either objective (provide a quantitative measurement of the various scar characteristics) or subjective (provide an overview of the quality of the scar as measured by an observer). The Vancouver Burn Scar Assessment developed by Sullivan and colleagues is a subjective way of rating the burn scar pigmentation, vascularity, pliability, and height, and it is widely used among clinicians.[2,89] Despite the fact that the Vancouver Burn Scar Scale is a subjective scale, it continues to be the most frequently utilized burn scar assessment scale by researchers to date. Baryza and Nedelec have attempted to improve the Vancouver scale through the years, and they have somewhat succeeded in doing so.[90–92] Other scar scale assessments include the Patient and Observer Scar Assessment Scale (POSAS) and the Manchester Scar Scale (MSS). The majority of scar scale assessments available are thought to be subjective in nature and are criticized for their lack of validity and reliability. Hambleton and colleagues studied the thickness of scars with ultrasonic scanning. This method, which is completely noninvasive, allows for a comparison of the thickness of dermal tissue in the traumatized area with that in normal skin at regular intervals following initial healing.[93] Darvey et al. described a technique for the objective assessment of scars utilizing a video camera image on a computer and quantitatively analyzing the color of the scars using a custom-written computer program.[94] Esposito used a modified tonometer to measure skin tone, which correlates to skin pliability and tension.[95] Bartell and co-workers used the elastometer properties of normal versus injured skin. In his study, Bartell showed that scars, if left untreated, will show improvement over time.[96] Hosoda utilized laser flowmetry to determine the perfusion of hypertrophic scars versus nonhypertrophic scars.[97] Other studies suggest that laser Doppler flowmetry and monitoring of transcutaneous oxygen tension may in the future be ways of determining scar maturation.[98,99]

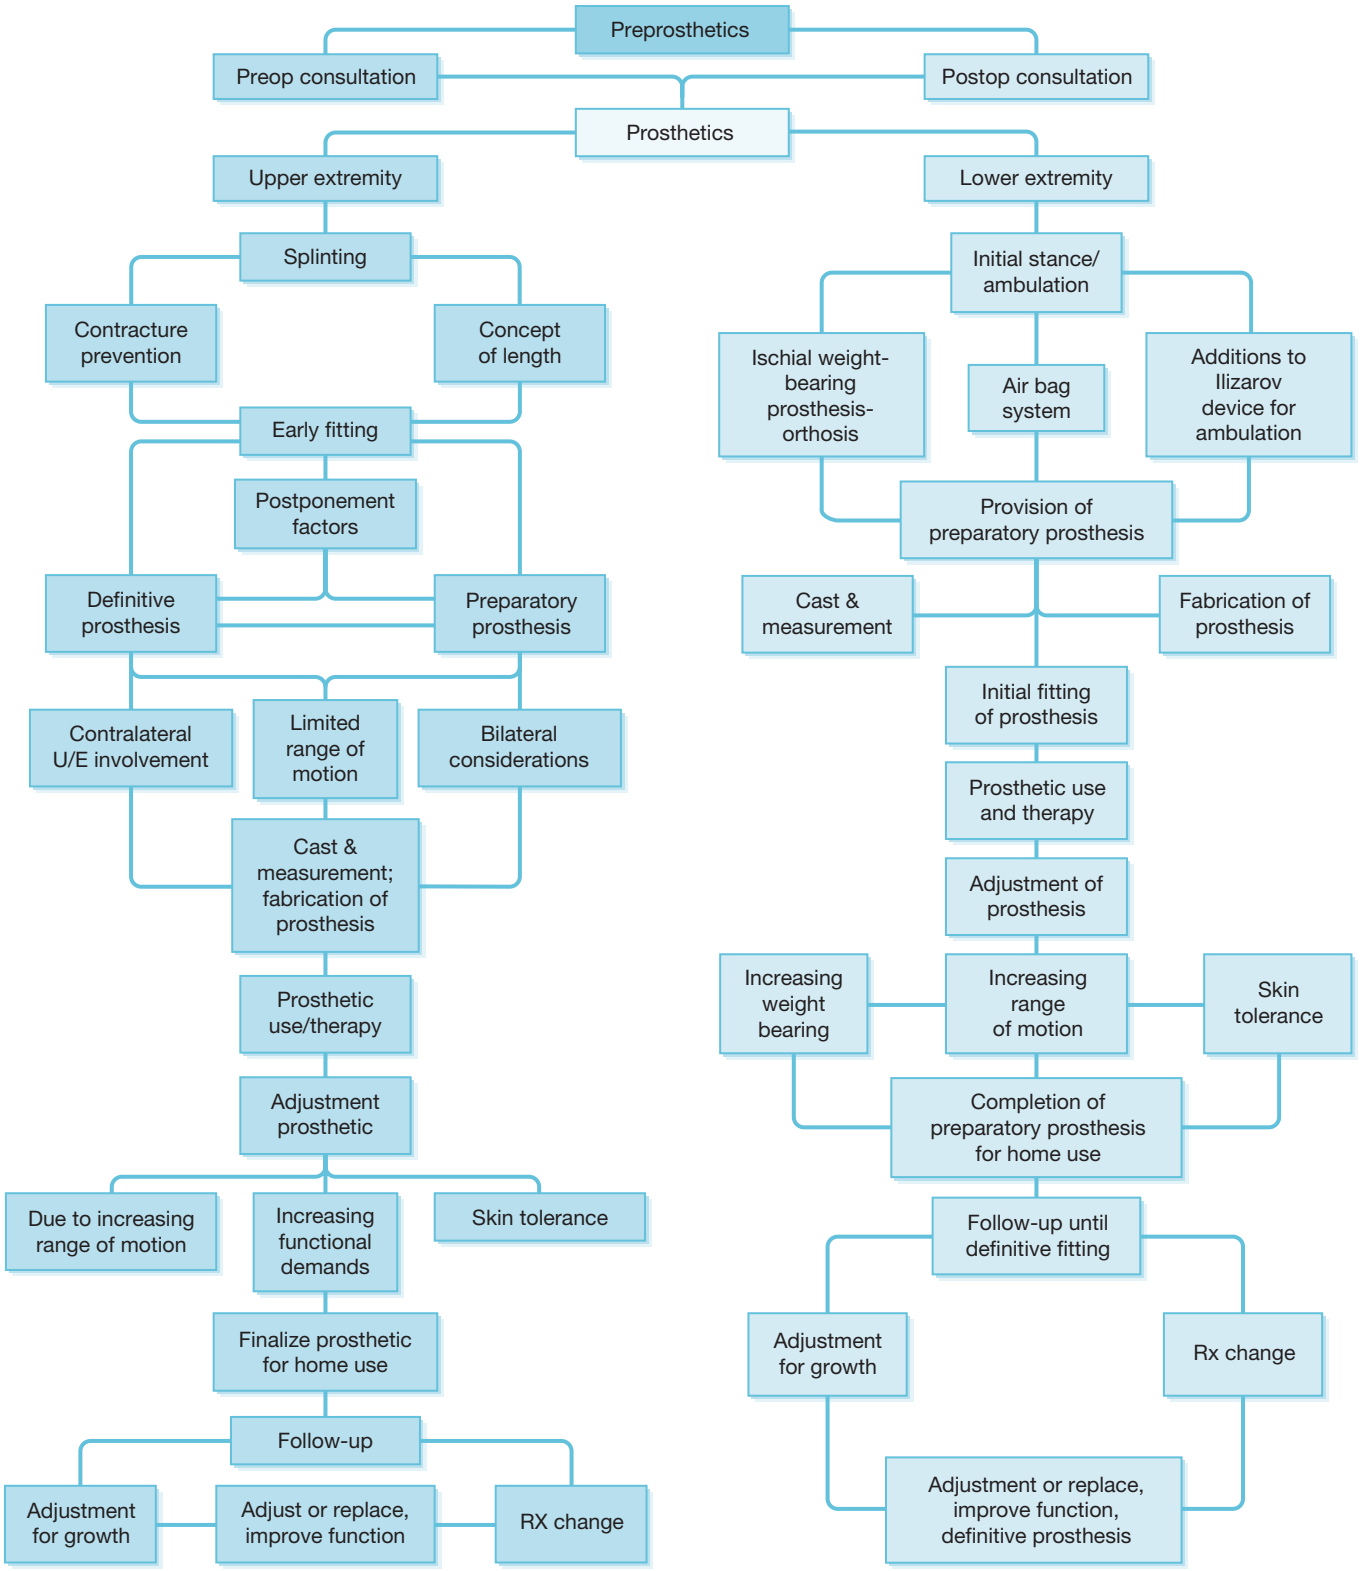

Fig. 47.20 Algorithm showing the process of prosthetic evaluation and fitting.

Fearmonti et al. have compared several scar assessments and individual scar measurement devices and have highlighted their insufficiencies and limitations.[100] A comprehensive, reliable, and valid burn scar assessment that is inclusive of all major scar characteristics relevant to burn rehabilitation has yet to be developed.[101] Individual scar characteristic assessment devices may, in some instances, show some reliability and validity; however, they are cost-prohibitive and impractical to use in the clinic on a daily basis.[102]

TREATMENT OF HYPERTROPHIC SCARS

To date, hypertrophic scars remain very problematic and difficult to manage. Even though the mechanism of scar maturation is not yet well understood, clinically, the accepted protocol to treat hypertrophic scars includes the use of pressure therapy, which should be instituted early on in the maturation process of the burn scar. Means of pressure therapy include pressure garments, inserts, and conforming orthotics. Once the skin has healed enough to withstand shearing, massage and heat modalities may be utilized as an adjunct in scar management. The use of pressure in effectively depressing scars was well documented by Silverstein and Larson in the 1970s; their observations and studies sparked the near-universal use of pressure garments. When an active scar is compressed, it blanches, which indicates decreased blood flow in the area.[88] Less blood leads to decreased oxygen in the tissues, which in turns leads to decreased collagen production, which brings a balance between collagen synthesis and collagen breakdown (lysis). When a balance in the production and breakdown of collagen is established, the resultant scar appears flatter.[103] Kealey et al. conducted a prospective randomized study to compare the efficacy of pressure garment therapy in patients with burns. Patients were randomly assigned to receive either pressure garment therapy or no pressure garment therapy. Assessment of the maturity of scar included use of the Vancouver Burn Scar Assessment Scale. The results on 113 patients studied in the follow-up revealed no significant differences between groups when age, body surface area burned, length of hospital stay, or time to wound maturation were compared.[104] In addition to this study, other studies have reported problems related to lack of adherence and discomfort, blistering, ulceration or scar breakdown, swelling of extremities, and skeletal and dental deformity due to excessive pressures, which often leads to cessation of treatment, significant side effects, and deformity.[88,104–109]

On the other hand, studies have also reported benefits of pressure garments.[110–112] The reader is referred to various recent excellent review articles on the efficacy or lack of efficacy of pressure garments in the management of hypertrophic burn scars.[113,114] The reason for the absence of unequivocal evidence is that garments must be worn continuously for a least 23 hours a day, making compliance or adherence difficult.[18,107,114] In addition, the optimal pressure that must be applied to the scar for treatment is not known.[107,115–117] Thus the studies and debates continue, and, at least until more evidence is gathered, pressure therapy with the familiar elastic garments is still prescribed. Patients and families would no doubt feel relieved if the data eventually show that pressure does not make a significant difference in long-term outcomes. However, it should be noted that the studies thus far include neither the examination of burns over joints nor do they include burns of the hands, neck, and face. In addition, none of the studies to date addresses the use of pressure in the form of splints, another source of discomfort and tension for burned children and their families.

None of the known studies has yet broached the face with an attempt to determine the efficacy of pressure versus no pressure. Facial pressure garments in children may pose problems due to interference with growth.[118,119] We recommend that these patients should be closely monitored for normal facial and dental development by physicians, including dental specialists. The elastic hood and underlying silicone face pad present special problems for patients, and some extreme challenges for the adults trying to assist a burned child or adolescent. The elastic mask and hood, covering head, face, and hair, effectively hides the identity of the person wearing it. It is perceived by children as sinister, associated with "bad men" or monsters, and most children who have worn this garment can relay stories of being ridiculed by strangers who did not know the purpose of the garment. Emotional expressiveness, usually apparent in facial movements, is hidden by the hood. More than one child has explained nonadherence with the prescribed wearing of the elastic mask with a statement similar to "I want my friends to see me laugh." A study by Groce et al. compared the elastic mask and hood with silicone pad to the transparent silicone face mask and found no significant differences between the amount of pressure applied by each to the forehead, cheeks, and chin.[120] Many children have expressed a preference for, and seem to wear more readily, the transparent mask. This study should make it easier for them to be granted their choice—an important event during a time when so much is happening to them outside of their control.

PRESSURE THERAPY

As long as the scars are active, they may be influenced by pressure therapy. However, not all burn scars require pressure. Patients with burn wounds that heal within 7–14 days do not need pressure therapy. Those patients whose wounds heal within 14–21 days are closely monitored for pressure therapy needs and may be generally advised to use pressure garments prophylactically. A wound that heals after 21 days will require the use of pressure garments.[103] The correct amount of pressure in suppressing the hypertrophic scar has not yet been determined. Pressure of as little as 10 mm Hg may be effective in remodeling the scar tissue over time. Pressures over 40 mm Hg, however, may be destructive to tissues and cause paresthesias.[88] Early use of pressure therapy may improve scar outcome and accelerate time to scar maturity.[121] The use of conforming thermoplastics along with elastic bandages may also be utilized as means of early pressure therapy.[122] Once the wounds are almost or completely closed, tubular elastic bandages such as Tubigrip may be utilized. These tubular bandages are offered in different sizes and accommodate all anatomical circumferences. Care should be taken in applying these tubular bandages so that the fragile skin or the freshly applied skin grafts do not shear or that the minimal dressing underneath is not disturbed. The burn therapist should be aware that these tubular bandages are materials made of a single elastic thread spiraling through the weave of the fabric, and disturbance of the continuous elastic by cutting holes into it will alter the pressure gradient provided by these materials. The tubular elastic bandages should be doubled over the skin surface area treated to provide adequate pressure.[123] Early pressure application over the hand and digits can be accomplished through the use of thin, elastic, and self-adherent wraps such as Coban (Fig. 47.21).

Fig. 47.21 A Coban wrap can be used to decrease edema and aid in the effective management of hand scar hypertrophy.

This form of pressure is excellent for adult and pediatric patients for controlling edema, and it aids in the early scar management of hands when the shearing forces of a glove cannot be tolerated. Small children are excellent candidates for Coban gloves versus a garment glove because of compliance issues, comprehension of instructions in assisting with the application of a custom glove, and difficulties in obtaining accurate measurements for a custom glove. Coban may be applied over the burn dressings or directly onto the healed digits. The burn therapist needs to be aware that if Coban is wrapped too tightly, it may deform the interosseous structures of the healing hand. However, if Coban is wrapped too loosely it may encourage swelling of the hands when used in combination with arm elastic garments. Coban strips are pre-cut approximately twice the length of the digits to be wrapped. Each strip is wrapped in a spiral fashion beginning at the nail bed of each digit, overlapping half of the Coban width and ending in the adjacent web space. Each fingertip needs to be exposed so that blood circulation can be monitored at all times. The Coban is stretched from 0% to 25% of the entire elasticity of each strip. Once all web spaces are covered, the rest of the hand is wrapped with Coban, extending approximately 1 inch past the wrist joint. No skin areas should be visible once the Coban glove is completed. If small hand areas remain uncovered, a small piece of Coban is stretched over the area and adheres to the rest of the Coban. When the glove is completed, the therapist should very superficially lubricate the entire glove with lotion to eliminate the adherent effect of the Coban and allow for the functional use of the hand. Coban should be removed on a daily basis by the therapist or caregiver. Removal of Coban should be done carefully by cutting off or unwrapping each digit individually to avoid disturbing any wound healing.

The use of prefabricated interim pressure garments is widely accepted and utilized in burn rehabilitation. These garments are available commercially from different companies, and they include pieces for the entire body. Interim garments, which are made of softer materials, introduce the burn patient to circumferential pressure and protect newly healed skin. Another reason for using these

Fig. 47.22 Custom-made pressure garments may be fabricated for the entire body.

garments prior to ordering custom-made garments is to allow for the patient's weight to stabilize (post-acute hospitalization) and any remaining edema to subside. In some cases where obtaining custom-made garments on regular intervals (approximately 12 weeks) is not an option, the recommendation should be that interim garments should be the choice for long-term pressure therapy. Once the patient's weight has stabilized, edema has subsided, and the skin is able to withstand some shearing (approximately 3–4 weeks post-wound closure), measurements are taken for the fabrication of custom-made pressure garments (Fig. 47.22). Today, several companies specialize in the fabrication of these garments. Clinically, custom therapeutic pressure for the prevention, control, and correction of scar hypertrophy averages 24–28 mm Hg, which is approximately equal and opposing to the capillary pressure (25 mm Hg). At this pressure level, many researchers believe that scars may be altered.[107] In order for pressure therapy to be effective, pressure garments need to be worn at all times, day and night. They should only be removed for bathing and on occasion during exercises should they interfere with movements. Each order is duplicated so one set of garments can be worn while the other is being washed. Today, pressure garment companies offer multiple colors of materials and, for the pediatric population, cartoon characters may be sewed on the garments to make them cosmetically appealing and improve patient compliance.[124,125] The burn therapist should choose a reputable company that provides excellent service and support for the patient and the therapist. The company's willingness and flexibility to manufacture nonstandard garments, availability of special options, cost, and turnaround time should be taken into

consideration when selecting the burn center's pressure garment provider.[126]

INSERTS

Inserts are widely utilized in burn rehabilitation as an adjunct to achieving effective pressure over certain anatomical locations where pressure garments do not provide adequate pressure. These locations include concave body areas such as the face, neck, antecubital fossae, sternum, palm of the hands, web spaces, upper back, and arches of the feet. These materials come commercially prefabricated or may be custom-made by the burn therapist. Inserts come in different forms, such as silicone/nonsilicone gels or gel sheets, elastomers, putties mixed with a silicone catalyst, skin care silastic pads, foam, and even in the form of hard thermoplastic materials contouring to different anatomical locations. The experienced burn therapist chooses the appropriate insert material best suited for the patient according to the stage of scar maturation and skin sensitivity. Generally, pressure therapy begins with a soft, thin, and elastic insert and progresses to a more rigid insert in depressing the more unyielding burn scar. Inserts need to be worn underneath pressure garments, starting with a few hours of application and progressing as tolerated toward a 23-hour application.[127] The inserts should extend approximately 5 mm beyond the scar margins and should be applied for several hours the first day then increased by 2-hour increments every other day until the patient is able to wear it for up to 23 hours per day.[128] They should be removed frequently for cleaning (warm water and soap), to avoid scar maceration and skin breakdown. Patients may be allergic to certain insert materials so the burn therapist may try different inserts until one is found to be best tolerated by the patient's skin. In cases of scar maceration, blisters, skin breakdown, contact dermatitis, a rash, or an allergic reaction, inserts should be removed immediately until healing occurs. Silicone, a polymer based on the element silicon, appears to be the trend in the treatment of hypertrophic scars. To date, the mechanism of how silicone affects the burn scar is not known. Clinically, silicone has been observed to depress the height of hypertrophic scars, prevent shrinking of fresh skin grafts (hard elastomer silicone pads vs. silicone gel pads), and increase the pliability of scars, thus allowing for increase in the ROM of affected joints. Silicone, being occlusive, may cause the collection of excessive moisture and cause skin maceration if not removed frequently for cleaning and drying. Its disadvantages are that it is very expensive and short-lived.[129–131] The therapist should look for silicone gel pads with a nonshearing protective medium on the nonskin surface in order for the gel to last longer. Also, buying larger gel pads and cutting them to fit the patient's need may be a cost-effective method for working with today's shrinking clinic budgets.

Other insert materials include liquid silicone elastomer, which when mixed with a catalyst forms a solid but elastic insert (Fig. 47.23). The experienced therapist is able to create custom inserts for difficult anatomical locations such as the face and web spaces using this technique. Prosthetic Foam is a liquid-based silicone elastomer which, when mixed with a catalyst, solidifies in the form of a very pliable foam insert that works best for the palm of the hands, where function needs to be preserved while pressure is applied. These foam inserts also work best for applying pressure to contour surfaces on the face (around the eyes, mouth, and nose) while protecting these sensitive areas from excess and rigid pressure. Elastomer putties such as Otoform K or Rolyan Ezemix form semi-rigid but still elastic inserts for different areas of the body where the scar can tolerate more pressure, such as in the web spaces to prevent syndactyly.[130]

Fig. 47.23 Silicone elastomer inserts for the dorsum of the hand and web spaces are utilized for the prevention of syndactyly and depression in scar tissue.

High-thermoplastic transparent masks were developed in 1968 by Padewski to be applied directly to the face to prevent, control, and reverse scar hypertrophy. These masks require the moulaging of the patient in creating a negative facial mold. A positive mold of the face is fabricated with the use of plaster. The patient's positive facial mold is then sculpted in an attempt to recreate the patient's nonburned face. A high thermoplastic material such as Uvex or W-Clear is then pulled over the positive mold to create the transparent face orthosis (Fig. 47.24A). Holes for the eyes, nose, and mouth are cut. The transparent face orthosis is worn with various harness systems designed to secure it to the face to address facial scar management.[132] The use of three-dimensional scanners can replace the traditional methods of face orthosis fabrication. Using a scanner greatly reduces patient anxiety by achieving the same accuracy as moulaging in a fraction of the time without physically touching the patient's face. The scan is sculpted on a computer and a positive tool is manufactured out of foam off-site. The positive tool is then sent to the facility for face orthosis fabrication. In the past, scanners were so large that facilities had to dedicate an entire room to their use; today, scanners are small enough to fit in a portable case and are run by laptops. These newer portable scanners give a therapist the freedom to scan patients in any setting in the hospital including intraoperatively. In cases of significant scar hypertrophy on the face, the positive mold is sculpted sequentially over a period of time to avoid excessive pressure over facial scar that could lead to skin breakdown. A silicone elastomer face mask may be created utilizing the existing positive facial mold and is worn under facial pressure garments

Fig. 47.24 (A) A Uvex clear face mask or **(B)** a silicon elastomer face mask provides pressure to the face to prevent scar hypertrophy and preserve facial features.

(Fig. 47.24B). The use of the clear and silastic masks is preferred over the use of just a facial garment because these masks provide conforming pressure around facial openings (eyes, nose, and mouth). Frequently, the burn therapist manufactures the clear orthosis to be worn during the day and the silastic mask along with the facial garment to be worn at night.[17,18,133,134]

BURN SCAR MASSAGE

Once the burn scars have matured enough to tolerate shearing forces, massage may be incorporated into the scar management regimen. Scar massage is an effective modality for maintaining joint mobility in the case of contractures. It aids in softening or remodeling the scar tissues by freeing adhering fibrous bands, allowing the scars to become more elastic and stretchy, thus improving joint mobility. Initially, the therapist may utilize a nonfrictional massage applying mostly stationary pressure to skin blanching and mobilizing the skin surface without friction. Utilization of lubricants during this massage technique should be avoided. As the skin begins to tolerate frictional massage, the scar tissue is manipulated in circular, parallel, and perpendicular motions, using a lubricant and mobilizing the skin to blanch when performing the desired technique.[135,136] Clinically, scar massage is found to alleviate itching and is utilized for desensitization purposes. An electrical massager with a heat attachment may be used along with lubrication because heat and massage in combination may increase scar pliability. Massage should be performed at least twice daily; the recommendation is three to five times daily for 5–10 minutes on each treated body surface. The burn therapist should frequently assess the skin condition to avoid further injuries. The patient and/or family are instructed on home massage techniques, and electrical massagers may be issued for home use. To decrease the effects of scar tissue, a burn therapist must utilize all available options to achieve a functional outcome. Therapeutic heat is the most common modality used in burn scar management. Application of heat may permit easier elongation of scar tissue through increased extensibility of connective tissue.[137] Heat relaxes tissues and makes them pliable in preparation for mobilization. Heat modalities may include hot packs, paraffin wax, fluidotherapy, and ultrasound. Even though the use of therapeutic heat as an adjunct to rehabilitation is well-documented, therapeutic heat modalities are infrequently utilized in burn rehabilitation.[138,139]

Caution should be used in the application of heat modalities on patients who have sustained a burn injury. Patients may not be able to tolerate heat over areas of healed or grafted burns due to hypersensitivity. Conversely, patients with diminished sensation are unable to determine if the temperature is appropriate and are at risk for further injury. Although caution needs to be taken, the use of therapeutic heat in burn patients can provide an effective method for increasing burn scar extensibility.

The use of passive stretch in conjunction with therapeutic heat greatly increases the effectiveness of the treatment. Studies have shown that the use of therapeutic heat during a slow load prolonged stretch is an effective method for attaining rapid and lasting increases in ROM when compared to low load prolonged stretch alone.[140] Warren et al. reported that low loads for prolonged periods of time were found to produce significantly greater residual length in rat tail tendon, especially at elevated temperatures.[141]

Hot packs can provide superficial heat to burn scars and assist with stretching contractures. Common treatments in burn rehabilitation include using hot packs alone before treatment or in conjunction with therapeutic exercise such as active ROM or prolonged stretch. Because of the shallow depth of heat penetration, hot packs may have little effect on deeper layers of scar tissue.[137]

Ultrasound has been used by rehabilitation therapists to increase temperatures deep within the tissue. Reported benefits of ultrasound in the treatment of burn scar include increased extensibility of collagen tissue, increased blood flow, and elevation of pain thresholds.[137] Application of topical therapeutic ultrasound to scar tissue has been reported to produce a tissue temperature rise that leads to an increase in the extensibility of collagen.[142] The combination of ultrasound and passive stretch was found to further increase tissue elongation.[137] Paraffin is an effective heat modality used most commonly for the hands or feet. Heated paraffin encourages collagen extensibility and may also be beneficial because of the softening of the scar by the mineral oil in the paraffin.[137] The use of passive stretch in conjunction with paraffin has been shown to increase joint ROM and was found to make patients' skin noticeably softer and more pliable after use.[143] Similar to other heating modalities, paraffin has been found to increase ROM in conjunction with stretching compared to stretching alone.[144]

Burn scar management is a complicated and lengthy process, and, for it to be successfully completed, the patient and caregivers should be committed to follow the therapist's recommendations. Extensive training should take place addressing the use and care of pressure garments, inserts, lubrication, and other therapeutic scar management procedures to be performed by patients and their caregivers. Lubricants that do not contain perfume and other skin irritants should be selected and applied (at least 2–3 times daily) to the healing skin. Lubricants with a sun protection

factor (SPF) of at least 15 are recommended.[145] Written instructions with pictures and diagrams along with videos addressing scar management should accompany the patient home on discharge from the hospital. Follow-up visits to the burn or rehabilitation clinic for the assessment of overall recovery, including garments, inserts, and other home therapeutic interventions, are needed so that the patient may successfully complete his or her burn rehabilitation during the first two years after the injury. The therapist's knowledge, creativity, and continuing research in improving the currently existing scar management techniques may be the key to positive outcomes in pressure therapy.

THERAPEUTIC EXERCISE

Burns often result in devastating injuries that severely affect a person's ability to perform functional activities through severe deconditioning, ROM limitations, weakness, and fatigue.[146,147] Therapeutic exercise is one of the central interventions used by physical and occupational therapists to combat the multitude of problems associated with burn injuries. Therapeutic exercise is defined as scientific supervision of bodily movement with or without apparatus, for the purpose of restoring normal function to diseased or injured tissues.[148] The use of therapeutic exercise in conjunction with a comprehensive rehabilitation plan helps to prevent deforming contractures and to maintain strength in both involved and uninvolved extremities.[149]

Even though painful and extensive therapy is required during the long rehabilitation process, the results are for the most part dependent on the patients' and families' understanding, involvement, and dedication to the treatment.[138]

The goals of therapeutic exercise in burn rehabilitation are to:

- reduce the effects of edema and immobilization,
- maintain functional joint motion and muscle strength,
- stretch the scar tissue,
- return the patient to optimal level of function.

Exercise prescription is an ongoing process that is altered according to the patient's medical status and changing needs.[150] In the conservative treatment of burn wounds, a vigorous physical therapy program is instituted immediately so as to maintain function.[151] Postoperatively, exercises involving autografted skin over joints are usually discontinued for 4–5 days. Escharotomies, fasciotomies, heterografts, and synthetic dressings are not contraindications for exercise.[152] Early mobilization to decrease edema, proper exercise techniques, and accurate documentation of function are more important than the type of wound closure.[151]

One of the most common and clinically significant complications after severe burn injuries is burn scar contractures that lead to decreased ROM and joint deformities.[147] Scar contracture and joint mobility limitations are the result of the shortening of immature connective tissue. Therapy aims to prevent deformity and the subsequent limitation of movement. In circumferential burns, both the flexor and extensor surfaces are at risk of contracture. Therapeutic exercise in conjunction with splinting should promote agonist and antagonist movements around those joints to maintain mobility.[153] Treatments are tailored to each individual patient, with independent living being the ultimate goal throughout the rehabilitation continuum.

Therapeutic exercise begins immediately following the burn injury. For a patient being treated conservatively, movement helps maintain strength and ROM and aids in circulation and healing. Exercise is initially painful, and the very first repetition is often the most difficult. Discomfort is due to stretching skin that has lost its natural lubricating mechanism and has become dry and tight. Movement itself decreases pain. Each subsequent repetition will be easier as the skin stretches and the muscle pumping action of active movement helps resolve edema, thus significantly reducing pain.

To show the progression of exercise throughout a patient's stay after a burn injury, exercise will be discussed in terms of the rehabilitation phases described by Richard.[154]

Exercise During the Acute Rehabilitation Phase

The acute rehabilitation phase is defined as the time from admission until about the time that a patient's wounds are 50% closed or skin grafting for wound closure has begun.[154] Early therapeutic intervention on the burn unit has long-term implications for restoration of function.[146] Early initiation of burn rehabilitation with an emphasis on several factors including early ambulation and a focus on preventing joint contracture through stretching exercise has been shown to be effective in reducing contractures.[155]

During the early part of the acute rehabilitation phase, the exercise goals are resolution of edema, maintenance of joint mobility, and prevention of respiratory complications, which can often be performed without interfering with life-saving measures.[150]

During this phase, patients spend long periods in bed due either to their medical status or postoperative immobilization after skin grafting. Results of patient immobilization due to burn injury include decreased cardiovascular fitness, disuse osteoporosis, increased risk of thromboemboli, pulmonary complications, decubiti, and muscle atrophy.[150] Due to the patient's medical status during the acute rehabilitation phase, the patient may not be able to tolerate vigorous exercise. It is therefore recommended that exercise programs focus on increased frequency of treatment sessions that are shorter in duration.

Active ROM exercises are significant in the reduction of edema in the extremities and can begin within 24–72 hours after burn injury.[150] Active ROM exercise is performed independently by a patient. This is the form of exercise most recommended because it stretches healing skin and provides strength-inducing benefits. Frequent exercise performed actively (with voluntary muscle contribution) by a patient promotes the greatest increase in movement. Active ROM exercises are vital during burn rehabilitation to counteract the effects of prolonged bed rest and muscle atrophy, as well as to maintain ROM and prevent contractures. The best exercise for a joint affected by burns is complete active ROM.[149] Active ROM more adequately addresses the patient's functional physiological and psychological needs than does passive ROM.[156] Although active ROM may be a superior form of exercise for a burn patient, its use during the acute burn phase may be somewhat limited. Medical status and intubation, as well as fear and anxiety may all make active ROM exercises difficult to carry out.

If a patient can actively participate in movement but cannot move actively through his or her full ROM, active-assistive ROM is appropriate. Active-assistive ROM exercises utilize the same principles as active ROM, but a patient is assisted by an outside force (therapist or assistive device) to achieve the full ROM. A patient will achieve improvements in strength and ROM, but not equal to those provided by active exercise. Therapists should use their judgment in letting the patient perform as much of the exercise as possible actively and only assisting when needed.

While active range may be the most beneficial, it can be difficult to initiate after admission due to the patient's medical status and level of responsiveness. Critically ill, septic, and heavily medicated patients are often unable to cooperate in active exercises.[150] In these conditions, passive exercise is used to maintain ROM, assess joint motion, and elongate tissue.[157] Passive ROM exercises are an important factor in preventing contractures and maintaining ROM when a patient cannot or does not willing actively move through his or her available ROM. Although passive ROM requires less energy expenditure, it does not fulfill as many of the patient's needs as active exercise.[156] The use of a continuous passive motion (CPM) device has been documented to be an effective modality for improving joint ROM.[152] Rehabilitation advances have shown CPM treatment to be a viable option because of its benefits to soft-tissue remodeling, joint nutrition, wound healing, and venous dynamics.[158,159] Care must be taken when applying CPM devices to reduce risk of shearing against skin.

Early exercise activity is beneficial in shortening the acute care hospitalization stay post burn injury, with studies currently being researched further. Strengthening exercises are of great importance throughout the continuum of burn rehabilitation to combat muscle atrophy and can begin during the acute rehabilitation phase. Resistive exercises are used to maintain or increase strength, ROM, proprioception, and coordination.[160,161] Due to the patient's level of consciousness and comprehension during the acute rehabilitation phase, strengthening exercises may be difficult to institute and should start with simple exercises progressing as the patient's status improves. Isometric exercises are beneficial to maintain muscle strength when a patient is on bed rest and are comfortable for the patient to perform while requiring a minimal amount of energy expenditure.[157] The benefit of isometric exercise is that the patient will not "forget" how to contract the muscle, a common phenomenon occurring with periods of prolonged immobilization. Isometric exercise also helps in maintaining muscle strength. Manual resistance can also be applied gently by the therapist as the patient contracts his muscles and attempts motion against the resistance, or the patient is asked to maintain a position and then resistance is applied.[150]

Another important aspect of a patient's recovery is the ability to ambulate. Ambulation can begin as soon as possible after admission as long as the patient is medically stable.[160] Severe weakness, impaired motor control, decreased cognitive status, pain, and risk of graft shearing are all factors that can make ambulation a difficult task.[162] An Unna boot may be applied at time of skin grafting to the lower extremity and contribute to early patient ambulation. The Unna boot is a bandage impregnated with calamine lotion and zinc oxide which, when applied over the grafted lower extremity (six layers), hardens to a semi-rigid dressing resembling a plaster cast. This cast-like total contact dressing provides uniform support to the fresh skin graft and facilitates early ambulation. An Unna boot may be applied for up to 7 days post-grafting, though it could be removed earlier for inspection of the skin graft. If removed, a new Unna boot needs to be fabricated depending on the burn center's lower-extremity postoperative immobilization protocol.[163]

Primary goals of ambulation include maintaining lower-extremity ROM, reducing the risk of thrombophlebitis, preventing decubiti, providing mild cardiovascular conditioning, and maintaining or increasing strength and endurance.[150] Ambulation exercises may also help increase appetite. In addition, ambulatory patients have fewer problems with lower-extremity contractures and physical endurance.[152]

All wounds must have the proper dressings applied prior to ambulation. Lower-extremity burn wounds should be wrapped with elastic bandages in order to facilitate capillary support. Wrapping that incorporates the figure-of-eight pattern has been reported to provide better pressure than the spiral wrap, perhaps due to increased vascular support.[164]

As with other exercise, proper positioning facilitates proper gait.[153] The patient who has been allowed to assume a position of comfort will have difficulty extending the hips and knees during ambulation. The ankle may be tight, limiting plantigrade position when in the upright position. If the joints are in normal alignment, the amount of pain and energy needed to mobilize these joints are greatly reduced.

In the past, it was common practice to have patients placed on bed rest for long periods of time after autograft application to the lower extremities, approximately 5–10 days after autograft application.[165–167] More recently, however, several studies have shown the benefits of earlier postoperative ambulation.[166,168–171]

The proposed benefits of early ambulation include decrease in the incidence of pulmonary embolism, deep vein thrombosis, and joint stiffness, as well as a shorter hospital length of stay.[168] Other benefits include maintaining strength and endurance, increased independence, a decrease in fear, and fewer complaints of pain.[170]

In preparing for ambulation, therapists may use a tilt table with patients who lack the capacity to stand and mobilize their lower extremities (Fig. 47.25).[162,164,172,173] Tilt tables provided passive weight-bearing with no active muscle contraction needed. Tilt tables provide gradual weight-bearing through the lower extremities and are also an effective treatment for orthostatic hypotension.[162] However, therapists should keep in mind that a tilt table represents a mostly passive introduction of gravity to the body and does not promote proper alignment of the musculoskeletal system. Creative efforts and aggressive techniques are sometimes necessary to encourage ambulation in patients who first appear incapable or unprepared to begin erect weight-bearing exercise.

Patients tend to perform much better when given an achievable goal, such as walking a specific distance or to a certain place. Children do well when provided with a desired incentive such as an age-appropriate activity or a game.

Fig. 47.25 The tilt table may be utilized prior to ambulation for those patients who may have difficulty assuming the upright position.

Frequent rest periods may be necessary secondary to decreased endurance levels or pain.

Exercise During the Intermediate Rehabilitation Phase

The intermediate phase is the time surrounding closure of the wound and extending up until the time of complete wound closure.[154] The prevention of functional impairments becomes the focus of therapeutic exercise as patients begin to achieve wound coverage. The goals of exercise during this timeframe include the stretching of healing skin, maintaining full joint ROM, preserving motor skill coordination, promoting functional independence, and maintaining strength and endurance to minimize muscle atrophy.[150,174]

As wounds close, scar formation begins, which leads to contractures that limit ROM and impede function, which makes exercise even more important. As a patient's medical status continues to improve and operations become less frequent, more time can be allotted to spend in rehabilitation. Increased alertness and improved medical status also lead to increased involvement of the patient in rehabilitation. As the patient advances medically, the therapeutic course should become more challenging.

While purely passive ROM should be utilized less during the intermediate phase of rehabilitation due to the patient's increased ability to move actively, it still serves an important purpose. Passive ROM provides an opportunity to assess joint movement and determine if the patient can attain as much movement actively as the therapist can passively.[160]

Another form of passive movement that can be utilized by a rehabilitation therapist is the sustained stretch. Sustained stretch becomes an important intervention as the formation of burn scars leads to contractures.

Sustained stretching exercises are performed with a slow, prolonged force. Gentle, sustained stretch is more effective than multiple repetitive movements in gaining length of burned tissues. Slow sustained stretch is considered to be one of the most effective methods to combat the strong destructive forces that lead to contracture formation.[175] Connective tissue has the characteristic of plastic elongation under constant tension. Therefore, correction of contractures around joints can be accomplished most effectively by the application of prolonged stretching to the shortened connective tissues.[176] When applying a sustained stretch, two factors may be considered when applying pressure to an extremity: blanching of the scar tissue and the patient's response.[160] While this is an effective treatment for ROM limitations, it can be uncomfortable or painful for patients. It is important to impart enough force on the affected extremity to produce plastic elongation without causing trauma to the tissues or to the patient.

Strengthening exercises move from manual resistance toward the use of weights and resistive tubing. Areas to be concentrated on should include areas of weakness found during strength assessments as well as muscles opposing scar tissue contractures.[157]

Concerning ambulation, it is important that the therapist set daily goals for the patient to achieve and to encourage the patient to walk farther while providing the least amount of support needed. As the patient begins to ambulate more, it is important that the rehabilitation therapist frequently assesses the patient's gait. Any gait deviations must be identified and corrected before they become lasting habits.

As patients begin to ambulate farther with less assistance, they become more confident in their abilities. Increased independence provides the patient with a sense of functional independence.[156]

Long-Term Rehabilitation Phase

The long-term phase occupies the timeframe from wound closure or discharge from the acute hospital setting until such time as the patient has received maximal benefit from rehabilitation services.[154]

As patients near discharge from the acute hospital setting, they will be given more responsibility over their exercise program. As patients progress, they will be expected to perform beyond their daily rehabilitation treatment sessions. Patient compliance with home exercise programs is vital to increasing functional independence.

During the long-term rehabilitation phase, patients should progress to independently ambulating community distances. Gait pattern should be refined to become more efficient without any gait deviations. If the patient is able to progress further, rehabilitation therapists can challenge the patient by having him or her ambulate on uneven surfaces, navigate around various obstacles, and climb stairs. It is important that the patient be able to ambulate in normal surroundings, not just in the confines of the rehabilitation department.

Most burn rehabilitation programs emphasize functional gains and prevention of contractures, with only modest attention to aerobic conditioning.[177] If ROM is lacking, the therapist's priority should be to treat the limitation in motion rather than strengthening the patient because

normal healthy muscle is unable to generate the force required to elongate burn scar tissue.[157]

The Role of Exercise Physiology in Burn Rehabilitation

EXERCISE FOR THE OUTPATIENT

This section describes the methodology used in designing an exercise training program for persons with severe burns who have been discharged from the hospital. Exercise training is defined here as "a planned, structured and repetitive body movement done to improve or maintain one or more components of physical fitness."[178,179] The evidence for the use of exercise in the outpatient setting and the methodology presented here are based primarily on the outpatient exercise program implemented in severely burned children at Shriners Hospitals for Children in Galveston, Texas, and in some severely burned adults.[180] This exercise program is supplemented by physical and occupational therapy. The program has proved beneficial in children 7–18 years of age.[180,181] In addition, the effects of a music- and movement-based exercise program on children younger than 7 years of age has been assessed in a small study also performed at Shriners Hospitals for Children in Galveston. The effects include increases in as well as maintenance of ROM in children who participated in a movement and music program versus those who did not.[182] The principles in designing an exercise program for children and adults with severe burns is based largely on guidelines offered to healthy, nonburned children and adults (Fig. 47.26).[178,179,183–186]

EXERCISE EVALUATION

It is important to perform an initial evaluation of risk factors and/or symptoms for various chronic conditions concomitant to the burn. These include pre-existing conditions such as chronic cardiovascular, pulmonary, and metabolic diseases. The objective of the exercise evaluations is to obtain information to optimize safety during exercise testing and training and also to develop a sound and effective exercise rehabilitation program.

Health screening before exercise evaluation should begin with the collection of subjective data. This should include evaluation of exercise or sports interests, objectives, level of activity prior to burn, functional limitations (e.g., loss of digits, lower-body bilateral amputee), and other pertinent information. To our knowledge, there are no burn-specific physical activity questionnaires. However, simple questionnaires for assessing pre-burn physical activity exist and can be modified to fit a specific given population.[187–189] This evaluation can consist of muscle strength, cardiopulmonary status, and muscle/joint flexibility testing. The information gathered during the subjective and objective evaluations can then be used to design a structured exercise program or plan to be carried out at home or at an exercise facility. Finally, a plan to periodically re-evaluate subjective and objective data and the exercise program itself should be incorporated.

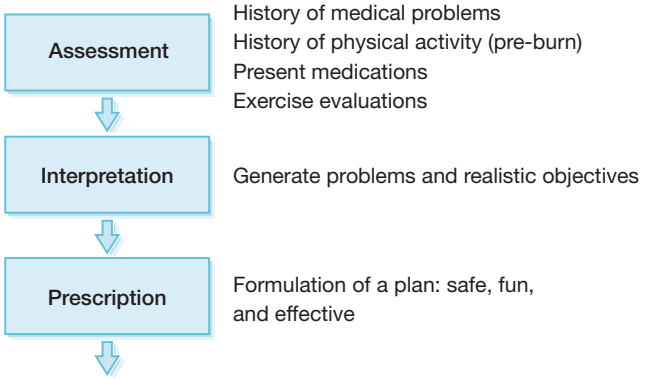

Fig. 47.26 Basic diagram depicting various components involved in the design of an exercise program.

Subjective Data

A patient's limitations or problems should be characterized. Obtaining a history of pre-burn physical activity or habits, present medical complaints, symptoms, and limitations is crucial to develop a sound exercise program. Symptoms or limitations that may affect exercise tolerance may include pain during ambulation, weakness in ambulation, itching, joint contractures, amputations, shortness of breath, or easy fatigability. In addition, the therapist should note present medications and the possible effects of these. Following the evaluation of subjective data, an exercise evaluation to gather objective data on the patient's exercise or physical capacity should be performed.

Objective Data

Assessment of objective data includes age, height and weight, percent TBSA burn, and percent full-thickness burn. Variables before, during, and after a cardiopulmonary exercise test (CPET) should be obtained if possible. These include heart rate, blood pressure, Borg's rated perceived exertion (RPE), basic electrocardiogram (ECG), and spirometry.[190,191] However, if a CPET is not possible, an effective exercise program can still be designed. Assessment of upper and lower body muscle strength should also be done. This includes assessment of peak strength levels (if possible), as well as determining the loads or weights that will be used during the resistive component of the exercise program. The assessment of peak muscle strength can be accomplished during knee or elbow extension but can also be accomplished during a handgrip.[180,192,193] These tests involve peak-to-maximal efforts, and good communication between patient and tester must exist. In addition, a certain level of developmental mental maturity must exist in order for many of these objective data to be maximally helpful. We recommend a chronological age of 7 years or older, although children as young as 3–4 have also been tested successfully.[194] Finally, major muscle/joint flexibility should be assessed using measures such as sit-and-reach or

goniometry for ROM. Other types of tests may include neuromuscular tests such as gait analysis, balance time, or reaction time. Finally, assessment of functional performance can also be done, such as sit-and-stand scores, timed walk or jog, and/or lifting. The results of these evaluations will be used to identify major problem areas, write an exercise prescription, design the exercise program, and assess progress during and after it.

EXERCISE TESTING

The objectives for exercise testing involve many factors. The primary objectives during cardiopulmonary testing are to evaluate physical work capacity and cardiorespiratory or aerobic fitness, observe cardiorespiratory and metabolic responses, establish bases for an appropriate exercise prescription, and assess changes in fitness due to exercise training. The primary objectives during muscular function testing include measuring muscle strength (absolute and relative to body weight), measuring antagonist-to-agonist muscle ratios, assessing changes in body composition (lean mass, fat mass, and bone density), and providing a basis for the progressive resistance exercise prescription. Exercise testing should be conducted prior to the start of any exercise rehabilitation program and again at the end to evaluate its efficacy. Sometimes if the program is of long duration, a mid-point evaluation can be done.

Peak Oxygen Consumption or Aerobic Exercise Capacity. All patients should undergo a standardized exercise test to objectively evaluate peak aerobic exercise capacity. We use the treadmill exercise test and the modified Bruce treadmill protocol. Note that other treadmill protocols, such as the "ramp protocol," can also be used.[195,196] In addition, if it is not possible for the patient to be tested on a treadmill, a cycle ergometer or arm ergometer can also be used to evaluate or assess physical conditioning before starting exercise rehabilitation or a training program. In addition, estimation of aerobic capacity is also possible with exercise field tests such as the Cooper 12-minute test or the 1.5-mile run test. Heart rate can be easily obtained with monitors. Oxygen consumption (VO_2) should be measured if possible, but requires more expensive equipment that can perform continuous breath-by-breath analysis of inspired and expired gases, flow, and volume. For the Bruce protocol, speed and grade begin at 1.7 mph and 0%, respectively. Thereafter, the speed and level of incline are increased every 3 minutes. Patients are constantly encouraged to complete 3-minute stages, and the test is terminated when peak volitional effort is achieved. Additional variables that can be collected during the test include blood pressure, Borg's RPE,[197,198] basic ECG, and spirometry. The peak VO_2 and peak heart rate, together with resting values, can then be used to establish or guide the intensity at which patients will exercise during the program.

Strength Measurements. Isokinetic dynamometry strength testing should be performed to assess muscle function and to later evaluate progress. If using the Biodex Isokinetic dynamometer, the test can be done on the dominant leg extensors and/or the leg with burns. We recommend testing at various angular velocities, such as 150 degrees/s, 90 degrees/s, or 180 degrees/s. The patient is seated and his position stabilized with a restraining strap over the mid-thigh, pelvis, and trunk. All patients should be familiarized with the equipment before the actual test starts. We recommend that the procedure first be demonstrated by the person administering the test. Second, the test procedure is explained to the patient, and then the patient is allowed to practice the actual movement during three submaximal repetitions without load as warm-up. Third, after the three submaximal warm-up repetitions, 10 maximum voluntary muscle contractions (full extension and flexion) can be performed consecutively without rest in between. The amount of repetitions and the number of repetition sets can be varied. For example, we recommend 10 repetitions and two sets, with a 2-minute rest interval between sets. Values of peak torque, total work, and average power are calculated by the Biodex software system, and progress of muscle function can be monitored.

Three-Repetition Maximum Test (3RM)

Typically, before starting a resistive training program, it is useful to determine a safe and effective load for patients to use during workouts. To determine the amount of weight or load that can be used as a baseline or starting load, the repetition maximum (RM) method can be used. We recommend the three-repetition maximum load (3RM), which is determined as follows. After an instruction period on correct weight-lifting technique, the patient warms up with a lever arm and bar (or wooden dowel) and is allowed to become familiar with the movement. After this, the patient lifts a weight that allows successful completion of four repetitions. If the fourth repetition is achieved successfully and with correct technique, a 1-minute resting period is allowed. After the resting period, a progressively increased amount of weight or load is lifted at least four times. If the patient lifts a weight that allows successful completion of three repetitions, with the fourth repetition not being volitionally possible due to fatigue or inability to maintain correct technique, the test is terminated and the amount of weight lifted from the successful set is recorded as the patient's individual 3RM. We recommend the order of exercises to be from exercises that involve large muscle groups to ones that involve smaller muscle groups: bench press, leg press, shoulder press, leg extension, biceps curl, leg curl, and triceps curl. Another alternative is to bypass the 3RM test and use 8–12RM method or 15RM method. These methods are typically easier to implement in children.

Body Composition Measurement

Patients with severe burns lose a significant amount of lean body mass (LBM). Therefore assessment of LBM should be made. Additionally, assessment of bone mass and fat mass should be made. We assess body composition using dual-energy X-ray absorptiometry (DXA). DXA with pediatric software can measure the attenuation of two X-ray beams; one high energy, the other low energy. These measurements are then compared with standard models of thickness used for bone and soft tissue. Subsequently, the calculated soft tissue is separated into LBM and fat mass. This is a great measurement to also assess the progress of the program and, if applicable, nutritional interventions. However, the DXA machine is expensive. It is not known if other methods to measure body composition, such as underwater

weighing or bio-impedance, are applicable to patients with burns because of the presence of hypertrophic burn scars.

When to Implement an Exercise Program

Traditionally, a 12-week exercise training program has been implemented immediately after discharge.[199] However, we have also reported improvements in function and psychosocial health when the 12-week exercise program is implemented at the 6-month post burn time point.[200]

Recently we have started a small pilot study to add aerobic exercise to standard physical therapy and occupational therapy. The aerobic exercise is quantitative because it incorporates the use of an arm ergometer in which the revolutions per minute and the load in watts can be adjusted.

COMPONENTS OF AN EXERCISE PROGRAM

An exercise program typically consists of a warm-up phase, an endurance phase, recreational activities (optional), and a cool-down phase. While aerobic training activities should be done 3–5 days per week, complementary flexibility and resistance exercises may be performed at a lower frequency (2–3 days per week).[201] Flexibility exercises can be included as part of the warm-up or cool-down, or be done at a separate time. Resistive training is often performed on alternate days to aerobic training; however, both types of activities can be combined into the same workout session. Typically the warm-up period will be of approximately 5–10 minutes, though it can be longer. This will be followed by a stimulus or endurance phase of 20–60 minutes and a cool-down period of approximately 5–10 minutes. Aerobic and resistance training should be prescribed in specific terms of frequency, intensity, duration, and mode of exercise. Each of these terms will be discussed in greater detail later. An optional recreational game may occasionally substitute the endurance phase. However, because of potential difficulties in setting an appropriate intensity for an appropriate length of time, it is suggested that recreational activities be done to complement the endurance phase. If a recreational activity is added to the endurance phase, then shortening the endurance phase should be carefully considered, although maintaining a minimum of 20 minutes.

Warm-Up Stage

Prior to the endurance phase, a variety of very light exercises or low-intensity calisthenics should be done to improve the transition from rest to the endurance phase of the exercise session. The emphasis at the onset of an exercise session is to gradually increase the level of activity until the proper intensity is reached to begin the endurance phase. Stretching exercises to increase the ROM of the joints involved in the activity were previously included in the warm-up. However, recently, evidence has been introduced to contraindicate the inclusion of stretching during the warm-up period.[202,203]

In fact, evidence suggests that a pre-exercise warm-up that consists of only light aerobic exercise to increase body temperature is adequate for increasing flexibility before an exercise session.[179] For example, patients might walk moderately fast during the endurance phase, but might conclude the warm-up period with slow, easy walking. However, a moderate walk (e.g., 3.5 mph) can be a warm-up for a patient who jogs at 5.5 mph during the endurance phase. Heart rate may be monitored or assessed if needed to ensure that the warm-up activity is not too strenuous.

Endurance Stage

The endurance phase develops cardiorespiratory or aerobic fitness and includes 20–60 minutes of continuous or intermittent (minimum of 10-minute bouts accumulated throughout the day) aerobic activity. Duration depends on the intensity of the activity; thus moderate-intensity activity should be conducted over a longer period of time (≥30 minutes), and, conversely, individuals training at higher levels of intensity (i.e., vigorous exercise) should train for at least 20 minutes.[201] The most effective exercises for the endurance phase employ large muscle groups in activities that are rhythmic or dynamic in nature. Sports such as soccer, basketball, or tennis also have aerobic conditioning potential if a sufficient amount of time for inducing aerobic improvement is achieved (minimum of 20 minutes total). On the other hand, activities like golf and bowling are unlikely to elicit a cardiovascular training effect, but are enjoyable and may yield health-related, as well as psychosocial, benefits.

Recreational Activities

The inclusion of enjoyable recreational activities during (or immediately after) the endurance phase often enhances compliance with the exercise program. Game rules may need to be modified to accommodate skill level requirements and competition, and to ensure safety. The outcome of the game (winning or losing) should be of lesser importance than the safety, participation, and enjoyment of the patient. It is important to remember that recreational activities complement the endurance phase and should not consistently replace it. Recreational activities may also promote development or improvements in psychosocial health by increasing the patient's amount of social interaction.

Cool-Down Stage

At the end of the activity session, about 2–5 minutes of cool-down activities—slow walking and stretching exercises—are recommended to gradually return heart rate and blood pressure to normal levels. This period includes exercises of diminishing intensities: slower walking or jogging, calisthenics, and stretching exercises. This part of the exercise session is important in reducing the chance of a hypotensive episode after the exercise session, as well as other cardiovascular complications.

Exercise Prescription

Some basic exercise physiology principles should be kept in mind when designing an exercise program for burned patients. Two such principles are *progressive overload* and *specificity principles*. The progressive overload principle refers to the observation that a body system must be exercised at a level above that to which it is presently accustomed in order for a training effect to occur.[178] The system

or tissue gradually adapts to this overload. The typical variables that comprise overload include the intensity, duration, and frequency (days per week) of exercise. The principle of specificity refers to the concept that the training effect is specific to the muscle fibers involved in the activity. Specificity also refers to types of training used in a very specific manner to produce a very specific adaptation or outcome. If a muscle is engaged in endurance-type exercise, the primary adaptations are in capillary and mitochondrial numbers, which increase the aerobic capacity of the muscle. These principles are applicable to burned patients; however, it must be noted that a high intensity of exercise is not needed to achieve health-related benefits. On the other hand, to achieve athletic performance or competitive-related goals, moderate to high levels of intensity will be required. Another consideration that should be kept in mind when designing an exercise program is the patient's age. Prepubescent children are very different in their physiological and mental response to exercise training than are postpubescent children. Older adults also have different health and physical problems than younger adults. It is for these reasons that medical exams as well as exercise evaluations are strongly recommended prior to starting an exercise program. It is beyond the scope of this chapter to address these differences and/or problems. However, general guidelines for both children and adults are offered, and the reader should seek additional information for population-specific recommendations or position stands on exercise and physical activity from associations such as the American College of Sports Medicine (http://www.acsm.org/publications/positionStands.htm), the American Academy of Pediatrics (http://www.aap.org/), the American Medical Association (http://www.ama-assn.org/), or the American Heart Association (http://www.americanheart.org/).

AEROBIC TRAINING

Intensity

To improve aerobic fitness, generally the intensity of exercise should be between 65% and 95% of the peak heart rate or between 45% and 85% of the heart rate reserve (HRR).[204] The heart rate reserve is the difference between peak heart rate obtained during a CPET and resting heart rate. The range of heart rate values associated with the exercise intensity needed to induce an improvement in cardiovascular fitness is termed the "target heart rate zone."

The peak heart rate (HR_{peak}) is obtained from the CPET. However, when this is not possible, one simple method to estimate HR_{peak} is to use the formula (220 minus age).[178] This formula may not be applicable to young children, so we recommend that, in children, rated perceived exertion (RPE; see later discussion), together with the heart rate obtained during a maximal exercise capacity test, be used.

The RPE scale can also be used as a guideline in setting the intensity of exercise.[197] The RPE is a valuable and reliable indicator of both exercise tolerance and intensity. This method of monitoring exercise intensity is useful when it is impossible to obtain an HR_{peak} or if patients are on medications that affect heart rate, such as β-blockers. There are currently two RPE scales that are commonly used: the original or category scale, which rates exercise intensity on a scale of 6–20, and the revised or category-ratio scale of 0–10. It is reported that the category-ratio scale uses terminology better understood by the subject, thereby providing the tester with more valid information. It has been found that an aerobic training effect and the threshold for the start of anaerobic training are achieved at a rating of "somewhat hard" to "hard," which approximates a rating of 12–16 on the category scale or 4–5 on the category-ratio scale.[205] Finally, if a patient cannot use the heart rate method or the RPE method, the "Talk Test" can also be used as a highly consistent method to set and monitor intensity of exercise.[206]

The "Talk Test," or the point at which speech first becomes difficult, approximates exercise intensity almost exactly equivalent to the ventilatory threshold. The patient is advised to exercise at an intensity at which speech is comfortable. When speech becomes uncomfortable, one can assume, based on previous studies, that exercise intensity is consistently above ventilatory threshold or above the desired intensity of exercise needed for general improvements in fitness.[206] It must be noted that when setting the exercise intensity, safety and effectiveness are linked. An appropriate intensity should also be well suited to result in a long-term, active lifestyle.

Duration

The duration of an aerobic exercise session is closely linked to the intensity of the activity (i.e., a longer duration of low-intensity exercise can be accomplished than of high-intensity exercise). In general, the duration of exercise for burned patients once discharged should be from 5 to 20 minutes in the first week. This will depend on the patient's functional status and also pain tolerance.

If the patient tolerates up to 20 minutes, then this duration is appropriate. The objective should be 20–60 minutes of aerobic activity. This can be accomplished continuously or intermittently throughout the day, with a minimum of 10-minute bouts. Typically a duration of 20–30 minutes at between 40% and 50% and up to 85% of HRR (excluding time for warm-up and cool-down) should induce health and fitness improvements.[201,207]

In burned patients with extremely low aerobic capacity or endurance, four to six 5-minute bouts with rest periods between bouts will provide benefits. The duration of the exercise sessions (or bouts) can be progressively increased over time. However, as mentioned earlier, a high intensity of exercise or a very long duration of exercise is not needed to achieve health-related benefits, particularly during the initial stages of outpatient exercise rehabilitation.

Frequency

It is reported that deconditioned persons may improve cardiorespiratory fitness with only twice-weekly exercise.[201] However, it is generally agreed that optimal training frequency appears to be achieved with 3–5 workouts per week. The additional benefits of more frequent training appear to be minimal, whereas the incidence of lower-extremity injuries increases abruptly. For those exercising at 60–80% HRR, an exercise frequency of 3 days per week is sufficient to improve or maintain VO_{2peak}. When exercising at the lower end of the intensity continuum, exercising more than 3 days per week is not deleterious. Patients with extremely

low functional capacities may benefit from multiple short (5 days per week) exercise sessions. Clearly the number of exercise sessions per week will vary depending on the patient's limitations, but also on the patient's and caregiver's lifestyles.

Mode

The most important consideration in choosing the mode of exercise for the endurance phase of the sessions is to engage large muscle groups in activities that are rhythmic or dynamic. The greatest improvements in aerobic fitness result when exercise involves the use of large muscle groups over appropriate periods of time (Fig. 47.27). The mode of exercises includes treadmill walking/running, rowing, or cycling. If no treadmill is available, then walking or jogging at a track or field is appropriate. Swimming is also an appropriate mode of exercise, although closure of burn wounds should be ensured to minimize wound infection or the contamination of others. Endurance games are also appropriate modes of exercise.

Progression of Exercise

We recommend starting slowly and safely progressing in duration and intensity, but also in transitioning from early activities to activities that are more difficult to perform. This method of progression decreases the potential for inducing excessive muscle soreness that might cause new injuries or aggravate old ones. The emphasis on slow to moderate walking as the primary activity early in the fitness program is consistent with this recommendation, and the participant must be educated to not move too quickly into more demanding activities. For example, if the individual can walk about 1–2 miles without fatigue, then the progression to a walk-jog or jogging program is a reasonable recommendation.

The recommended rate of progression in an exercise conditioning program depends on functional capacity, medical and health status, pain tolerance, location of burns, age, individual activity preferences and goals, and an individual's tolerance to the current level of training. For burned patients, the endurance aspect of the exercise prescription can be divided into three stages of progression: initial, improvement, and maintenance.[179]

Initial Conditioning Stage. The initial stage should include light and moderate muscular endurance activities (e.g., 40–60% of HRR). These exercises typically have a low potential for injury and induce minimal muscle soreness

Fig. 47.27 Aerobic training should incorporate the use of large muscle groups over appropriate time periods.

and pain. Exercise adherence may be compromised if the level or intensity of exercises in the program is initiated too aggressively. The amount of time spent in this stage varies depending on the individual's adaptation to the exercise program. We recommend at least 4 weeks of initial conditioning. The duration of the exercise session during the initial stage may begin with approximately 15–20 minutes and progress up to 30 minutes, at least three times per week. Deconditioned individuals should be allowed more time for adaptation at each stage of conditioning. The age of the individual should also be taken into account when progressions are recommended because adaptation to conditioning likely takes longer in older individuals, but also in extremely debilitated individuals.[201]

Improvement Stage. The goal of the improvement stage of training is to provide a progressive increase in the overall exercise stimulus, which will allow for significant improvements in aerobic fitness. The improvement stage of the exercise-conditioning program differs from the initial stage in that the participant is progressed at a more rapid rate. This stage is reported to usually last from 4 to 5 months, during which intensity is progressively increased within the upper half of the target range of 50–85% of HRR. However, our experience in a 12-week training program in children 7–18 years of age indicates that after 3–4 weeks of initial conditioning, some patients are able to start the improvement stage. In this stage, duration may be increased consistently every 2–3 weeks until participants are able to exercise at a moderate to vigorous intensity for 20–30 minutes continuously. During this stage, interval training may also be beneficial, provided the total time engaged in moderate to vigorous exercise is at least 20 minutes.

Maintenance Stage. The goal of this stage of training is the long-term maintenance of the cardiopulmonary fitness level developed during the improvement stage. This stage of the exercise program may begin at any time the participant has reached previously agreed objectives. During this stage, the individual may no longer be interested in continually increasing the conditioning stimulus. Also, in this stage, further improvement may be none to minimal, but continuing the same workout routine enables individuals to maintain their fitness levels, as well as develop the healthy exercise habit. At this point, it is suggested that program goals be re-examined and new goals or objectives set.

RESISTIVE TRAINING

Strength is defined as the ability to produce force, and the ability to produce force over an extended period of time is referred to as *muscular endurance*. Both muscle strength and endurance affect ADLs because it requires a percentage of an individual's muscular capacity to perform these everyday tasks. Severe burns result in extensive and prolonged loss of muscle mass; therefore resistance training, which increases LBM, should be part of an exercise rehabilitation program for burned individuals.[180]

Just as when designing the aerobic portion of an exercise program, the resistive training portion of an exercise program follows similar principles of training. Both the overload principle and specificity principle are applicable. Strict rules of proper technique and safety must be observed to reduce potential for injury or accidents. A normal breathing pattern should be maintained, with breath-holding avoided. Breath-holding during lifting can induce excessive increases in blood pressure that, in individuals with hypertension, diabetes, or other medical risks, can be dangerous.

Similarly to the aerobic exercise program, testing or evaluation of muscle function precedes the resistive exercise program. This helps individuals identify problem areas (areas in need of required improvement), set goals, and track progress. In addition, muscle strength tests have value in determining back-to-work status.[208] Some of these tests involve peak to maximal muscular efforts. These tests can be done on weight machines or using dumbbells.

Typically, these tests are done at 100% of one-repetition maximum (1RM), but can also be done at 3RM. For extremely deconditioned individuals or for very young children, modification of these guidelines can involve testing using 3RM up to 12RM if needed. An important point to remember is that safety of the individual is crucial. Therefore, correct technique during all testing and training must be observed. The order of exercises or muscles tested is also important. It is recommended that large muscle groups are tested first and alternate between upper body and lower body. For example, a 3RM test may be done in the following order of exercises: bench press, leg press (or squats), shoulder press, leg extension, biceps curl, leg curl, and triceps curl. The 3RM load can be determined as follows. After an instruction period on correct weight-lifting technique, the patient warms up with a lever arm and bar (or wooden dowel) and is allowed to become familiar with the movement. After this, the patient lifts a weight that allows successful completion of four repetitions. If the fourth repetition is achieved successfully and with correct technique, a 1-minute resting period is allowed. After the resting period, a progressively increased amount of weight or load is lifted at least four times. If the patient lifts a weight that allows successful completion of three repetitions, with the fourth repetition not being volitionally possible, because of fatigue or inability to maintain correct technique, the test is terminated and the amount of weight lifted from the successful set is recorded as the individual 3RM. This weight is then used to determine the amount of weight or load that will be used during the first 1–2 weeks (of, e.g., a 12-week program) as a baseline load.

Exercise Type

There are many resistance training exercises. However, these can be divided into core exercises and assistance exercises. *Core exercises* recruit one or more large muscle groups (e.g., chest, shoulder, and back). *Assistance exercises* typically recruit smaller muscle groups such as biceps, triceps, and calves. A good program should typically involve both types of exercises.

Training Frequency

The number of days to train varies according to the individual's training status. For severely burned individuals, we recommend 2–3 days per week of resistance training.

Type of Contraction

Resistance exercise programs or exercises that emphasize accentuated lengthening or contractions (eccentric) are not recommended for severely burned individuals. These types of contractions have a high potential for acute delayed onset of muscle soreness while having similar outcomes to concentric or isometric muscle contractions. The muscle soreness, if severe enough, has the potential to discourage further participation in exercise activities. The movements during weight-lifting should be rhythmic and done at moderate repetition and duration.

Amount of Load Lifted

Commonly, a certain percentage of the 1RM or 3RM is used as a guideline for choosing a training load. The amount of load lifted can be as much as 100% of 1RM or as little as lifting no load. We recommend initially, during the first week of training, allowing the individual to become familiar with the exercise equipment and to be instructed on proper weight-lifting techniques. Initially, the weight or load the subjects will lift should be set at 50–60% of their individual 3RM for 12–15 repetitions for the first 1–2 weeks. Thereafter, the load lifted can be increased to 70–75% (8–10 repetitions) of their individual 3RM and continued for weeks 2 or 3, to week 6. After this, the training intensity can be increased to 75–85% (8–12 repetitions) of the 3RM and implemented from weeks 7–12 or longer. Note that these guidelines provide an estimate of training load and have some limitations.[185] Another method of determining training load is to perform multiple RMs based on the number of repetitions planned for the specific exercise. For example, if 8 repetitions were desired for biceps curl, then one would test the individual by having him or her perform 8RM testing sets.

Number of Repetitions

It is believed that muscle strength and endurance can be obtained simultaneously by performing a specific number of repetitions within a certain range (e.g., 6–10 repetitions). The number of repetitions will depend on load lifted (% of 1RM) and on the objective or goals set at the start of the exercise program. We recommend 8–12 repetitions done at moderate to high intensity to improve both muscle strength and endurance.[180]

Number of Sets

There are very limited data in children as to whether three sets or one set is required to increase muscle strength. Much of the adult-based literature supports similar responses in muscle strength, muscle endurance, and hypertrophy for single- and multiple-set resistance training programs.[201,209–212] Finally, it is important to stress two points: (1) the difference in strength gains is typically more pronounced in trained individuals, and (2) both single and multiple training increases strength. The first point is usually not the case with burned patients, and the second point stresses the fact that an increase in strength is expected with resistance training compared to the standard of care in burned individuals.

Exercise Order

There are many methods of ordering resistance exercises. One of these is to arrange core exercises, then assistance exercises.[212] Another method is to arrange large muscle groups and then small muscle groups.[213–215] Yet another method, which allows the individual to recover more fully between exercises, is to alternate upper-body with lower-body exercises. This is especially well-suited for deconditioned or untrained individuals.[213,214] For example, in severely burned children, we have successfully implemented the following order of resistive exercises: bench press, leg press or squats, shoulder press, leg extension, biceps curl, leg curl, triceps curl, and toe raises. These exercises can be done on variable resistance machines or free weights.[180] Free weights, bands, or variable resistance machines are appropriate for burned individuals wishing to participate in an exercise program (Fig. 47.28).

Rest Periods

As a general rule, it is important to allow enough time between exercises to perform the next exercise in proper form. The rest period also varies depending on the individual's training status and specific training objectives.

Progressive Overload

In order for improvements to continue over time, it is important to carefully monitor and chart the individual's workouts or loads lifted. Progressive overload can be applied in a variety of ways, such as increasing the weight lifted, increasing repetitions while keeping load constant, or decreasing rest periods. A conservative method termed the "2-for-2 rule" is suggested. This rule states that "if an individual can perform two or more repetitions above his or her assigned repetitions goal in the last set, for two consecutive workouts for a specific exercise, then weight or load should be added to that specific exercise for the next training session."[215] For example, say that the assigned number of sets and repetitions is three sets of 8–12 reps in the chest press machine and the individual can perform 12 reps in all three sets after several workout sessions (the specific number of sessions depends on many factors). If the individual is able to complete 12 reps in the third set (i.e., the last set) for two consecutive workout sessions, then, in the following training session, the load for that exercise should be increased. The amount of weight (load) that should be added depends on factors such as the physical condition of the individual (strong or weak) and the body area (upper body or lower body). In general, an increase of 1–2 kg for a less trained, weaker individual is suggested for upper-body exercises, while an increment of 2–4 kg is suggested for lower-body exercises.[185]

Example of an Exercise Program

An example of our exercise rehabilitation program is described here (Table 47.3). The results of this program are published.[17,133,134] This program has been successfully implemented at discharge from hospital, but also at 6 months post-burn.

Fig. 47.28 Resistance training consists of exercises with free weights or variable resistance machines.

Table 47.3 Brief Description of the Shriners Hospitals for Children—Galveston Hospital Outpatient Exercise Rehabilitation Program

AEROBIC WORKOUT	
Intensity	70–85% of each individual's previously determined individual peak aerobic capacity. However, heart rate and rated perceived exertion are obtained at regular intervals during aerobic exercise
Duration	20–40 min
Frequency	3–5 days per week
Mode	Aerobic exercise on treadmills, cycle ergometers, arm ergometers, rowing machines, and outdoor activities such as soccer or kickball
RESISTANCE WORKOUT	
Exercise type	Upper and lower body of core and assistance exercises
Amount of load lifted and number of repetitions	The weight or load-lifted set at approximately 50–60% of each individual 3RM and lifted for 4–10 repetitions for three sets. During the 2nd week, the lifting load increased to 70–75% (3 sets, 4–10 repetitions) of their individual 3RM and continued for weeks 2–6. After this, training intensity is increased to 80–85% (3 sets, 8–12 repetitions) of the 3RM and implemented from weeks 7–12
Frequency	2–3 days per week; alternating days of work with days of recovery
Number of sets	2–3 sets
Exercise order	Bench press, leg press or squats, shoulder press, biceps curl, leg curl, triceps curl, toe raises, and abdominals
Type of exercises	Eight basic resistance exercises done using variable-resistance machines or free weights: 4 for upper body, 3 for lower body, and abdominals
Rest period	A rest interval of approximately 1 min between sets

Note: Each exercise training session consists of resistance and aerobic exercises, with aerobic exercise preceding resistance exercise. This outpatient exercise program should be supplemented with outpatient physical and occupational home therapy or home activities.

IMPORTANT CONSIDERATIONS

- The ultimate goal of an exercise rehabilitation program should be to improve physical function. However, the means by which this is achieved are also important. An exercise program should be challenging, effective, but also must be safe and fun. It should also promote lifelong healthy habits. This will maximize compliance with the exercise program.
- The American College of Sports Medicine (ACSM) has an extensive list of absolute and relative contraindications to exercise and exercise testing that should be carefully considered when designing an exercise program for adults or children. These contraindications will also pertain to individuals with severe burns.
- Individual goals should be established early in the exercise program. Whenever possible, they should be developed by the participant with the guidance of an exercise professional. The goals or objectives must be realistic, and an intrinsic or extrinsic rewards system should be implemented at that time.
- It is recommended that exercise professionals work together with an occupational and/or physical therapist to avoid duplication of services, as well as to identify areas in need of special attention.
- Based on our clinical experience with children and adolescent patients, individuals with severe burns should participate, as soon as possible after hospital discharge, in a structured exercise program. This program should be supervised and, if possible, conducted in the presence of a trained professional. However, if this is not possible, the exercise program, with some common sense guidelines, should offer a choice for safe and effective participation.
- For adults, a careful medical and exercise evaluation should be conducted prior to starting an exercise program. Cardiovascular or pulmonary problems, as well as other conditions such as diabetes, must be identified prior to starting an exercise program to avoid potential fatal or near-fatal complications.
- It is important to get the burned individual started with an exercise program or a more active lifestyle as soon as possible, but it is never too late to get started regardless of the time post-burn.
- When beginning the exercise program, it is better to start slowly and build up gradually than to start too fast and risk injury.
- For children, avoid using very intense or maximal (1RM) resistance training or testing. Gradual progression is of utmost importance to avoid injury and to promote exercise adherence.
- The individual should listen to his or her body. During and after workouts, the individual (and supervisor) should be alert to signs of a potential health problem as a result of overexertion. Signs may include pain, shortness of breath, dizziness, or nausea.
- Be flexible and allow individuals to be flexible. Do not rigidly stick to a schedule if the patient does not feel up to it. If he or she is overly tired or under the weather, take a day or two off.
- Monitor the individual's progress. Reassess fitness every 6 weeks. You may notice that you need to increase the amount of time you exercise in order to continue improving (if part of the original goals).
- The exercise professional or individual should keep an exercise diary or logbook to help chart progress.
- If the patient loses motivation, try setting new goals or try a new activity (or activities). Sometimes bringing a friend or family member into the program may help in motivation. Incorporate variety into the exercise routine.
- Finally, work on conveying to the patient or client that a fun and safe exercise program can result in maintenance of lifelong physical as well as psychosocial healthy habits (Fig. 47.29).

Patient and Caregiver Education

When patients are being discharged from an acute hospital stay, it is vital that they leave with an individualized home exercise program. Splinting and positioning, ADL performance, scar control measures, and psychosocial issues should also be addressed. This program can then be advanced to allow for progression during the phases that the burned individual goes through in what may be in excess of a 2-year recovery period. During follow up visits, the patient's progress is assessed and adjustments to the home exercise program are made as indicated. This detailed knowledge of the patient's status will allow the burn team to coordinate care so that recommendations can be followed through. Providing the patients with a checklist is a valuable tool to enable him or her to assume some control of the rehabilitation process, track progress, and encourage continuation of the program. Many patients and their caregivers are often overwhelmed by the rehabilitation program. It takes an extraordinary amount of time and energy to plan and participate in a home exercise/instruction program. Continuous communication among the patient, caregiver, and the burn team will ease the patient's transition into recovery.

One way of helping patients with the exercise program is to establish communication with a community-based exercise center, such as a commercial or hospital-based facility. Often, direct and constant communication between a burn hospital's rehabilitation department, exercise physiologists and/or physician, and a community-based exercise facility (i.e., personal trainer) will maximize the potential for adherence to and efficacy of such home exercise programs by adding supervision and structure.

Conclusion

The rehabilitation of burn patients, although challenging, can be rewarding to all involved in their care. Continuous evaluation of the interventions provided will ensure each patient's maximum functional outcome. Experience, education, and research will produce therapeutic interventions that will optimize each patient's recovery. Ultimately, the goal of the rehabilitation team is to provide the patient with the means for a productive life.

Fig. 47.29 Overall long-term burn rehabilitation should result in lifelong physical as well as psychosocial healthy habits and improvements in quality of life.

48 Musculoskeletal Changes Secondary to Thermal Burns

KELLY CARMICHAEL, DAVID YNGVE, and CARLOS JIMENEZ

Acknowledgment

This chapter was originally written by E. Burke Evans, MD. He passed away in May 2012. We are indebted to his knowledge of burn care. Care was taken to preserve as much of his original material while adding new information.

Introduction

Burn injuries have a tendency, even as they heal, to create musculoskeletal deformity. In addition, the protracted burn illness that accompanies severe burns may result in other skeletal changes. Box 48.1 presents a classification of musculoskeletal changes secondary to burns; from this, the most commonly occurring and clinically significant alterations have been selected for discussion.

Changes Confined to Bone

OSTEOPOROSIS

Osteoporosis is the most frequently occurring postburn change involving bone. Klein et al.'s ongoing studies suggest that, among persons with serious burns, reduction of bone mass density is pervasive.[2] Stated causes of osteoporosis in thermal burns are bed confinement, immobilization, hyperemia,[3] reflex vasomotor phenomena,[4] and adrenocortical hyperactivity.[5] In Chapter 26 of this book, Klein reviews the effects of burn injury on bone metabolism.[2,6] Klein et al.[9] noted very limited bone formation after a severe burn. Other endocrine changes that lead to loss of bone after burns have been described by Dolecek et al.[10] This coupled with the relatively high resorption leads to osteopenia postburn. Endogenous corticosteroid production is likely responsible for the decreased bone formation, and inflammatory cytokines are responsible for the bone resorption. In this section, only what is clinically apparent is discussed.

The more extensive the burn and the greater the number of complications, the longer the patient may be confined to bed and relatively immobile. The onset of osteoporosis is accelerated, and its intensity is more marked in the burn illness that features a hypermetabolic state. Klein et al. found that osteoblasts and probably osteocytes underwent apoptosis in response to the glucocorticoid stress hormones. The overall effect of burn is catabolic, and muscle wasting is also noted. If a single extremity of an otherwise normal person is immobilized for a long period of time because of local trauma, as with a fracture, loss of bone density can be easily seen on plain radiographs. So, with burns isolated to the extremities, the bones of affected extremities become osteoporotic, and in persons with generalized burns, the bones of deeply burned extremities may show more profound mineral loss than is observed in nonburned extremities or in the axial skeleton (Fig. 48.1). This tendency for more osteoporosis in severe burns was also noted by Pandit et al.,[11] who found that 56% of postburn patients had radiographic evidence of osteopenia. Van der Wiel et al.[7] found in an X-ray absorptiometry study of 16 adults with fractures of one tibia that there was eventual loss of bone mineral density in the contralateral femur and in the lumbar spine but to a lesser degree than in the ipsilateral femur. These findings, although not strictly analogous to those observed in burns, nevertheless point to the occurrence of generalized osteoporosis in other trauma states and the difference in loss of bone density relative to local factors. In fractures or in burns, impaired mobility and local hyperemia could account for this difference.

Another characteristic of the osteoporosis of burns that seems to set it apart is its persistence, not just until restoration of the anabolic state but also for months and years after the burn has healed (Fig. 48.2). This phenomenon may be most clearly observed in patients who have survived 90% burns, but Klein et al. record less than normal bone among even moderately burned children as long as 17 months after injury.[2] Muscle atrophy or the failure or inability of the person to return to the preburn level of physical activity may account in part for this protracted state of reduced bone mineralization.

There is no way to prevent osteoporosis in a patient whose burn is of such severity as to require an extended period of bed confinement. Methods of medical treatment described by Klein[12] and Rousseau et al.[13] include anabolic hormones, bisphosphonates, and cholecalciferol. Cholecalciferol was noted to have a positive effect on muscle health but little effect on bone. The advance of bone atrophy can at least be favorably modified even among patients with large burns if mobilization and active exercise are initiated soon after the burn. The bones of the axial skeleton, the pelvis, and the lower extremities are most efficiently stressed by weight bearing. Thus, standing is a priority measure, and it is common practice now to walk patients to tolerance before permanent wound cover. Muscle contraction alone may help forestall bone atrophy, and bone is better stressed if the contraction is resisted. Isometric muscle contraction is possible from even extensively burned patients and is important for bone stress and for maintaining muscle tone and muscle. Passive motion has no effect on bone and thus does not figure in the prevention of osteoporosis. Other preventive measures, such as closure of the wound and maintenance of nutrition, are routine in critical burn care. Treatment of established osteoporosis involves the more aggressive use of measures for prevention. There are no

Box 48.1 Classification of Musculoskeletal Changes Secondary to Burns

Alterations limited to bone

- Osteoporosis
- Periosteal new bone formation[1]
- Irregular ossification[1]
- Diaphyseal exostosis[1]
- Acromutilation of fingers[2]
- Pathological fracture
- Osteomyelitis
- Necrosis and tangential sequestration

Alterations involving pericapsular structures

- Pericapsular calcification
- Heterotopic paraarticular ossification
- Osteophyte formation

Alterations involving the joint proper

- Dislocation
- Chondrolysis[3]
- Septic arthritis
- Spontaneous dissolution[4-6]
- Ankylosis

Alterations involving muscles and tendons

- Desiccation of tendons[7]
- Fibrosis of muscles[8]

Alterations secondary to soft tissue

- Muscle and joint contractures
- Malposition of joints
- Scoliosis

Soft tissue injury

- Compartment syndrome
- Nerve injury

Abnormalities of growth

- Acceleration and retardation
- Destruction of growth plates

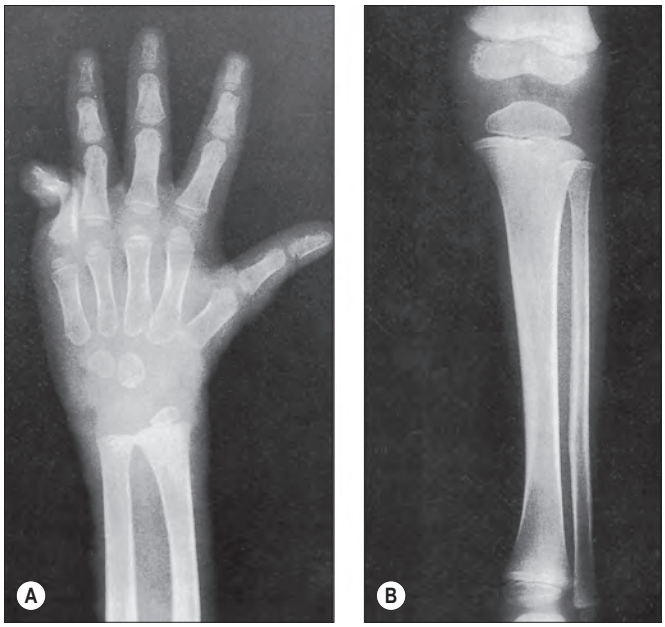

Fig. 48.1 (A) At 6 months after injury, there is the coarsened trabeculation of marked osteoporosis of bones of the left hand and forearm of a 4-year-old boy whose 70% full-thickness burn involved the head, chest, and both upper extremities. **(B)** A radiograph of the left tibia and fibula obtained on the same date as that of the hand shows minimal atrophy.

long-term comparative studies, however, that persuasively measure the effectiveness of exercise, diet, medication, or modality in the treatment of osteoporosis in any state. Thus, osteoporosis can be lessened by active muscle contraction and weight bearing. Medical treatments that show promise include anabolic hormones, bisphosphonates, and possibly cholecalciferol.

OSTEOMYELITIS

In burns, bones can become infected by exposure of bone by the burn, by an open fracture accompanying the burn, by extension of infection from a septic joint, by introduction of organisms along traction pins or internal fracture fixation devices, or by bloodborne organisms of bacteremia. Considering the apparent risk for seriously burned patients to develop osteomyelitis, it is surprising that it does not occur more regularly. Clinically significant osteomyelitis in burned patients is uncommon. Antibiotics given for the general state may prevent seeding of the bone or may repress any small focus of bone infection.

The cortex of long bones is a good barrier to surface organisms. Even exposure of cortex will have little adverse effect if the blood supply of the bone remains intact. Prolonged exposure will kill the outer layer of the cortex, which will in time sequestrate, separating at a well-defined fissure between dead and living bone. With minor or moderate exposure, the bone will usually survive long enough for bordering granulation tissue to cover it. For large defects, it may be useful to drill closely spaced holes through the exposed cortex so as to encourage buds of granulation tissue to emerge from the still vascular medullary canal. Another way to encourage granulation tissue formation over exposed bone is with superficial decortication with an osteotome or burr to expose the capillaries of the inner cortex.[14] With these practices, there is little risk for infecting the bone. It may be that there is sufficient centripetal pressure to discourage the invasion of organisms when the holes are fresh and that the holes are rapidly sealed by blood clot and advancing tissue. There are no reports of deep bone infection related to cortex drilling.

With open fractures at the site of a major soft tissue burn wound, bone infection is probably inevitable. These infections can often remain localized to the fracture site and not involve the rest of the bone. Local debridement and stabilization of the soft tissue wound are all that are required for treatment. Dowling et al. reported osteomyelitis of the tibia related to an open bimalleolar fracture in an extensively burned extremity.[8] English and Carmichael[15] showed three cases of osteomyelitis out of 28 fractures, and all were found in open fractures. On the other hand, osteomyelitis developed in neither of the two open fractures reported

Fig. 48.2 **(A)** Advanced osteoporosis in the hands of a 14-year-old boy 9 months after a 100% total body surface area burn. All growth plates are open. **(B)** At 24 months after injury, osteoporosis persists, and there is irregular closure of the metacarpal and phalangeal growth plates. **(C)** At 8 months after injury, the growth plates of the distal tibiae and fibulae remain open. **(D)** At 24 months after injury, the distal growth plates of the tibiae and fibulae are closed. Other major growth plates remain open. Osteoporosis is unchanged.

separately by Choctaw et al.[16] and Wang et al.[17] We treated three patients in whom open fractures of the femur complicated thigh burns. Each case required aggressive and repeated debridement. One fracture was treated in traction, and the other two were treated with external fixators. In one of the patients, who was admitted 8 months after acute burn, there was established osteomyelitis of the femur in relation to the exposed fracture. Osteomyelitis did not develop in either of the other patients; in the end, all three had sound femurs.

When traction pins are directed through burned skin for the treatment of fractures or for suspension of a burned extremity, the factors favoring development of infection along the pin track and the formation of cigarette sequestra are:

- The introduction or migration of organisms from the burn wound
- Thermal necrosis during introduction of the pins
- Linear pressure of the traction pin
- Prolonged traction
- Excessive movement of the extremity leading to loosening of the pin
- Sealing of the skin of the pin sites.

For traction or suspension, pins may be inserted through acutely burned skin, through eschar, through granulation

tissue, or later through ischemic burn scar, which may be colonized with uncommon and antibiotic-resistant organisms. No amount of local cleaning is likely to sterilize the surface through which the pin must pass, yet it seems that organisms in sufficient numbers to colonize and infect are rarely introduced in this manner.

Local low-grade infections usually resolve when pins are removed if the pin sites are vigorously curetted of granulation tissue. In one case in which a four-pin custom external fixator was used in the treatment of an open infection of the elbow, diffuse osteomyelitis of the humerus and radius resulted. The infection was controlled with antibiotics and without surgery after the pins were removed. This case was included in Barret et al.'s report of skeletal pinning in 41 severely burned children.[18] In experience with the Ilizarov system for correction of skeletal deformity in burns, one patient developed a pin track infection of such severity as to require removal of the pin, curettage, and intravenous antibiotics for control of meticillin-resistant *Staphylococcus* spp.[19] In an ongoing yet unpublished study, we treated nine patients with open joints in external fixation for an average of 7.1 weeks, and none of them developed pin tract infections or osteomyelitis. The open joints were treated in joint-spanning external fixators. Most patients had multiple failed skin grafting procedures before fixator placement. The fixators were thought to have decreased the need for additional skin grafting.

Hematogenous osteomyelitis and that caused by spread from an infected joint are rare. There is no report of the occurrence of either entity in association with burns. If bone infection of this sort were be recognized, effective treatment would depend on the identification of the offending organisms for organism-specific antibiotic regimens.

FRACTURES

Pathological fractures were at one time common in burn management because of the practice of delayed excision of eschar and of keeping patients in bed until wounds were completely covered. During that time, fractures occurred because of bone collapse when patients first stood or walked or when stiff joints were manipulated (Fig. 48.3).[20] The bones most commonly affected were the femur at its distal metaphysis and the tibia at its proximal one. The only treatment required was support of the extremity until the fracture consolidated, usually in 4–6 weeks. Children were more often affected than adults, and the fractures usually compressed one cortex, producing an angular deformity that rapidly corrected with growth. Klein et al.'s study[2] strongly suggests that fractures occur more frequently in burned children than in a matched normal population even months after the acute burn. Now, however, in acute burn management, the most frequently seen fractures are those occurring at the time of, or in association with, the burn injury. Falls or violent trauma account for many of the fractures, and the sites are those common to the causes, bearing no relation to the burn itself.

Although fractures complicate burn treatment and occasionally delay mobilization of patients, their management need not be complex. Fractures in extremities not burned can be treated by manipulative reduction and cast immobilization, by open reduction and fixation, with an external fixator, or with skeletal traction (Fig. 48.4). Fractures in extremities with first-degree or superficial second-degree burns can be managed in the same way. Deep second- and third-degree burns present a different problem only with respect to the early bacterial colonization of third-degree burns and the degradation of deep second-degree burns to full-thickness burns that will in turn become colonized. There is a precious window of time when fractures requiring open reduction and internal fixation (ORIF) can be definitively treated without increased risk for infecting the bone; however, fracture reduction and stabilization are so important in the functional management of a severely burned patient that the risk for bone infection should be acknowledged and shouldered at any postburn stage. English and Carmichael[15] showed that if fractures were treated with open reductions within the first 48 hours postburn, the risk of infection is minimal. Therefore, early stabilization is encouraged in the first 48 hours before the risk of infection increases. Skeletal traction is used infrequently today. The disadvantages of skeletal traction are the confinement to bed and the imposed relatively fixed position of the affected extremity. External fixators make it possible to align and stabilize fractures in burned extremities without open operation and provide mobility to the patient. Brooker's extensive favorable experience supports this concept.[21] With both skeletal traction and external fixation, there is an added risk for bone infection because of the path from surface to bone provided by the pins. Pin tract infections can be minimized by scrupulous pin site care and by removal and replacement of any loosening pins. Frye and Luterman

Fig. 48.3 Pathological fracture of the osteoporotic femur of a 9-year-old girl sustained on the first day she stood after 5 weeks of confinement for a 40% total body surface area burn.

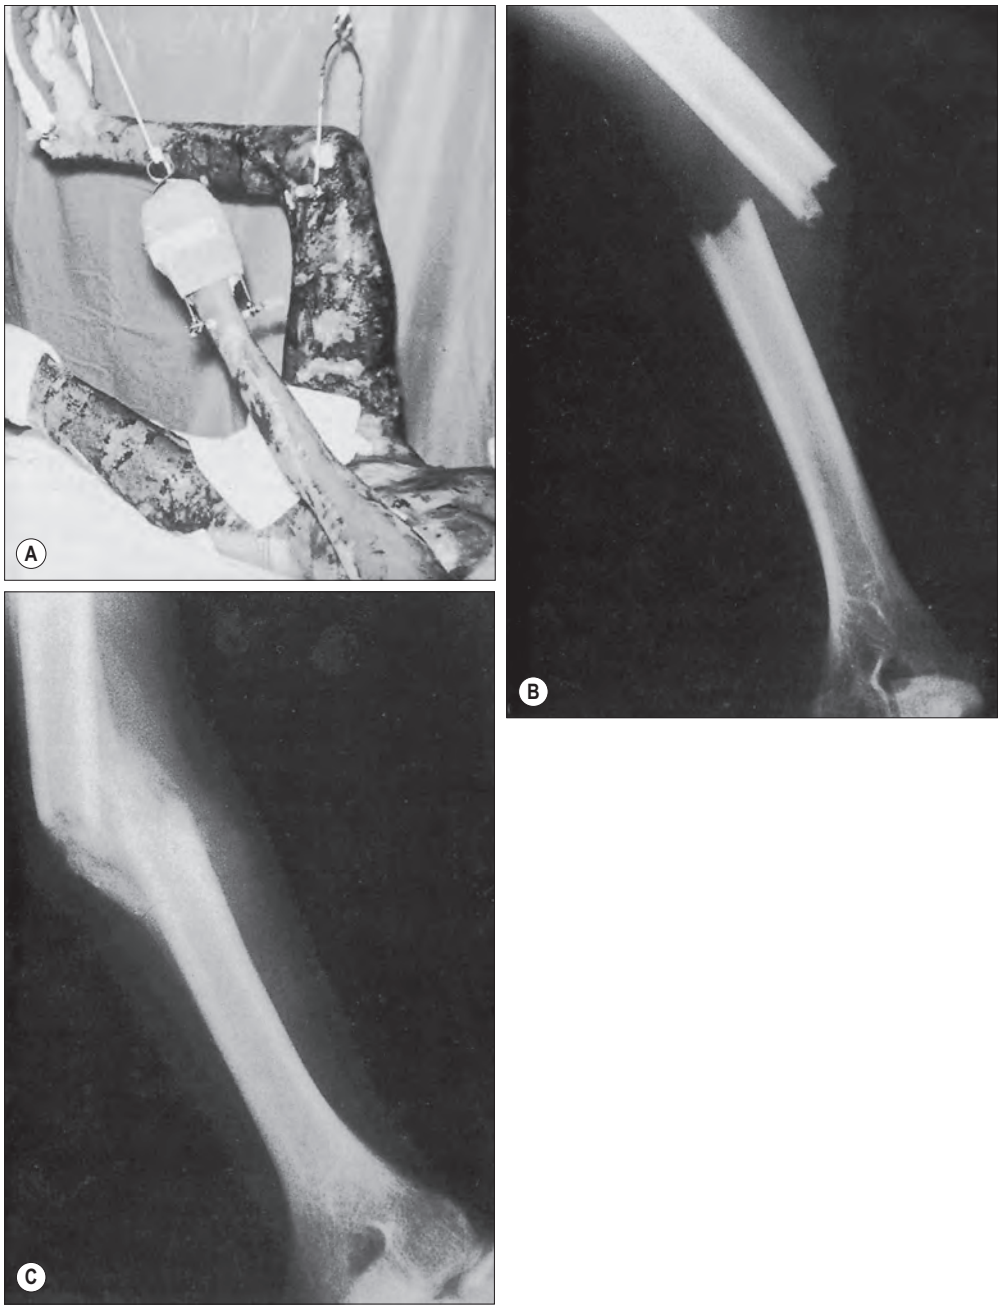

Fig. 48.4 **(A)** This 15-year-old boy sustained closed fractures of the right femur, left tibia, and left humerus at the time of a 46% total body surface area burn involving mainly the trunk and right lower extremity. The femur and humerus fractures were treated in skeletal traction. Suspension of the right lower extremity aided management of circumferential deep burns of that extremity. Lesser burns of the left leg made it possible to treat the minimally displaced fracture of the left tibia in a circular cast. All fractures consolidated in 6 weeks in satisfactory alignment. **(B)** Fracture of the left humerus as it appeared at the time of admission to the hospital. **(C)** At 5 weeks after injury, the fracture shows maturing callus. Traction was discontinued at 6 weeks.

recognized and discussed the specific and continuous difficulties encountered in the management of fractures and burns.[22]

When casts are used for stabilization of fractures in burned extremities, the wound is made inaccessible, and there is an abiding fear that the unattended wound will seriously degrade or at best not improve. Such fear may be well founded; however, Wang et al.[17] showed that a bivalved circular cast could be used effectively for an open comminuted fracture of a proximal tibia with overlying deep burns, and Choctaw et al.[16] reported successful use of a cast for immobilization of an open comminuted fracture after immediate postburn grafting of the affected extremity. Common sense should dictate which fractures can be treated with circular or bivalved casts or with splints. If casts are used over burn skin, they would need to be removable to allow burn care. If a reduced or moderately displaced but aligned fracture is so stable as to require external support only for maintenance of alignment, then cast or splint immobilization should be all that is needed. On the

other hand, if a fracture, because of instability, requires maintenance of reduction by three-point pressure or molding of the cast material, it will be better treated by other means.

English and Carmichael had 28 fractures that were treated over a 20-year span. In that study, 22 of 24 fractures available for long-term review healed in appropriate time. There were five infections noted, including two superficial pin tract infections from external fixation and three cases of osteomyelitis, all of which were open fractures. In contrast, there were no infections among Saffle's 42 fractures, nine of which were treated by ORIF.[23] With two fractures of the femur, each of which was exposed at the base of a deep chronic burn, aggressive debridement of the wounds and the fracture ends was followed by treatment with skeletal traction in one and by external fixation with the Ilizarov system in the other. Both fractures healed without further complication. Coverage of exposed bone can be done with skin grafts, local flaps, and free flaps. Burring of the exposed bone to stimulate bleeding and induce granulation tissue can be used alone or with other procedures to help cover exposed bone.[14] Newer techniques using graft substitute have shown promise in coverage of exposed bones in burn patients.[24,25]

Among severely burned patients, nondisplaced or minimally displaced fractures may not be detected until unusual local pain in an affected extremity prompts radiographic examination. A radiograph obtained for other reasons may reveal a fracture as an incidental finding. These fractures are usually of no functional significance. Modest angular deformity near a joint is more of a problem in adults than in children who still have remodeling potential. Undetected transphyseal fractures in children can be a major functional threat, however.

Changes Involving Pericapsular Structures

HETEROTOPIC OSSIFICATION

Heterotopic ossification (HO) is a rare but functionally important complication of thermal burns. The incidence in a general burn population is reported to be somewhere between 1% and 3%.[1,26–31] In select populations, the incidence may be higher, as it will be if patients with periarticular calcification are included in the statistics. For example, Tepperman et al. reported a 35.3% incidence among patients referred to a tertiary care center for rehabilitation.[32] Jackson and Mac made the observation that the incidence of HO could be expected to be less in institutions that admit patients with minor burns.[33] Munster et al.'s[34] radiographic survey of 88 adult and teenaged patients with 160 burned upper extremities yielded a 16% incidence of pericapsular calcification; the 23% incidence reported by Schiele et al.[1] included both HO and heterotopic calcification. In the early routine radiographic study reported by Evans,[20] periarticular calcification that did not progress to HO was excluded from the final calculation of an incidence of 2%. The 3.3% incidence recorded by Kolar and Vrabec[35] included patients with pericapsular calcification. Pandit[11] noted pericapsular, periarticular, and tendon calcifications at around 1.25% each in a radiographic study. Even if HO occurs infrequently in thermal burns, it remains that after it develops, it often compromises joint motion and is difficult to treat. In addition, its pathogenesis is still incompletely understood; thus, protocols for prevention may in fact miss the mark.

PATHOGENESIS OF HETEROTOPIC OSSIFICATION

The metabolic changes occurring after thermal burn are increased metabolic rate, protein catabolism, ureagenesis, fat mobilization, glycogenolysis, gluconeogenesis, elevated glucose flow, and eventual total body weight loss.[36,37] There is an accompanying suppression of the immune system that favors wound infection but at the same time favors survival of skin allografts. Infection, failure of skin graft take, or anything that delays closure of a burn wound will extend the altered metabolic state. Although it might be assumed that there occurs, along with the metabolic upheaval, an adverse change in connective tissue milieu, the exact nature of such a change is not known. It is also not known what the metabolic changes have to do with the development of HO, but it is apparent that the burn disease is necessary to its formation. Other factors to be considered in the genesis of HO are percentage of burn, location of burn, period of confinement, osteoporosis, superimposed trauma, and genetic predisposition.

Percentage of Burn Effect on Heterotopic Ossification

Most reported cases of HO have had a 20% or greater total body surface area (TBSA) burn; however, it has been found in patients with as little as 10% third-degree burn.[20] Peterson et al.,[29] Munster et al.,[34] and Elledge et al.[28] have reported affected patients with TBSA burns of 8%, 14%, and 12%, respectively. In addition, with the now extensive experience with salvage of patients with 80% or greater burns, it is clear that HO occurs no more frequently among these patients than in the general burn population. Thus, the percentage of burn is not a determining factor.

Location of Burn Effect on Heterotopic Ossification

By no means has all of the reported HO occurred in joints with overlying burn. In their initial report, Evans and Smith described HO occurring a distance from any third-degree burn involvement.[38] Johnston noted that in one of his three patients, the skin overlying one affected joint was not even superficially burned.[39] If degradation of connective tissue milieu in burns is a total-body phenomenon, it follows that heterotopic bone formation need not be burn site dependent. Thus, the location of the burn cannot alone be a determining factor.

Period of Confinement Effect on Heterotopic Ossification

Evans and Smith expressed the belief that length of bed confinement was an important factor in the development of HO.[38] At the time of that report, patients with even moderate burns might be kept in bed for several weeks. The consequences of prolonged confinement were loss of active range of joint motion and bone demineralization; it was

thought that each of these adverse changes might contribute to the formation of HO. Thus, any maloccurrence that necessitated longer confinement could be a factor in the pathogenesis. Kolar implicated wound sepsis as an independent factor along with the length of confinement.[35] Other investigators have not addressed the period of confinement as specifically as Kolar, and there have been no comparative studies of groups of confined and nonconfined patients. Thus, it may never be determined whether the current aggressive practice of early mobilization of patients will have an effect on the incidence of heterotopic bone. We believe the incidence of HO is lower at our institution after the advent of early mobilization postoperative protocols.

Osteoporosis and Heterotopic Ossification

Only Schiele et al. have found a relation between HO and osteoporosis.[1] Among their group of 70 adults with burns confined to the upper extremities, 11 of the 16 who developed HO had radiographically identifiable osteoporosis. In their series of patients, there were 24 with osteoporosis. Thus, fewer than one half of these developed HO, and there were two in the group who developed HO who did not have osteoporosis. If the findings in that study are not altogether persuasive, the matter is further confused by the knowledge that the survivors of extensive TBSA burns, who may develop profound osteoporosis, seem to have no greater liability to the formation of heterotopic bone than the general burn population.

Superimposed Trauma on Heterotopic Ossification

In one of the patients reported by Evans and Smith, the elbow of the more often used and minimally burned right upper extremity developed HO, but the elbow of the less used but more seriously burned left upper extremity did not.[38] In the same patient, the right hip spontaneously dislocated. After reduction, that hip developed extensive HO in the planes of the rectus femoris and iliopsoas. The opposite hip developed only a small, inoffensive spicule of HO anteriorly at the joint line. Experience with this one patient reinforced the authors' belief that there occurs with burns a general compromise of connective tissue that renders it particularly susceptible to superimposed trauma and that it is this liability to injury that accounts for the appearance of HO at sites of repeated stretching of soft tissue, as at the minimally burned elbow or at sites of recognized abrupt excessive stretching as with the dislocated hip. According to all reports, the elbow is the most common site of HO in adults and children.[28,29,35,40–47] Perhaps it is the regular use of this joint that accounts for that orientation. Jackson has pointed out that the elbows are subjected to pressure posteriorly and medially when they are used for leverage or are simply in contact with the bed.[33] He suggests with this observation that external pressure is a factor in the orientation of HO to the elbow. There may be other factors that favor the elbow. Commonly, the elbow is splinted in extension to prevent flexion contracture. If flexion range is lost, passive stretch and encouragement of active flexion are part of the rehabilitation effort. The posterior structures most affected by this effort are those attached to the olecranon. HO often develops medially in line with and deep to the medial fibers of the triceps. If a flexion contracture develops, the HO is commonly in the line of brachialis or biceps attachments to coronoid process and biceps tubercle. And if there is loss of pronation and supination range, stretching may cause HO to form in line with the proximal radioulnar ligaments and interosseous membrane. There is an implication here that both the quality and timing of postburn exercise may be important. Gentle passive and active motion should cause less tissue disruption than abrupt passive or active or even chronically repeated motion, and the effect of any mobilization effort must vary with the relative stiffness of the joint and the intrinsic resistance of soft tissue. The longer a joint is limited in its motion, the stiffer it will become and the greater will be the soft tissue damage with any forced manipulation.

The concept of superimposed trauma as a cause of heterotopic bone is supported by the experimental work of Evans[48] and of Michelsson and Rauschning.[49] Evans found that all burned and nonburned rabbits given a single necrotizing injection in one quadriceps muscle readily healed the lesions, but rabbits burned or nonburned that were given a second same-site injection 7 days after the first uniformly developed well-defined and histologically identifiable HO. In this experiment, it was clear that in susceptible animals, it was not the burn that made the difference but the chronicity of the wound. Michelsson and Rauschning determined that forceful or regular active remobilization of rabbit knees that had been immobilized for 1 to 5 weeks resulted in the development of heterotopic calcification and ossification in the muscles that were stretched. The response was more consistent in the quadriceps of the knees immobilized in extension than in the hamstrings of those immobilized in flexion. The longer the period of immobilization and the more vigorous the remobilization, the greater was the response. Muscle necrosis was a prominent histologic finding.[50]

Superimposed trauma is implicated in the development of HO in head-injured patients or those with posttraumatic or infectious transverse myelitis.[51–53] In these patients, it is assumed that tissue media are altered by injury to the central nervous system. The secondary injury, as in burns, is periarticular. In posttraumatic myositis ossificans, the development of HO depends on persistence of the muscle lesion and local necrosis and thus, at least by inference, on repeated insults to the affected muscle.

The development of HO in burns has been associated with the agitation of patients and their resistance to physical therapy.[38,54] Two affected adults and one affected child in a 10-year study resisted physical therapy programming.[48] One adult refused to move, and the other was extremely apprehensive. The child was likewise apprehensive and refused to cooperate with the therapist. The development in all three of posterior HO in both elbows could have been ascribed both to the difficulty encountered in mobilizing the elbows and to the continual pressure on the elbows in bed.

Genetic Predisposition to Heterotopic Bone

It is difficult to explain the low incidence of HO among great numbers of patients similarly burned except on the basis of some, as yet unidentified, inherited factor. It is known that persons with proliferative noninflammatory arthritis of the hip are more likely to develop HO after total hip replacement than persons who have hips replaced for other reasons. In this instance, the predisposing inherited abnormality is

identifiable. Although HO formation may occur more regularly among spinal cord-injured and head-injured patients than among burned ones, by no means do all persons with head and spinal cord injuries develop HO. The total burn experience at the University of Texas Medical Branch has yielded only two similarly affected siblings. Twin brothers who had 19% and 20% TBSA burns and who were mobile throughout much of their treatment and recovery period developed near-identical HO of both elbows.[55] There is, however, no scientific proof that genetic predisposition has anything to do with the formation of HO in burns. Nor is there any literature to support the idea that a person who develops HO when burned will be liable to develop it if he or she sustains head or spinal cord injury. Vrbicky,[56] in a comprehensive review of postburn HO formation, suggests that a key for the genetic predisposition may be in the human leukocyte antigen (HLA), reporting that an HLA B27 survey showed a 7% HLA distribution in the normal population compared with 70% in a population with HO.

CHARACTERISTICS AND BEHAVIOR OF HETEROTOPIC BONE

Heterotopic ossification associated with burns has been reported to occur about all major joints. The joints most commonly affected are elbow, shoulder, and hip, in that order of frequency. The early manifestations are joint swelling and tenderness not unlike any acute inflammatory process. The patient may call attention to the process by a reluctance to move the affected joint. Onset may be as early as 1 month and as late as 3 months or more after the burn, but it is more likely to be associated with the acute recovery phase of treatment than later. Crawford et al. reported that the clinical diagnosis was made in advance of radiographic changes in 9 of his 12 patients.[40] Tepperman et al.[32] and Peterson et al.[29] found that bone scans could help make a diagnosis before there were radiographic changes. The earliest radiographic alteration is local periarticular increase in soft tissue density. There follows diffuse, stippled calcification in the same distribution in or about the capsule of the joint. It is at this point that the process may reverse itself, perhaps because of the improved state of the patient. Owing to this change in course, there may be patients whose periarticular calcification is not detected. If the calcification persists, it may be assumed that bone will develop by either the intramembranous or the enchondral route or both, as it does in animal models.

The flecks of calcification appear radiographically to lie within the capsule, but HO not only may involve capsular structures but also may extend into the planes of muscles and tendons. At each major joint, there is a more or less characteristic distribution of HO, which is similar to that associated with patients with head and spinal cord injury. At the elbow, posteriorly disposed bone extends from the olecranon to the medial epicondylar ridge of the humerus in line with the medial border of the triceps muscle (Fig. 48.5A and B). At the joint, it may extend medially to bridge the ulnar groove.[57,58] The medial, rather than lateral, orientation of the heterotopic bone may be related to the medial position of the olecranon and the greater tension on soft tissue on that side, and as Jackson points out, the contact area of the elbow is consistently medial.[33] HO on the anterior surface of the elbow develops in the planes of the brachialis and biceps muscles extending from the humerus to the coronoid process or the biceps tubercle. Occasionally, a bridge of HO develops between the radius and ulna just distal to the joint. More rarely, bone has been found to fill the olecranon fossa and even to ensheathe the entire joint. At the shoulder, bone has been found to extend from the acromion to the humerus in the line of the rotator muscles or deep to the deltoid (Fig. 48.5C), to lie anteriorly in the plane of the pectoralis major, and more deeply, to parallel the subscapularis. Hoffer et al.[59] reported that HO at the shoulder lay anteriorly in the plane of the capsule. At the hip, HO may extend from pelvis to femur in the planes of rectus or iliopsoas anteriorly or in the plane of the gluteal muscles laterally. Jackson has reported HO in the plane of the quadratus femoris.[33] Similar to the shoulder, the hip may be ensheathed anteriorly with HO that appears to originate in the capsule.

When HO bridges a joint, it becomes part of the skeleton and may, if loaded, increase in dimension as a fully developed ossicle with mature cortex and medullary cavity. In children, if the bone does not bridge a joint, it will gradually disappear when the burn wound has healed and the child is healthy. In recovering adults, nonbridging bone will, in time, diminish in size, but it may not disappear. The same tendency for heterotopic bone to regress after resolution of disease was noted by Lorber, who reported on two patients with paraplegia secondary to tuberculosis in whom deposits of heterotopic bone diminished in size after return of motor function.[51] Bottu and Van Noyen[60] reported a similar experience with a patient who had transient viral meningoencephalitis, and Jacobs reported almost complete resorption of large bilateral deposits of heterotopic bone in a patient who recovered from paralytic measles encephalomyelitis.[52] Serum concentrations of calcium, phosphorus, and alkaline phosphatase (ALP) have been reported by most authors to be normal or, at best, insignificantly higher in burned patients who have developed HO.[26,34,38,61,62] In addition, there is no convincing evidence that calcium intake affects heterotopic bone formation one way or the other. Evans and Smith's limited routine studies of affected and unaffected patients led the authors to believe that the values of serum calcium, phosphorus, and ALP were so consistently normal as to make further investigation unnecessary.[38] One interesting observation was that of Koepke, whose studies suggested that those patients who were susceptible had elevation of serum ALP before development of heterotopic bone but not afterward.[27]

PREVENTION AND TREATMENT OF HETEROTOPIC BONE

The incidence of HO in burns is so low as to make it impractical to administer indometacin or other nonsteroidal antiinflammatory drugs (NSAIDs) that are currently used for patients at risk for development of heterotopic bone after major hip surgery. Rather, the thrust in prevention should be toward reducing the period of bed confinement and the duration of the postburn hypermetabolic state. The now prevailing practice of early wound excision and grafting may, in fact, address both of these problems as nearly as it is possible to do so. Even patients with extensive TBSA burns

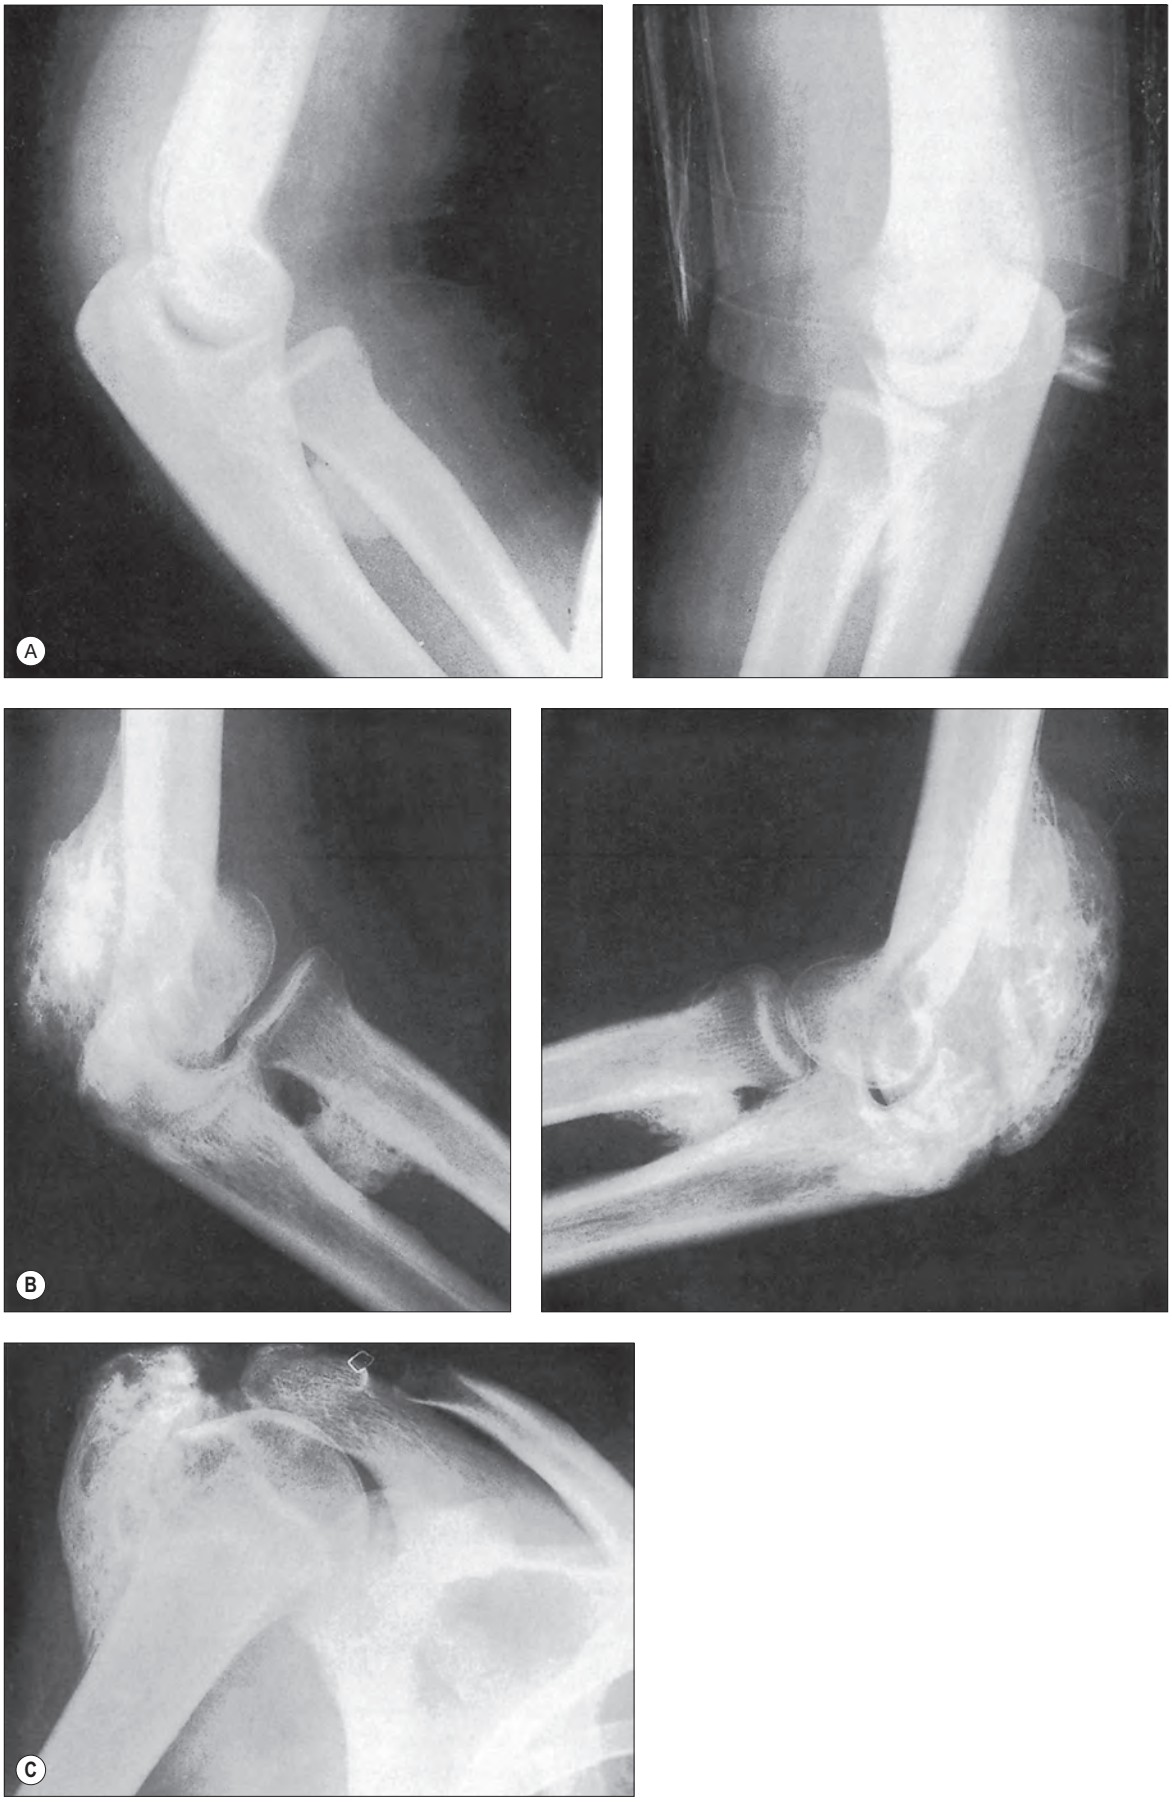

Fig. 48.5 **(A)** At 3 months after a 94% total body surface area burn of a 16-year-old man, resistance to motion, local swelling, and pain of both elbows prompted obtaining radiographs, each of which showed spotty linear soft tissue calcification and ossification along the distal humerus and between the radius and ulna at the level of the biceps tubercle. **(B)** At 6 months after burn, elbow flexion and extension were reduced to 10 degrees on the left and to less than 5 degrees on the right. Bridges of immature heterotopic bone extended from the medial epicondylar ridges to the olecranon. Forearm rotation was 0% because of interosseous bridges of heterotopic bone at the level of the bicipital tuberosities. The prognosis for restoring functional range of motion in the elbows is poor. **(C)** At 6 months postburn, glenohumeral motion on the right was limited to a few degrees by heterotopic bone underlying the deltoid. At the same time, a lesser deposit of heterotopic bone at the left hip did not limit motion.

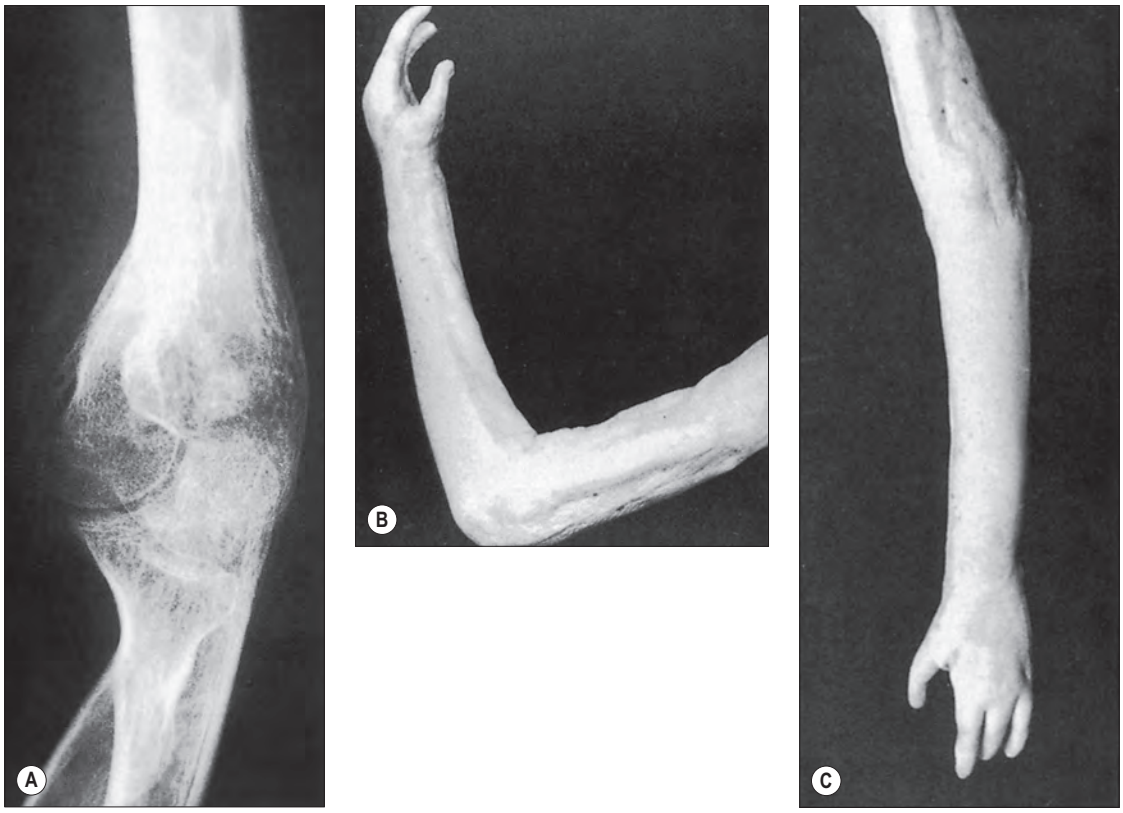

Fig. 48.6 (A) A mature sheet of heterotopic bone extends from humerus to olecranon, obliterating the olecranon fossa 11 months after a 53% total body surface area burn in a 13-year-old girl. Elbow flexion and extension range were less than 10%. Pronation and supination were near normal range. **(B** and **C)** At 3 months after excision of heterotopic bone, the patient had attained 90 degrees of elbow motion, and a continuing increase to functional (hand to mouth) range was predicted. Now the patient can extend the elbow and can flex it to 90 degrees.

may now be out of bed and walking within the first postburn week.

If certain patients are predisposed to the development of HO, the quality and timing of joint mobilization for those patients may be critical. Stretching edematous pericapsular structures in the early postburn period may very well be hazardous if additional tissue damage is the result; however, maintenance of joint motion and muscle function is part of the early excision and grafting program, and it is certain that the longer joint motion is restricted the more likely it is that pericapsular structures will be damaged by stretching. We like to think that secondary injury to soft tissue can be avoided by controlled and assisted active range of motion (ROM) and terminal resistance.

When a patient is reluctant to move a joint previously moved with relative ease, and certainly when there is evidence of unusual swelling about the joint, radiographs should be obtained to determine if there is pericapsular calcification or ossification. After heterotopic bone or calcification is recognized, joint exercise should be restricted to gentle passive and assisted active motion only. Crawford et al.[40] observed that ossification progressed to complete ankylosis in all patients who persisted in moving an affected joint beyond the pain-free range. They concluded that active ROM exercises and stretching were contraindicated if heterotopic bone or calcification was suspected, but that active ROM could be safely resumed within pain-free range after the diagnosis had been confirmed. In the series of Peterson et al.,[29] patients suspected of having HO had active ROM exercises only. Ten regained functional ROM, and eight developed ankylosis.

Surgical excision of heterotopic bone is indicated when joint motion is lost or significantly compromised by bridging bone or exostoses. Evans has suggested that surgery be postponed until the burn wound has healed, scars are soft and associated with no inflammatory response, the patient is healthy, and the offensive bone is radiographically mature (i.e., well-defined and not increasing in dimension) (Fig. 48.6).[20] This position makes sense considering the behavior of heterotopic bone (i.e., proliferation while there are open burn wounds or active scars and regression with wound healing and scar softening). For removal of heterotopic bone, surgical exposures should be planned with extensible incisions so as to facilitate total excision. When there is a bridge of bone, each end of the bridge should be slightly excavated. When there is attachment at only one end, the cartilaginous or fibrous extension should be removed along with the bone. Capsular sheets of bone should be removed completely. If bridging heterotopic bone is incompletely excised, the bridge is likely to recur. When a joint is bridged by bone in only one plane, removal of the offending bone will usually restore functional motion, and recurrence of the bridge is unlikely. When a joint is bridged in more than one plane, recurrence is more likely, and the chance for restoration of functional ROM is correspondingly diminished. When the local inflammatory process has

caused intraarticular synovial proliferation and cartilage destruction, the joint is most likely destined for ankylosis. Removal of the heterotopic bone about a joint so affected may allow more functional positioning of the joint, but it is not likely to arrest the process. On the other hand, extraarticular arthrodesis by a bridge of heterotopic bone may preserve the joint. This is particularly the case at the elbow when there is only one posterior bridge of bone from olecranon to the medial epicondylar ridge of the humerus. In this situation, the olecranon is fixed in the trochlea, but the radiocapitellar and radioulnar joints remain functional. In Evans' experience with removal of single bridges at the elbow, joint cartilage was found to be healthy as long as 5 years after ankylosis. Preservation of pronation and supination was credited with maintaining the synovial bath to provide nutrition for the humeroulnar cartilage. Indeed, when pronation and supination additionally are blocked by bridging bone, cartilage degradation is certain. Evans' further experience with long-term survival of glenohumeral cartilage after ankylosis by bridging bone from acromion to humerus is not as easily explained.

Reported experience with excision of heterotopic bone in burns has not been uniformly favorable. Dias,[62] Hoffer et al.,[59] and Peterson et al.[29] reported restoration of functional ROM in most of their patients with timely excision of heterotopic bone. Gaur et al.[41] reported good functional return in seven burned children with nine affected elbows. Ring and Jupiter[42] reported good results in a varied population, and Chung et al.[43] and Tsionos et al.[45] have reported good results with early excision a mean of 9 months after the burn. Other surgeons have reported less satisfactory results.[31] In our own experience, results have varied, as anticipated, with the severity of the condition. We have learned that if heterotopic bone recurs after excision, it is worthwhile to excise again if the joint affected remains structurally identifiable. For the most part, however, attempts to improve joint function with second operations have failed. We believe that ultimate failure can be predicted at the time of initial surgery; we are convinced that the single most important factor in successful initial excision is in timing surgery to coincide with the patient's return to good health.

Changes Involving the Joints

DISLOCATION

Luxations and subluxations of joints in burned patients may occur as a result of direct destruction by the burn of ligaments and capsules, loss of articular cartilage caused by infection, faulty positioning, and eventually scar contracture. In all phases of management, but particularly in the acute phase, positioning is of prime importance in the prevention of joint deformity. The preferred positions, listed in Table 48.1, serve as a guide for the prevention of dislocation of joints and of malposition secondary to scar contracture.

The joints most liable to structural compromise caused by exposure by the burn and loss of soft tissue support are knee, elbow, proximal interphalangeal joints of the hand, and metacarpophalangeal joints. These hinge joints have in common a subcutaneous dorsal surface, accounting for their ready exposure. The bone and joint changes are found mostly in severely burned patients and include contractures and even ankyloses of smaller joints.[11]

Table 48.1 Preferred Positions for Major Joints

Joint	Preferred Position
Neck	Midline in neutral or slight extension
Shoulders	Scapulothoracic retraction and depression, 85 degrees of glenohumeral elevation with 20–25 degrees of horizontal flexion
Elbows	Extension
Wrists	Slight extension
Metacarpophalangeal joints 2–5	80–90 degrees of flexion
Fingers	Proximal and distal interphalangeal extension
Thumbs	Carpometacarpal flexion and abduction, metacarpophalangeal flexion 5–10 degrees, interphalangeal extension
Spine	Extension with no lateral deviation
Hips	Extension and slight external rotation in 15 degrees of symmetric abduction
Knees	Extension
Ankles	Neutral
Feet	Neutral

The elbow, for its trochlear architecture, is more intrinsically stable than the other joints in this group. It requires loss of collateral support to render it easily displaceable. The knee, on the other hand, is immediately in danger of subluxation if there is loss of continuity of its central slip, the patellar tendon, even if the retinacula remain intact. In this circumstance, gravity alone will displace the tibia posteriorly in relation to the femur if the patient is recumbent. The hamstring muscles contribute to the displacement force regardless of the position of the extremity. Loss of collateral ligaments compounds the problem, but loss of collateral ligament stability in the presence of an intact patellar tendon and functioning quadriceps constitutes far less a threat than loss of patellar tendon. For the lower extremity, persistent posterior translation of the tibia beneath the femur with inefficient quadriceps function leads to severe functional problems.

For both the elbow and the knee, the protecting position is extension. These two joints are rarely at risk for articular displacement from contracture alone and, if there is no ligament or tendon loss, extension resting splints will give adequate positional support. When there is soft tissue disruption, splinting may not adequately protect either joint. An external fixator with two-pin, four-cortex fixation above and below the joint will provide stability and will permit access to the wound. For the elbow, it allows fine adjustment to the normal carrying angle as well. If the knee is accurately reducible at the time of application of the fixator, there is a good possibility that the reduction can be maintained. If the tibia cannot be brought forward completely by manual manipulation, it may be necessary to

suspend the tibia through a transverse pin at the level of the tibial tubercle. For static vertical traction, the extremity must be elevated from the bed. For dynamic traction, enough weight must be used to accomplish the same elevation. If the tibia can be brought forward by this means, an external fixator will hold the reduction. For the knee to remain stable with the tibia forward, the patellar tendon must be reattached and quadriceps integrity reestablished; otherwise, when the fixator is removed, the tibia will again begin an incremental posterior shift toward its own point of stability. No amount of external splinting or bracing is likely to prevent this shift.

The proximal interphalangeal joints of the hands are more frequently exposed by burn than any others. If the central extensor slip remains intact, there is less risk for subluxation of the joint. Even if there is loss of continuity of the central slip but preservation of the lateral bands, subluxation is easily prevented if the joint is maintained in extension while soft tissue cover is being achieved. It is with loss of the support of lateral bands and collateral ligaments that the joints become liable to dislocation. With the metacarpophalangeal joints, the tendency to displacement or subluxation may be greater because these joints are functionally multiplanar, but the interphalangeal joints are uniplanar. Fortunately, the metacarpophalangeal joints are less often exposed than the interphalangeal ones.

The protecting position for the proximal interphalangeal joints is full extension. If only the central slip is lost, the position may be held with an external splint. In states of greater instability, it may be necessary to use intramedullary transarticular Kirschner wires to hold the position. The wires, although reasonably efficient, do not control rotation, and they carry with them a risk for posttreatment joint stiffness. In small children, it is impossible to introduce the Kirschner wires through the distal phalanx; thus, it is better, with the proximal phalanx flexed to 90 degrees, to place the wire through the corresponding metacarpal head into the proximal and middle phalanges. Short-term transfixation does not harm the joint, and metacarpophalangeal flexion is the favored position for functional restoration. Pin traction through the distal phalanges in a skeletally stabilized metal splint is another method for maintaining extension of threatened digital joints.[63,64] It has the advantages of patient comfort and mobility; secure positioning of hand and upper extremity; easy maintenance of elevation; and easy access for dressings, for additional surgery, and for exercise of lesser affected joints. The system likewise makes it possible to keep digits separated, thus facilitating local care. Traction should not be used if collateral ligaments are not intact. By whatever means attained, the corrected position must be maintained until the joint is covered with graft. Protection should continue with a standard splint or brace until the joint is sound.

The two joints most likely to dislocate because of faulty positioning are the shoulder and the hip. These two ball-and-socket, multiplanar joints sacrifice stability in favor of mobility. This is particularly true of the shoulder, where the shallow glenoid contains at any one time only one third of the head of the humerus. In burns, the head of the humerus may begin to subluxate forward if, during prone positioning for management of back and buttock wounds, the arms are maintained in full abduction in the coronal plane. In this position, the arms are in at least 15 to 20 degrees of extension from the more secure neutral position in line with the scapulae, and the humeral heads are forced forward against the anterior capsule. Even when the patient is supine, full abduction and extension of the arms should be avoided. For short-term management, particularly when the patient gets out of bed each day, this position probably does not threaten the joint. But if the patient is to be bed confined and the position unrelieved for days or weeks, the head of the humerus may begin to subluxate forward. In the extreme situation, the head of the humerus will dislocate to a medial subcoracoid position. In patients with deep burns extending from the chin to the axillae to the chest, the common posture of elevation and protraction of the scapulae may be associated with upward subluxation of the humeral heads.

The head of the humerus is most secure in the glenoid fossa when the arm is adducted to neutral and internally rotated, a position that is incompatible with wound management of burns of the trunk, neck, and upper extremities. The protecting position that accommodates the need for abduction for axillary burns is elevation of the arms in line with the scapulae. The arm is then approximately 20 degrees forward of the coronal plane or in 20 degrees of horizontal flexion. When the patient is prone, the protecting position can be gained only if the chest is supported on a chest width mattress, folded blankets or towels, or a foam rubber pad, any of which will allow the arms to drop forward. When the patient is positioned this way, whether supine or prone, the forearms will be pronated, and the arms will be in sufficient internal rotation to favor seating of the head of the humerus in the glenoid.

The hip will tend to subluxate posteriorly if the thigh is persistently allowed to remain flexed, adducted, and internally rotated during the acute burn phase. For the most part, however, the protecting position of extension to neutral or 180 degrees and 15 to 20 degrees of symmetric abduction is easy to attain and maintain and is, in fact, the most desirable position for wound management.

Infection of a joint may result in its subluxation or dislocation. Hip displacement because of apparent spontaneous dissolution has been described by Evans and Smith.[38] Eszter and Istvan[65] and Cristallo and Dell'Orto[66] reported similar cases. In none of these cases, however, could it be determined that the joint destruction was attributable to infection.

SEPTIC ARTHRITIS

A joint exposed by a burn or by removal of burn eschar is presumed to be infected. The joints most frequently exposed are the knee, the elbow, the proximal interphalangeal joints of the hand, and the metacarpophalangeal joints, all on the subcutaneous dorsal surfaces. The wrist and ankle are less often affected, and other joints are affected rarely. Treatment requires stable positioning of the joint for maximum reduction of wound size so as to facilitate soft tissue closure or grafting and to allow aggressive daily lavage. The position for all of the joints listed except the ankle is extension. The ankle is positioned in neutral. External fixation, intramedullary pinning, or skeletal traction may be required to secure the position. To maintain ankle position, it is

sometimes appropriate to insert a large vertical Steinmann pin through the calcaneus and talus into the tibia. The position should be maintained until the exposed joint is covered with epithelialized granulation tissue or skin graft. Exposed adjacent bone can be shaved or drilled, as previously described, to encourage surface granulation. Drilling is particularly useful at the elbow where the olecranon is regularly exposed. Often, however, granulation tissue will quickly extend the wound margins and effectively close the wound so as to allow split-thickness skin grafting. If the burn is isolated to the joint or if the extremity is not otherwise seriously burned, a local muscle, skin, or compound flap may be used to close the joint. Free vascularized flaps are useful and should always be considered if it is anticipated that nerve graft or tendon graft or transfer at the site will be required in the future. Incremental remobilization of the joint may proceed when wound closure is sound. Culture of material from an exposed joint will likely yield a variety of organisms consistent with those of the general burn wound, thus requiring broad-spectrum antibiotic management.

The incidence of hematogenous septic arthritis is obscured by its frequent association with severe burns and because there are rarely separable clinical signs such as local heat and swelling, elevation of temperature, and elevation of sedimentation rate. Local tenderness and greater than usual pain with motion may focus attention on the affected joint. Aspiration of the joint will confirm a diagnosis. A radiograph is helpful but in the early phases of infection will show only local cellulitis as increased periarticular soft tissue density. If a patient has been receiving broad-spectrum antibiotics, material aspirated from the affected joint may not grow an organism in culture. Clearly, without organism identification and sensitivity determinations, specific antibiotic therapy cannot be initiated.

We are of the opinion that surgical debridement and exteriorization of the joint and regular vigorous lavage are as important as antibiotics in the treatment of closed infected joints. We believe now that arthroscopic debridement and closed irrigation should be considered as an alternative method of management whether or not skin over the affected joint is burned. Rarely in burns, a joint may become infected from adjacent metaphyseal osteomyelitis. In this situation, joint preservation is the treatment priority, and measures are the same as for septic arthritis of strictly hematogenous origin.[55] In children, most infected joints can be salvaged. Adult joints are less resilient. Persistent joint infection will destroy cartilage and lead to ankylosis.[67,68] All chronically infected joints are liable to dislocation because of surface destruction and capsular laxity.

AMPUTATIONS

In thermal burns, major amputations are most often performed because of nonviability of the extremity or because a surviving extremity is rendered useless by scar, deformity, or insensitivity. Occasionally, in an extensive burn, a severely burned extremity that might be salvaged in part is sacrificed to reduce the extent of the burn or as a lifesaving measure. In thermal burns, the level of extremity amputation is determined by the viability of muscles and tendons. The more distal the site, the better, and it is important to retain joints even if motion will be restricted. For example, if a forearm or leg must be sacrificed, the elbow or knee should be spared if the more proximal muscles controlling that joint are intact, if the bone bleeds, and if there is the possibility that the remaining tissue of the stump has sufficient blood supply to produce granulations for grafting. Aside from affording a better functional prospect, sparing the joint will provide the surgeon opportunity at a later time to choose an appropriate revision level if the joint does not function. The patient will at that time be healthier, and stump closure will be routine. Jackson suggests that it may be technically feasible to cover even nonviable bone with a free flap to maintain extremity length.[33] In electrical burns, the level of amputation is most often determined by muscle viability. Stump care is the same as with thermal injury.

Prostheses can be easily fitted over stumps covered with split-thickness grafts. Ridges of hypertrophic scar will break down if there is friction within the socket of the prosthesis, but scar often softens and flattens with the constant, even pressure of a well-fitted socket; prostheses fitted early over grafted stumps may prevent scar thickening. Breakdown may occur at points where the graft is adherent to bone. This problem may require surgical freeing of the adherent graft and reshaping of the bone. Minor hip and knee flexion contractures complicate the fitting and function of a prosthesis; thus, every effort should be made to maintain full extension of these joints. Late revisions of amputations in children are required when the bone overgrows in length and when offensive terminal exostoses develop. The overgrowing bone can be shortened and the exostoses removed. Klimisch et al.[69] studied 259 amputations for burns at our institution. Stump overgrowth requiring revision surgery occurred in 10% of patients and 5.8% of amputations. Lower-extremity amputations had overgrowth in about 16% of stumps and the upper extremity in 2%.

It is important in the early management of upper-extremity amputations in infants and young children to supply temporary prosthetic extensions. This provides functional orientation to a prosthesis, maintains muscle bulk and tone, and encourages continuing bimanual activity at normal extremity length until a prosthesis with an appropriate terminal device can be applied. Children quickly acquire prehension and transfer skills if they have an opposable stump, and they may reject prostheses if they are not applied early. It is equally important to restore bipedal function as soon as possible. If delay of healing or ulceration of a lower-extremity stump prevents early prosthetic fitting, an ischial weight-bearing device that suspends the stump will permit the child to walk in advance of prosthetic fitting. Inflatable plastic air bags provide both even pressure and accurate fit for weight bearing in container sockets. Early prosthetic fitting is desirable in teenagers and adults as well but is not as critical as it is in children. As in nonburned persons, an upper-extremity prosthesis may be rejected at any age if the opposite extremity is fully functional.[70]

Alterations in Growth

In 1959, Evans and Smith reported that a patient who was 24 years of age when burned had a subsequent 1.5-inch increase in height. It was suggested that one explanation

for this growth spurt might be local change in hemodynamics with stasis, passive hyperemia, and chronic inflammation. We have not since documented height changes in burned adults, but we have observed children whose growth after burn has seemed to be retarded. If growth plates remain open, it is difficult to explain overall growth retardation except on an endocrine or humoral basis. It is easy, however, to explain extremity length differences on the basis of premature closure of growth plates caused by direct involvement of the bone or the severity of an overlying burn. Frantz reported lower-limb length discrepancy in four patients with foot and ankle burns.[71] Growth plates closed prematurely in only two of the cases. Jackson described two patients with digital and lower-extremity deformity, respectively, caused by partial closure of growth plates.[33] In Ritsilä et al.'s case, contracture alone was apparently the cause of growth retardation in an upper extremity.[72] It seems reasonable, although hard to prove, that growth in a severely burned extremity would be retarded because of functional impairment.

There is yet another confusing aspect of premature closure of growth plates in that within an extremity with total full-thickness burn, only a few of the growth plates will close prematurely. The explanation for this capricious selectivity is at best obscure. Evans and Calhoun recorded an example of spotty closure of growth plates in a 14-year-old boy with a 90% total TBSA burn.[19] There was complete closure of distal tibial and fibular epiphyses 1 year after burn together with closure of all digital epiphyses in the feet and of several digital epiphyses in the hands. Other major epiphyses were spared (Fig. 48.2).

In early experience, abnormal growth plate closure was observed in a 6-year-old girl with a 50% TBSA third-degree burn that did not involve the legs or ankles.[73] Rapidly destructive septic arthritis of one ankle resulted in closure of the adjacent tibial growth plate.

Only occasionally can growth changes be anticipated because of obvious affection of the bone. More often the changes are subtle. It seems clear, thus, that among seriously burned children, regular height and extremity length measurements must be part of ongoing postburn assessment until it is determined that the extremities and trunk are developing symmetrically and on schedule. Extremity and trunk alignment must likewise be part of the assessment because subtle angular deformity can occur because of partial closure of a growth plate. Jackson's report addresses this problem.[33]

So-called growth arrest lines seen in the radiographs of nonburned children, who have serious illness or major trauma other than burns, are commonly observed in burned children. In burns, as in other conditions, these transverse markers of relatively increased mineralization represent normal recovery from an insult to enchondral bone formation due to serious stress. They are of no clinical or functional significance. They are more related to total burn than to involvement of select burned extremities as all major long bones are affected. There is no evidence that growth arrest lines per se have any effect on growth.

49 Reconstruction of Bodily Deformities in Burn Patients: An Overview

LARS-PETER KAMOLZ, PAUL WURZER, and TED HUANG

The severity of burn injuries can usually be ascertained if not by patient survival then by the consequences of the injury: scar hyperplasia/hypertrophy, scar contracture, and structural deformities due to loss of bodily components. Since bodily deformity is closely related to the magnitude of injury, restorative procedures are seldom indicated if the depth of injury is superficial and the burned area limited (Fig. 49.1). However, these procedures are required for deep burns (Fig. 49.2).

Formation of scar tissues at a wound site and contraction of those scar tissues are the normal consequences of an injury. At a microscopic level, thickened and contracted scar tissues (i.e., changes that are "normal" and "expected" consequences of the wound-healing processes) appear as collagens arranged in whorls and nodules. These changes can be observed as early as 3–4 weeks following the injury, and they are cosmetically unsightly and disturb function (Fig. 49.3).

Reconstruction of Burn Deformities

GENERAL PRINCIPLES

Burn injury is a traumatic condition resulting in aberrant physiological processes caused by thermal destruction of the skin. These physiologic alterations affect not only healing of the original burn wounds, but also healing as part of secondary surgical procedures. The treatment should aim to repair the burn wounds first, and attempts to restore deformities should be delayed until recovery from the initial phase of injury is complete.[1] As initially described by Knobloch and Vogt,[2] each surgical approach and reconstructive procedure interacts with another. Hence burn reconstructive surgery can best be viewed as reconstructive clockwork (Fig. 49.4).

EARLY TREATMENT OF DEFORMITY AND TIMING OF SURGICAL INTERVENTION

Making a decision of *how* to operate on a patient with burn deformities is quite simple. In contrast, deciding *when* to operate on a patient with burn deformities can be difficult. Creating a realistic plan to restore physical function and to alleviate pain and discomfort in the area of injury requires an in-depth analysis of the physical deformities and psychological disturbance sustained by the patient. Psychiatric, psychosocial, and physiotherapeutic care, in this sense, must be continued while the surgical treatment plan is instituted.

Although the true efficacy of a nonsurgical regimen, such as pressure garments (Fig. 49.5), to control deformities has not been established, the frequency of secondary joint release among individuals who endured the morbidities associated with proper joint splinting for a period of at least 6 months has been noted.[3,4] The use of pressure dressings, especially in areas such as the upper and lower limbs, with proper splinting of the hand and fingers, is strongly recommended soon following the injury. The nonsurgical management of burn deformities must include daily physiotherapy and exercise to maintain joint mobility and to prevent muscle wasting.

The basic principle of restoring bodily deformities that impose functional difficulties before directing surgical efforts to restore appearance should be followed. The surgeon's efforts should be concentrated on restoring the deformed bodily parts essential for physical functions. For example, an exposed skull or a calvarial defect, contracted eyelids, constricted nares, contracted major joints, and a urethral and/or anal stricture in individuals with severe perineal burns are prime indications for early surgical intervention. In contrast, restoration of contour deformity can be delayed until the scars reach their final structure. In fact, in children reconstruction of the nose and the ear, for instance, should not be initiated until their growth patterns have reached the growth peak; ear reconstruction may be initiated once the child has reached 6–8 years of age, while nasal reconstruction should be delayed until 16–18 years.

Although the exact scientific basis remains unclear, it has been advocated that attempts at reconstructing burn deformities should be delayed for at least 2 years after burn—the time needed for scar maturation. During the interim, the use of pressure garments and splinting is recommended to facilitate scar maturation and minimize joint contracture. The true efficacy of pressure garments in facilitating scar maturation remains undefined. Lack of a reliable method to determine various stages of scar maturation and subjective differences in assessing scar appearance could account for the controversy. On the other hand, splinting a joint embedded in burn scars with an external device to maintain a proper joint angulation has been found to be effective in reducing the need for reoperation to achieve joint function. However, this is possible only if the patient wears the splint faithfully for a minimum period of 6 months. A physical exercise regimen providing vigorous movements of burned joints has been found to be effective in reducing the need for surgical intervention.

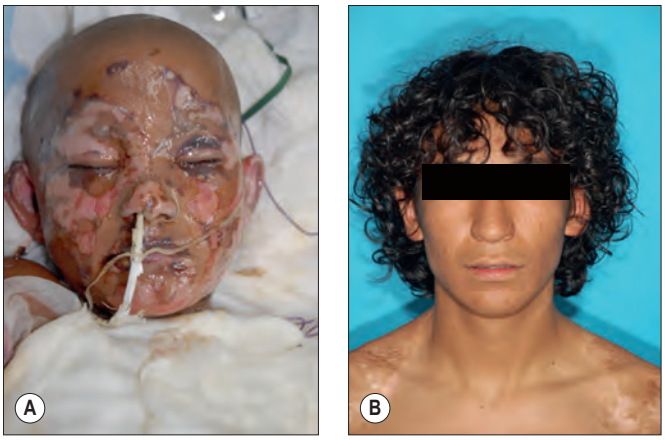

Fig. 49.1 **(A)** An 8-year-old boy sustained flash flame burns of the face. The depth of injury was judged to be superficial. **(B)** The wounds healed spontaneously. The scar formed was judged to be minimal 5 years later.

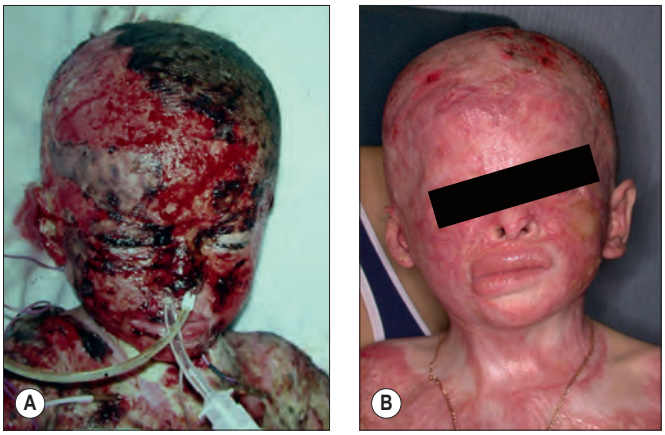

Fig. 49.2 **(A)** A 4-year-old boy sustained flame burns involving 75% of his total body surface. **(B)** The injury was extensive; the wound required staged debridement and skin grafting, resulting in extensive scarring.

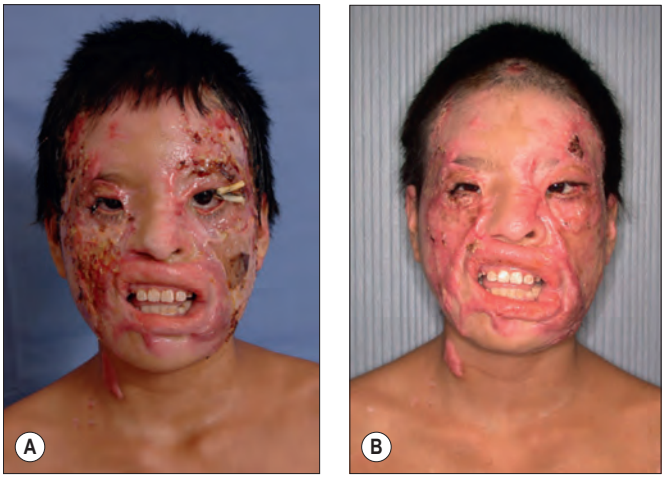

Fig. 49.3 **(A)** Scarring around the injured sites became apparent within 3 weeks. **(B)** Thickening of the scar continued during the subsequent 5–6 months. Contraction of scars caused difficulty in closing and opening the eyelids and mouth.

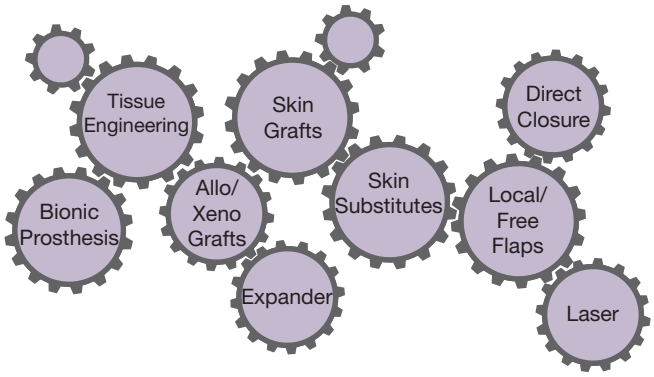

Fig. 49.4 Reconstructive clockwork shows the interaction between the different reconstructive methods.

Fig. 49.5 The use of splints over the mobile joints and pressure garments is an essential component of patient management.

The 2-year moratorium on early burn reconstruction is, in some ways, justifiable. Operating on an immature scar characterized by redness and induration is technically more cumbersome; hemostatic control of the wound is difficult, and inelasticity and lack of tensile strength of scar tissues render tissue manipulation more difficult. A high rate of contracture has been noted in instances where a partial-thickness skin graft is used to release a wound showing active inflammatory processes, further supporting the 2-year delay in initiating burn reconstruction.[5]

We have recently changed our approach to handling individuals in need of reconstruction based on the finding that contracted bodily parts can be effectively reconstructed in the first 2 years postburn if skin flap, fasciocutaneous (FC) flap, or musculocutaneous (MC) flap techniques are used. Reconstruction is initiated in individuals as early as 3–6 months following the initial injury. The approach is well-suited for those encountering functional difficulties because of scarring and scar contracture.[6]

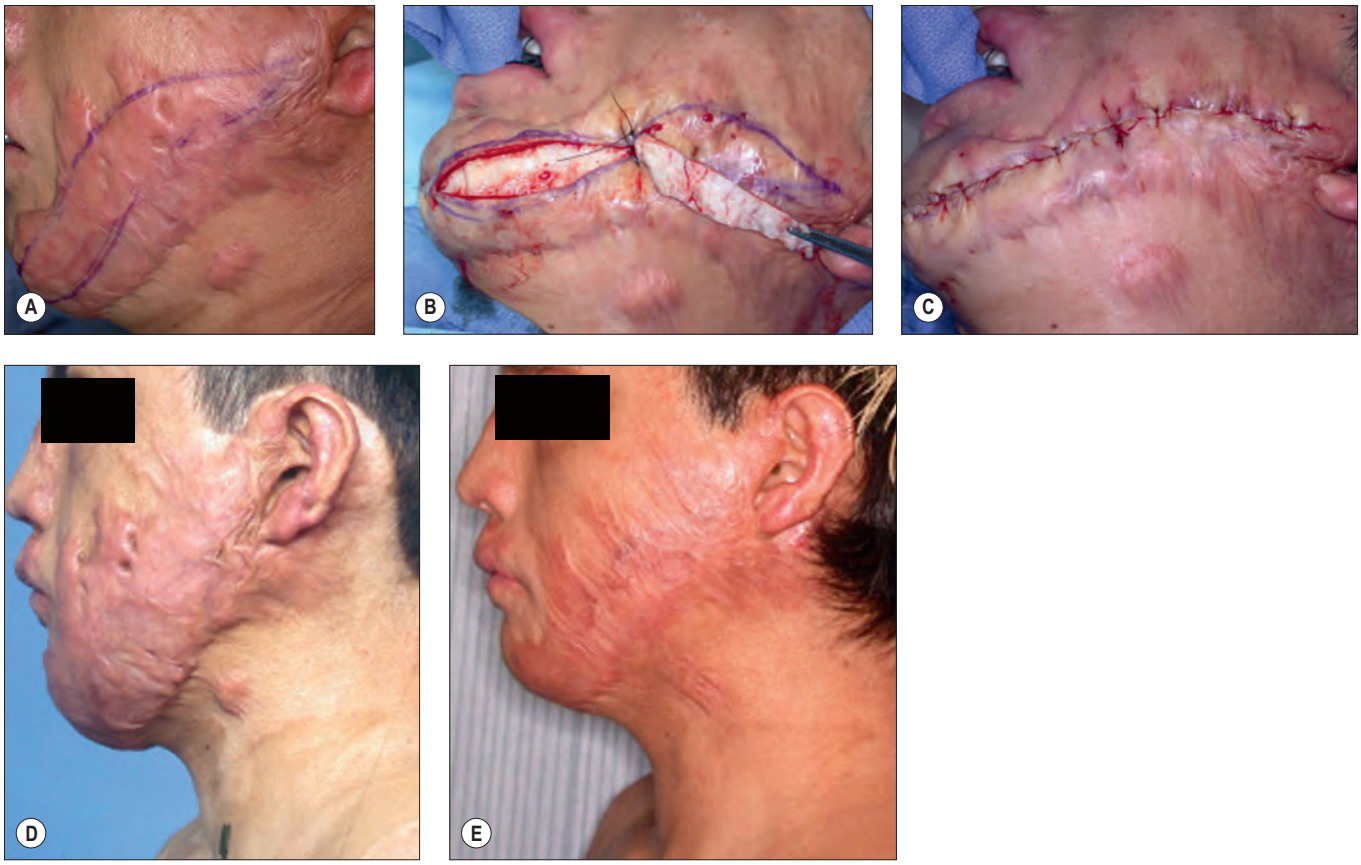

Fig. 49.6 **(A)** The scar formed in the left submental area was pruritic and unsightly. The extent of the excision was marked, and the area was infiltrated with 0.25% lidocaine containing 1 : 400,000 epinephrine to achieve hemostasis. **(B)** The epidermal layer was sharply excised, leaving the dermal layer intact. **(C)** The wound edges were closed primarily in layers using nylon sutures. **(D)** The extent and appearance of scarring noted before excision, 10 months following the initial burns. **(E)** The appearance of the operative site 5 years following partial scar removal.

THE TECHNIQUES OF RECONSTRUCTION

There are several techniques routinely used to reconstruct bodily deformities common to burn injuries (i.e., unsightly scars, scar contractures, and joint contractures). Principally they are as follows: (1) excision of scars with a primary closure technique; (2) wound closure following scar excision with grafting of a piece of free skin, with or without the use of a dermal template; (3) an adjacent skin flap technique; (4) an adjacent FC flap technique; (5) an adjacent MC flap technique, and (6) a distant skin, FC flap, or MC flap via microsurgical technique.

Primary Wound Closure Technique

Excision of an unsightly scar with layered closure of the resultant wound is the simplest and most direct approach in burn reconstruction. The margins of the scar requiring excision are first marked. It is important to determine the amount of scar tissue that can be removed, yet will allow the resultant defect to be closed directly. "Pinching" the edge of scar at three or four different sites along its length to determine the mobility of the wound edges is the simplest yet most reliable method to determine the amount of scar tissue that can be safely removed. Leaving a rim of scar tissue is generally necessary unless the scar is so small that removal and direct closure of the resultant wound would not lead to contour deformity. A circumferential incision is made along the marked line and is carried through the full thickness of the scar down to the subcutaneous fatty layer. While the outer layer of the scar tissue is excised, 4–5 mm of collagen layer is left attached to the base. The conventional approach of wedged scar excision will result in a depression along the scar excision site, an iatrogenic consequence that could be difficult to amend secondarily. To minimize interference to the vascular supply along the wound edges, the undermining of scar edge should be kept minimal. Synthetic sutures are preferred for wound closure (Fig. 49.6).

Skin Grafting Technique

Free Skin Graft Without Incorporating a Dermal Template. Covering an open wound with a piece of skin graft harvested at an uneven thickness is the conventional approach to wound closure. While the whole structure of the skin removed as an intact unit (i.e., epidermis and dermis) is defined as a full-thickness skin graft, a piece of skin cut at a thickness varying between 8/1000ths of an inch (0.196 mm) and 18/1000ths of an inch (0.441 mm) is considered to be a partial- or a split-thickness skin graft. The thickness of a full-thickness skin graft is quite variable depending on the body site. A full-thickness skin graft harvested from the back, for instance, will be 16/1000ths of an inch (4 mm) in thickness, whereas one harvested from the upper eyelid will be around 35/1000ths of an inch

(0.8 mm). The difference is attributable to the difference in the thickness of the dermis.

Although a power-driven dermatome is usually used to harvest a partial- (split-) thickness skin graft, a free hand knife can be used to cut a piece of full-thickness skin graft. A paper template may be made to determine the size of skin graft needed to close a wound. The skin graft is laid onto the wound, colloquially known as the "wound bed," and is anchored into place by suturing the graft to the wound edge-to-edge at various sites. An apposition of the skin graft with the wound bed is essential to ensure growth of the vascular network into the graft within 3–5 days and to ensure graft survival. Any mechanical barriers, such as blood clots or pools of serous or purulent fluid, will prevent the vascularizing process and lead to graft loss. A gauze or cotton bolster tied over a graft has been the traditional technique to anchor the graft and to prevent fluid from accumulating underneath it even though no objective evidence supports the efficacy of this maneuver. A quilting technique has been found to be more effective than the bolstering technique in immobilizing skin grafts and is associated with fewer morbidities (Fig. 49.7).

Free Skin Graft With Prior Incorporation of a Dermal Regenerative Template. For the past several years, artificial dermal substitutes have been manufactured from alloplastic or xenographic materials (e.g., Alloderm and Integra; the manufacturing process was initially described by Yannis and Burke in 1980). These biosynthetic, two-layered membranes are composed of a three-dimensional porous matrix of fibers and cross-linked bovine tendon and glycosaminoglycan (chondroitin-6-sulfate). When implanted over an open wound, this material forms a layer of parenchymal structures resembling a dermis, enabling wounds to be covered with an autologous skin graft when immediate closure is not possible. The need for a staged approach to wound grafting, however, is considered cumbersome (Fig. 49.8).

Skin Flap Technique

The approach of using a segment of skin with all attached structural components to restore a destroyed and/or absent bodily part follows the fundamental principle of reconstructive surgery. However, this approach will cause not only skin scarring at the flap donor site, but also a donor site contour alteration that may be considered cosmetically unsightly. Loss of a skin flap, more commonly encountered in burn patients when the vascular supplies to the skin are altered by injuries and surgical treatment, could render this technique unsuitable, if not undesirable. Despite the drawbacks, the approach to restoring a damaged bodily part with a piece of analogous tissue is technically sound, and the procedure will restore bodily function and contour. The technical innovation of incorporating a muscle and/or

Fig. 49.7 A partial-thickness skin graft was used to cover an open wound resulting from releasing of a contracted lower lip.

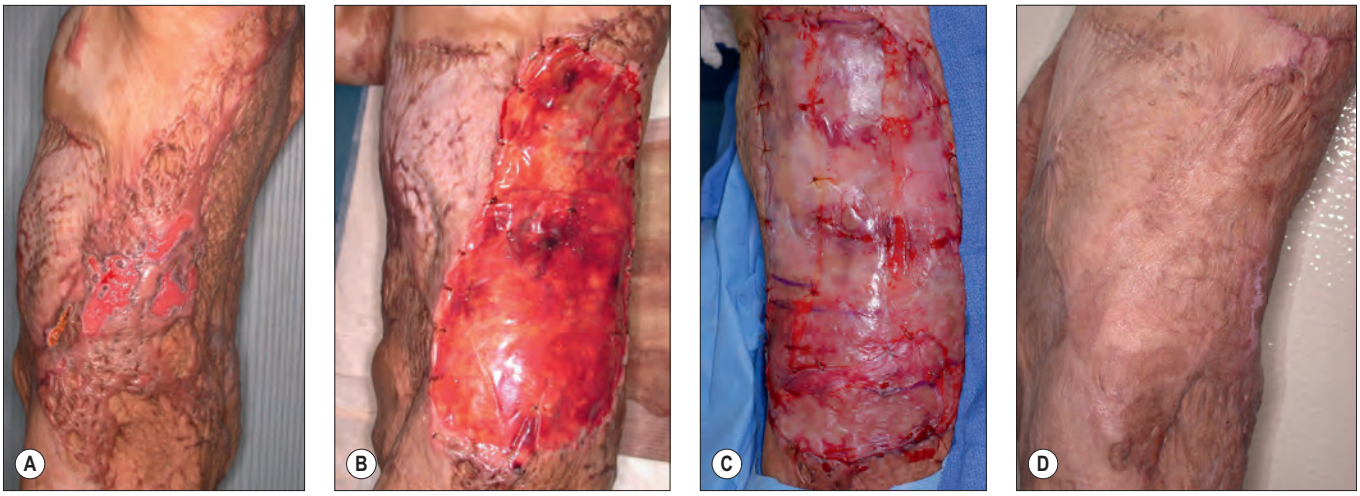

Fig. 49.8 **(A)** A 6-year-old girl bothered by recurrent infection caused by scar-embedded inclusion cysts in the left flank area that extended from the lower axilla to the upper trochanteric region. **(B)** A piece of Integra was used to cover a wound that was 25–30 cm × 10–15 cm. **(C)** The vascularized Integra-covered wound was covered with a partial-thickness skin graft of 8/1000ths of an inch in thickness 3 weeks later. **(D)** The appearance of the grafted area a year following the operation. The scar was noted to be soft and pliable.

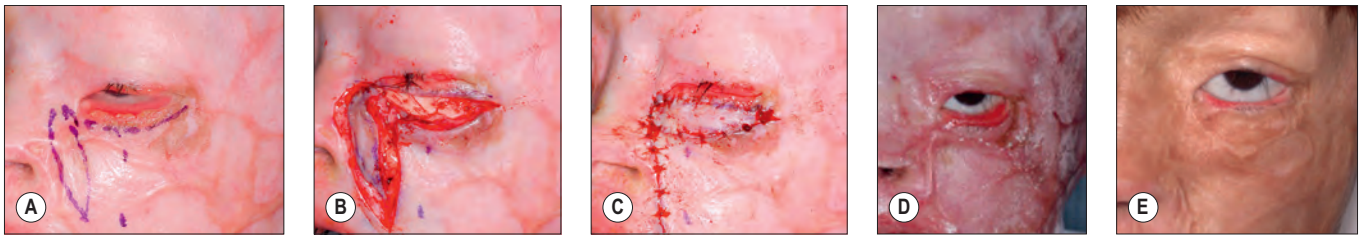

Fig. 49.9 **(A)** A triangular skin mark made over the right nasolabial area to mark an axial skin flap fabricated for left lower eyelid ectropion reconstruction. **(B)** The size of skin flap was equal to the size of the lower eyelid defect to cover an open wound that had a cartilage graft for tarsal replacement. **(C)** The triangular flap was rotated cephalad and laterally to fill the left lower eyelid tissue defect. **(D)** The left lower eyelid ectropion consequential to the loss of eyelid skin and the tarsus. **(E)** Appearance of the left lower eyelid 3 years following the reconstructive procedures.

fascial layer in skin flap design, especially in burned areas, has further expanded the scope of burn reconstruction because more burned tissues can now be used for flap fabrication.

The Axial Skin Flap. The skin in many areas is nourished directly by known cutaneous arteries. A skin flap, regardless of its length-to-width ratio requisite, may be fabricated if the vascular trees are included in the flap pattern (Fig. 49.9).

The Z-Plasty Technique. Briefly described, this technique is based on the principle of mobilizing a full segment of skin, with its vascular supplies undisturbed, from an area adjacent to the site needing tissue replacement. This is conventionally achieved by interposing two skin flaps of an equilateral triangle (i.e., 60 degrees) that has a common limb drawn along the scarred area. A scarred and contracted area is released as the flaps are interposed in an opposite direction. Any space defect due to skin and underlying tissue movement is made up by mobilizing tissues from an adjacent area (Fig. 49.10).

The Modified Z-Plasty Technique; Alias Three-Quarters Z-Plasty Technique. As in the conventional z-plasty technique, two flaps of a right-angled triangle are used. That is, one has an internal 90-degree angle, and the other has a "modified" 45-degree angle; the angle for the triangular flap has decreased from a conventional 60 degrees to 45 degrees; hence the "three-quarters" *z-plasty technique*. The limb of the 90-degree triangle is made in the scarred area resulting from the tissue loss. The second limb of the triangle is made perpendicular to the first one. The angle formed by the second limb of the right-angled triangle and the hypotenuse of the second right-angled triangle is 45 degrees. A triangular skin flap fabricated in this manner is rotated to fill a tissue defect formed from surgical release of a contracted scarred area. The procedure, in this sense, is a variant of the conventional rotational/interpositional skin flap technique in which the 45-degree triangular skin flap is singularly rotated to make up the defect (Fig. 49.11).

Musculocutaneous or Fasciocutaneous Flap Technique

Inclusion of not only the skin, but also the subcutaneous tissues, fascia, and muscle is necessary to fabricate a skin flap to reconstruct tissue defects in individuals with deep burn injuries. That is, fabricating a flap in a burned area is possible if the underlying muscle or the fascia is included in the design.

Musculocutaneous Z-Plasty Technique. While the skin pattern in this technique is identical to that in the conventional z-plasty technique, the muscle underneath must be included in the flap fabrication. Although physical characteristics of normal skin (i.e., the skin pliability and expandability) are absent if scarred skin is included in the flap design, a scarred-skin MC or FC flap can be safely elevated and transferred to close an open wound. In practice, the MC z-plasty technique is useful in neck release and in the eyelid because of the character of the underlying muscle; the platysma and orbicularis oculi muscles are thin, pliable, and easily movable (Fig. 49.12).

Fasciocutaneous Z-Plasty Technique. This is a technical modification of the MC z-plasty technique in which only the muscular fascia is included. Separation of skin and its subcutaneous tissues from the underlying fascia must be avoided to ensure that the blood supply to the flap is not impaired. In practice, the technique is useful in reconstructing contractural deformities around the knee and ankle areas.

Three-Quarter Fasciocutaneous Z-Plasty Technique. A 45-degree triangular FC flap that includes the fascial layer may be fabricated anywhere in the body. The flap is elevated and then turned 90 degrees to cover a tissue defect resulting from a released contracted wound. Although unburned skin is more versatile when used to fabricate a triangular flap, scarred skin with or without subcutaneous tissues may also be used for flap fabrication. Suturing the fascia to the skin edge is a useful maneuver to avoid accidental separation of the fascia from the overlying skin and interrupting vascular supply to dermal structures (Fig. 49.13).

Paratenon Cutaneous Z-Plasty and Three-Quarter Paratenon Cutaneous Z-Plasty Techniques. In instances where fabrication of a composite skin flap is indicated in the distal section of the upper and lower extremities (i.e., wrist and ankle), the paratenon, a fascial extension of the voluntary musculatures, should be included in the flap design and fabrication (Fig. 49.14).

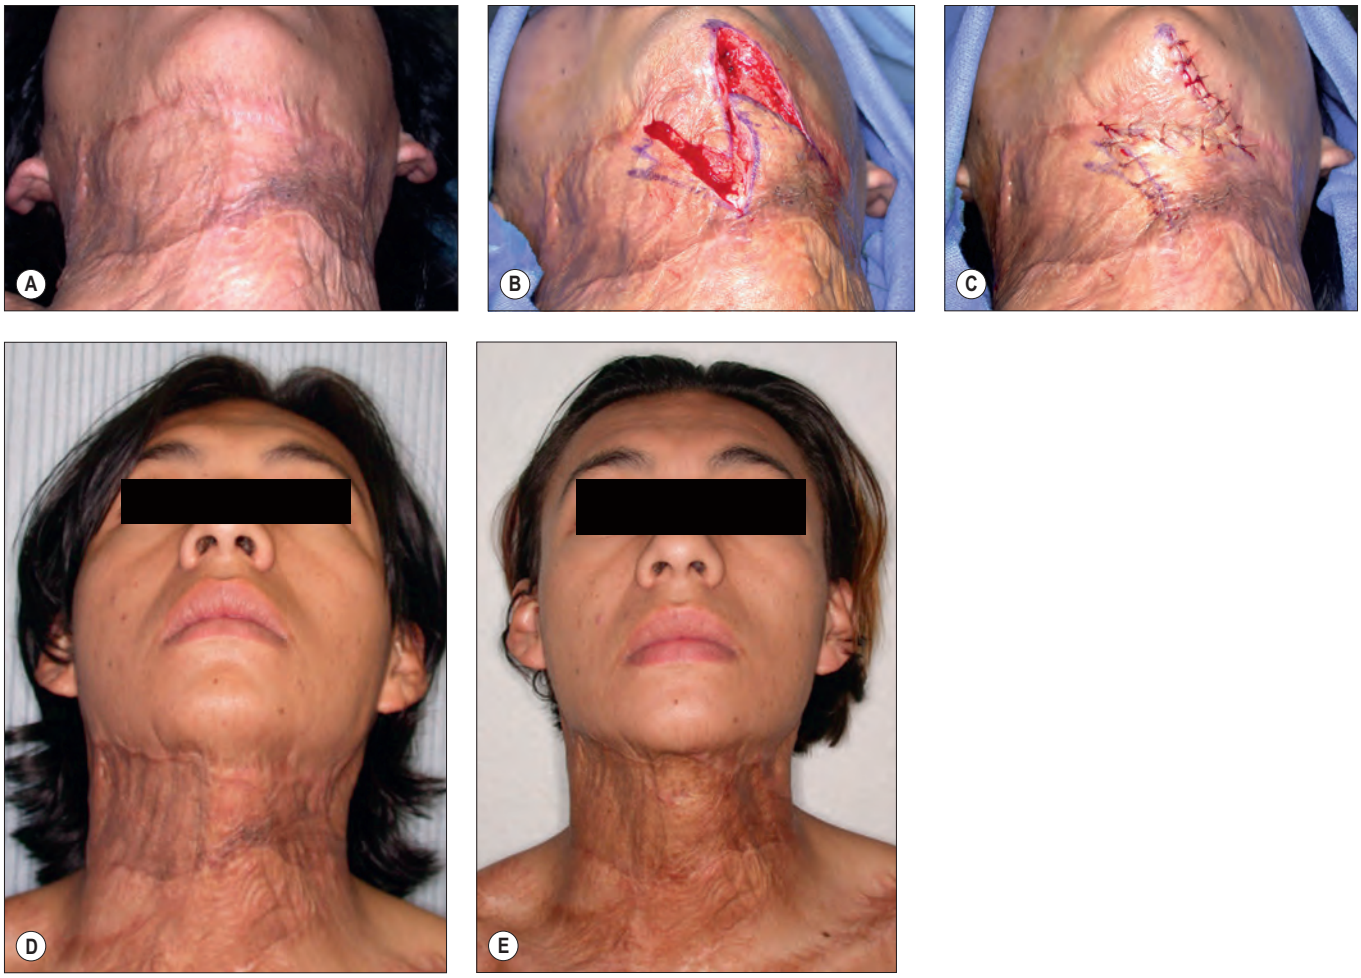

Fig. 49.10 **(A)** Neck scar. **(B)** Two equilateral triangles were marked into a "z" and incisions were made to free up two triangular skin flaps. **(C)** Two flaps were interposed to achieve the release. **(D)** Before release, the patient, a 13-year-old boy, complained of tightness over the neck area caused by a tight scar band. **(E)** The appearance of the neck 4 years following releasing procedures. The z-plasty procedure alleviated the neck tightness.

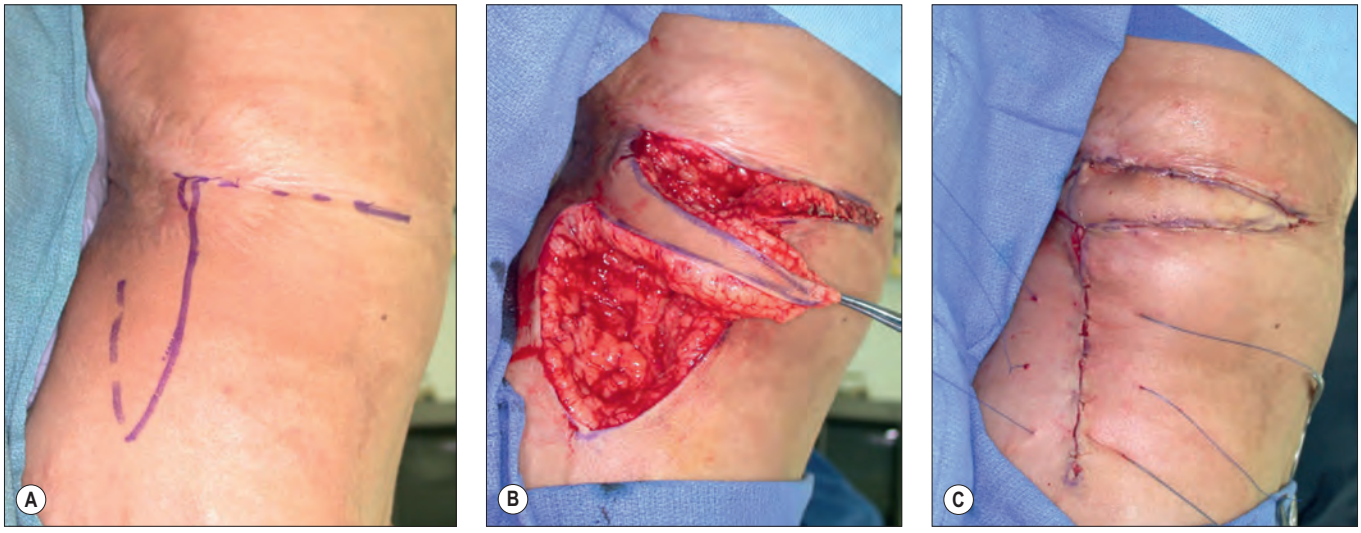

Fig. 49.11 **(A)** A horizontal line was drawn along the site of tightness. A triangular skin marking was also drawn with its cathetus perpendicular to the line of release. **(B)** The triangular flap was rotated cephalad and medialward to make up the wound defect that resulted from release. **(C)** The flap donor site closure as well as the inset of flap was achieved primarily.

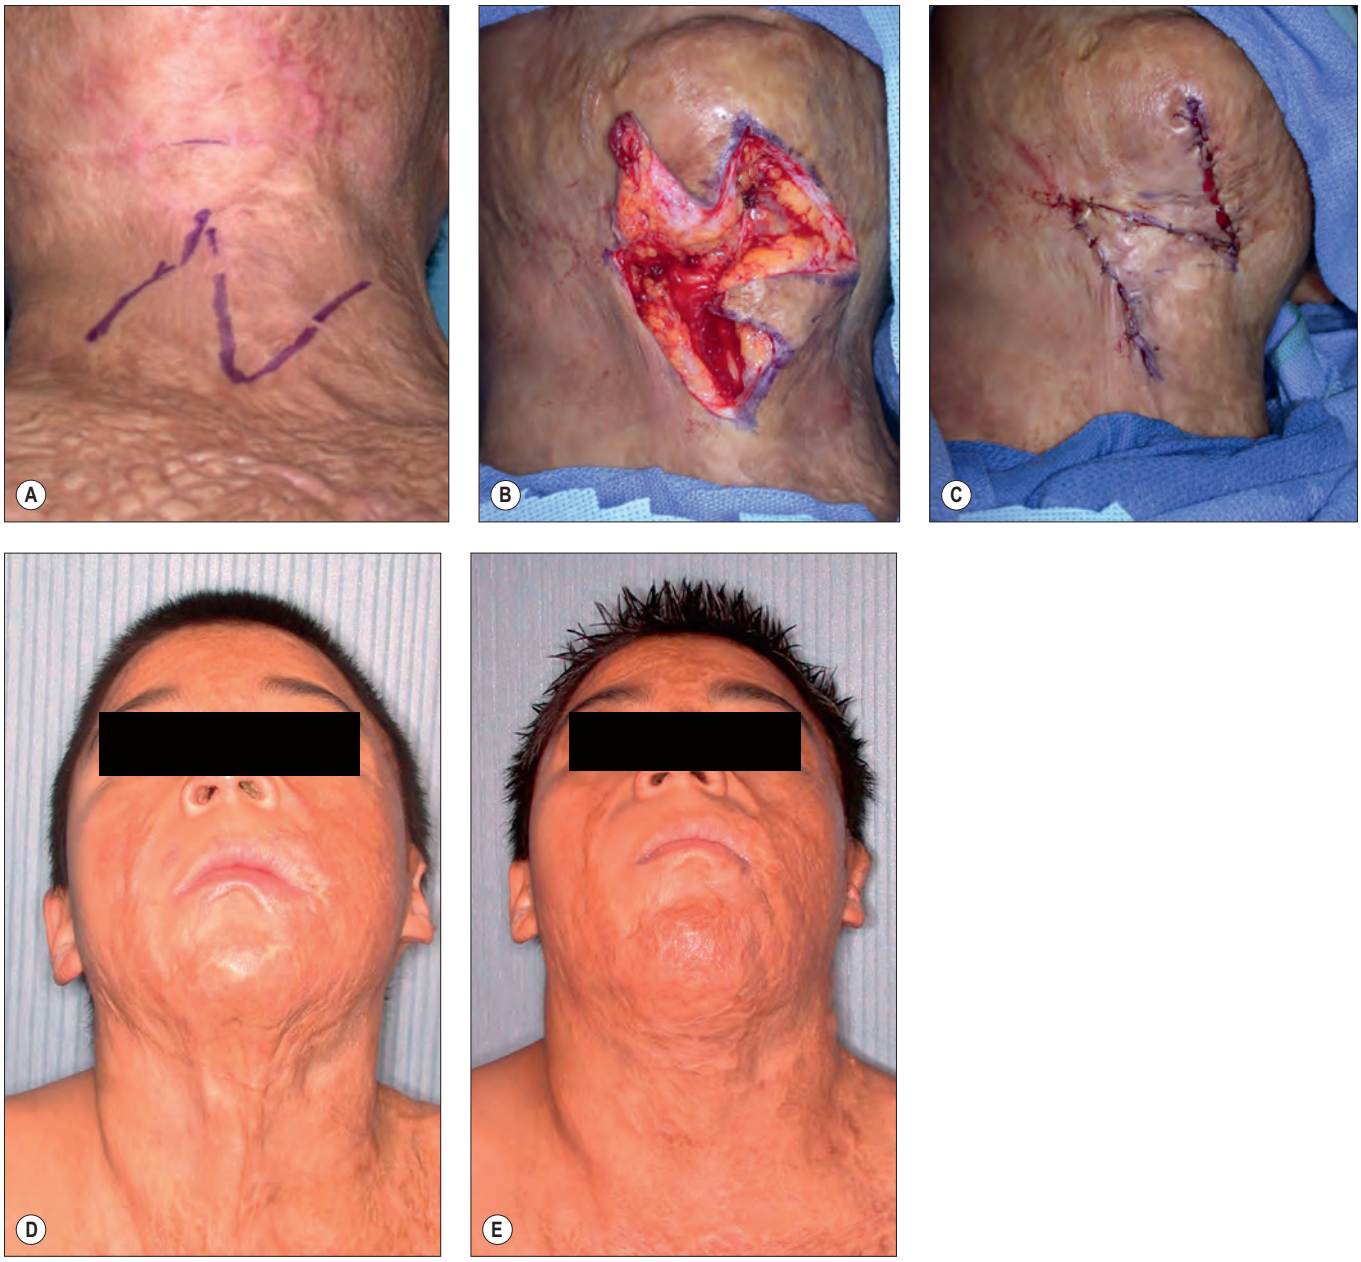

Fig. 49.12 **(A)** Two equilateral triangles were marked into a "z." **(B)** Incisions were made to free up two triangular skin flaps that included the platysmal musculatures underneath. **(C)** Two flaps were interposed to achieve the release. **(D)** Before release, the patient, a 9-year-old boy, complained of tightness over the neck area caused by a tight scar band. **(E)** The appearance of neck 4 years following releasing procedures. The z-plasty procedure alleviated the neck tightness.

Tissue Expansion Technique

An extreme stretching of the integument is quite commonly observed in human bodies. The tissue expansion technique follows the same principle, except it is carried out intentionally with an inflatable device, known as a *tissue expander*. Because excessively active scarring processes are frequently seen after burns, especially during the period immediately following the accident, choosing a time to initiate the procedure is difficult. Use may be limited because of pain and discomfort associated with expansion (Fig. 49.15).

Free Composite Tissue Transfer via Microsurgical Technique

With the advent of microsurgical techniques, transplantation of a composite tissue can now be carried out with minimal morbidities. However, opportunities for using this approach may be limited in burn care because of a paucity of donor materials. It is ironic that burn patients with suitable donor sites seldom require such elaborate treatment. Those who are in need of microsurgical tissue transplantation are inevitably those with no appropriate donor sites because of extensive tissue destruction.

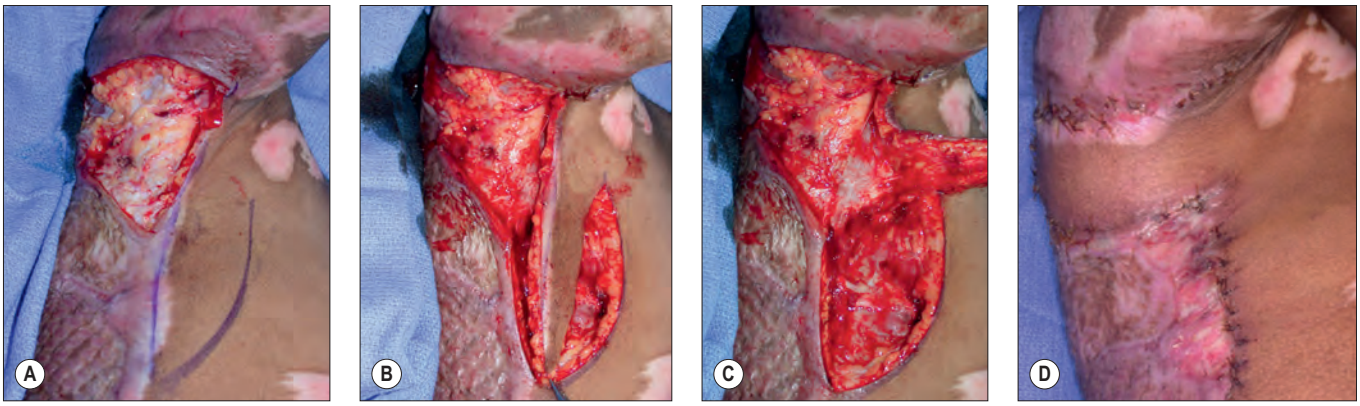

Fig. 49.13 **(A)** A triangular skin marking was made with its cathetus drawn along the line of contracture and perpendicular to the inferior wound edge resulting from the release. **(B)** Incisions were made along the skin marking for flap fabrication. **(C)** The triangular skin flap was elevated to include the fascial layer to form a random fasciocutaneous flap. **(D)** The appearance of flap and the wound 10 days following the release and flap reconstruction.

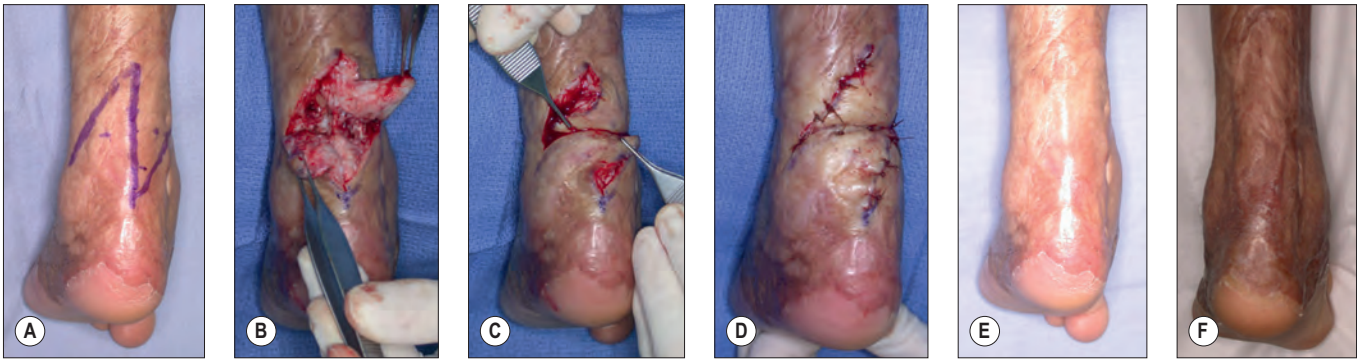

Fig. 49.14 **(A)** Two equilateral triangles were marked over the left heel cord, the area felt to be tight. **(B)** The skin flap was fabricated to include the fascial layer underneath. **(C)** Two fasciocutaneous flaps were interposed to achieve the release. **(D)** The inset of two flaps completed. **(E)** The appearance of left heel cord before release. **(F)** The appearance of left heel cord 4 years following release.

Fig. 49.15 **(A)** A 4-year-old patient with scalp alopecia resulting from extensive burns involving the scalp and the face area. **(B)** No attempt was made to reconstruct the scalp alopecia until she was 8 years of age. The tissue expander technique was used to expand the left side of the scalp for wound coverage. **(C)** The appearance of right temporal scalp following two scalp expansion-advancement procedures.

Fat Grafting Technique

Recently the use of subcutaneous fat has been gaining popularity as a tool to increase postburn wound healing and reduce scarring.[7] The fat is usually harvested by lipoaspiration. Current research is focused on several approaches that can be taken to use fat as a source of stem cells or as an additional layer between the wound and skin graft. Fat can be sprayed directly onto the wound site, transferred with dermal replacements onto the wound, or directly injected into scars to make them smother. Further prospective clinical trials are warranted to prove the safety and efficacy of fat grafting in burn patients.

Allotransplantation: Facial Transplantation

The face may be the most challenging area to reconstruct after burns. Every face is unique and matches each personality. Moreover, facial expressions are important parts of daily conversations and interactions between people. Hence composite tissue transplantation and face transplantation are more topical than ever. In 2009, Lantieri[8] performed the first face transplant in a burn patient. Unfortunately, the patient died during the recovery phase from severe infection and heart failure. The same group recently published long-term results on patients who received facial transplantations; not all were burn patients, but they showed that careful preoperative patient selection and strict local as well as institutional regulations are needed to improve outcomes following composite tissue transplantation and face transplantation.[8]

Comments

Burn treatment regimens have changed drastically over the past 60 years, and a more aggressive approach in managing burned wounds was adopted in the 1980s. Early debridement and wound coverage initially with biological dressing and later with autologous skin grafts has enhanced the survival rate. Ironically this improved survival has caused an upsurge in patients needing reconstruction: everyone now surviving burns is in need of reconstruction, functional or otherwise.

Unsightly hypertrophic scars, scar contractures (particularly those affecting the joint structures), and destroyed body parts are still the most common sequelae of burn injuries. Although the use of skin grafting and skin flaps has remained a mainstay of burn reconstruction, the outcomes can still be suboptimal because the techniques cannot correct the three above-mentioned problems.

The exact time at which to initiate reconstruction of burn deformities remains unsettled. Difficulty in obtaining suitable tissues for replacement, morbidities associated with surgical procedures that involve tissues with active scarring processes, and outcomes that cannot be assured may account for the controversy. Novel approaches using adipose-derived stem cells and other cultured cells may open new avenues, but the safety of these techniques must be proved in daily clinical practice. On the other hand, flap techniques, particularly the three-quarter FC z-plasty and three-quarter paratenon cutaneous z-plasty, are established approaches that enable reconstruction of contractural deformities involving the major joints as well as eyelid deformities as early as 4–6 months following the injury.

Although many questions remain concerning the ideal approach in managing burn deformities, the science of regenerative medicine and tissue engineering, which includes bionic prostheses, could lead to the formation of body parts that could be used to replace absent or destroyed body components.

50 Reconstruction of the Head and Neck after Burns

MATTHIAS B. DONELAN and BRANKO BOJOVIC

Introduction

Reconstruction of the head and neck[1] following burn injuries presents great challenges and great opportunities. Successful treatment requires sound surgical judgment and technical expertise, as well as a thorough understanding of the pathophysiology of the burn wound and contractures. Many disciplines are required to successfully care for patients with burns of the head and neck. These include skilled nursing, experienced occupational and physical therapy, and psychological and social support systems. The surgeon must also have familiarity and expertise with nonsurgical treatment modalities such as pressure therapy, steroids, and laser therapy. Realistic expectations on the part of both patients and surgeons are essential to achieve successful treatment outcomes. Burns to the head and neck of a serious nature result in tissue injury with scarring, and complete removal of scars is not possible. A scar can only be modified or exchanged for another scar or tissue of a different variety. Despite this fundamental limitation, reconstruction of the burned face and neck creates great opportunities for plastic surgery to significantly improve functional and aesthetic deformities resulting in profound improvement for this large group of challenging patients.

Recent advances in technology and improved understanding of wound-healing physiology are transforming the ways we should look at, and think about, burn scars and contractures. This change in perspective is particularly important in the head and neck because normal appearance and normal function in this area are of paramount importance. The presence of visible scarring and even minimally grotesque deformity is particularly debilitating in the face and neck. Since the early 20th century and the brilliant work of Sir Harold Gillies reconstructing facial deformities with tubed pedicle flaps, scar excision in the head and neck and replacement with flap tissue, either from regional or distant donor sites, has dominated facial burn reconstruction thinking. This was further popularized by the concept of aesthetic unit scar excision coupled with ever-improving surgical ability to transplant tissue. It is time to rethink this paradigm. It is now possible to dramatically rehabilitate hypertrophic and contracted scars on the face and neck to the point where the scars are often the patient's best reconstructive anatomy. That is because the scars are autologous, in the right location, and the closest match to normal because they are the "original equipment." Excision and replacement of facial scars creates iatrogenic donor sites and requires extensive surgery to replace the scars with uninjured tissue from other areas of the patient's body. This surgery is typically complex and morbid with potentially severe complications. Scar rehabilitation is minimally morbid and has few complications. The secrets to success with scar rehabilitation in the head and neck are accurate early diagnosis, conservative management, and the effective use of new technologies and treatments to enable patients to reap the maximum benefit from their own amazing wound-healing and scar remodeling capabilities (Fig. 50.1). This new approach will be discussed in this chapter along with more traditional methods of reconstruction in the head and neck.

Burn injuries constrict and deform the face; distorting its features, proportions, and expression.[1] Burns also alter the surface of the facial mask by causing scars and altering texture and pigmentation. The changes to the surface of the skin are deforming but are much less important to facial appearance than are the changes in proportion, features, and expression. The removal of scars *should not* be the primary goal of facial burn reconstruction. A normal-looking face with scars is always better looking than an even slightly grotesque looking face with fewer scars. Mature scars that result from burn injury will often be less conspicuous than surgically created scars after excision or surgically transferred flaps or grafts. The subtle and gradual transition between unburned skin and burn scar is an excellent example of nature's camouflage and can render scarring remarkably inconspicuous. New techniques of scar rehabilitation using lasers and carefully crafted, minimally morbid surgery helps scars blend even better. The principal goal of facial burn reconstruction should be the restoration of a pleasing and tension-free facial appearance with appropriate animation and expression.[2] If this goal is kept in mind and is pursued with persistence and determination, the amount of improvement that can result after severe facial burn injury can be remarkable. Ignoring this basic principle can result in iatrogenic catastrophes during reconstructive surgery of the head and neck following burns.

Successful reconstruction of burn deformities of the head and neck requires a well-functioning and extensive team.[3] Major burn deformities in this area can easily be intimidating and overwhelming. Experience and a specialized infrastructure are required to take care of these patients comfortably and successfully. Familiarity with their unique problems and a firm commitment to correcting their challenging deformities is required from all members of the reconstructive team. The care of a patient from the onset of a major burn involving the head and neck to a successful reconstructive outcome requires skill, patience, determination, and enthusiasm from all who are involved.

Fig. 50.1 (A,B) A 9-year-old boy from the Dominican Republic 2.5 years after 30% flame burns with severe hypertrophic scars and contractures. His chin was attached to his chest, and he had an axillary contracture that had been open for a year. **(C,D)** Five years later, after four Z-plasty procedures, six fractional ablative laser treatments, and one small split-thickness graft to the base of his right neck, his appearance and function are very close to normal. No scar tissue has been excised.

Acute Management

Although the main focus of this chapter is the reconstruction of established facial burn deformities, an understanding of the acute care of facial burn injuries is necessary in order for the surgeon to have an accurate perspective. Excision and grafting of deep second-degree and full-thickness burns has become the standard of care since it was first proposed in 1947.[4–6] It remains controversial whether this is the optimal treatment for facial burn injuries. Early excision and grafting of the face is problematic because of difficulty in diagnosing the depth of the facial burn and accurately predicting an individual patient's long-term prognosis both functionally and aesthetically. Laser Doppler imaging is a validated way to improve diagnosis in these difficult cases and can decrease the risk of overly aggressive excision. Preventing unnecessary early excision is particularly important with current improved techniques to rehabilitate hypertrophic scars. The overwhelming majority of facial burns treated conservatively with a moist regimen of topical antibiotics will heal within 3 weeks. Burns that are clearly full-thickness are best treated by early excision and grafting within 7–10 days to promote early wound closure and minimize contractile forces (Fig. 50.2). The problem cases are those where healing has not occurred by 3–4 weeks or longer. Early tangential excision and grafting has been proposed for these patients in order to achieve more favorable healing with less eventual contracture deformities.[7] Proponents of conservative therapy argue that early excision and grafting may result in a patient with a grafted face who would otherwise have healed favorably by successfully epithelializing their partial-thickness burn from skin appendages.[8] Conservative management has been facilitated by the

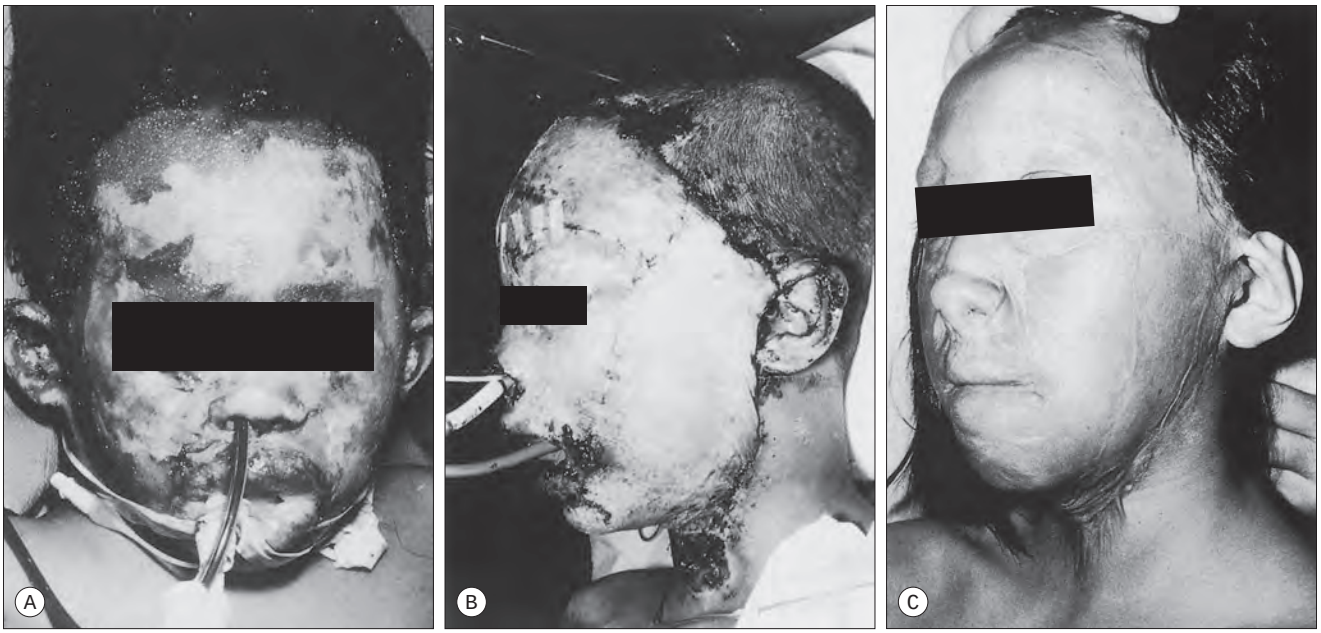

Fig. 50.2 **(A)** A 5-year-old Native American girl, 3 days after deep second- and third-degree burns to her face. **(B)** Tangential excision and split-thickness autografting were performed on the 10th postburn day. **(C)** Five years after facial excision and grafting. She has had a subsequent nasal reconstruction.

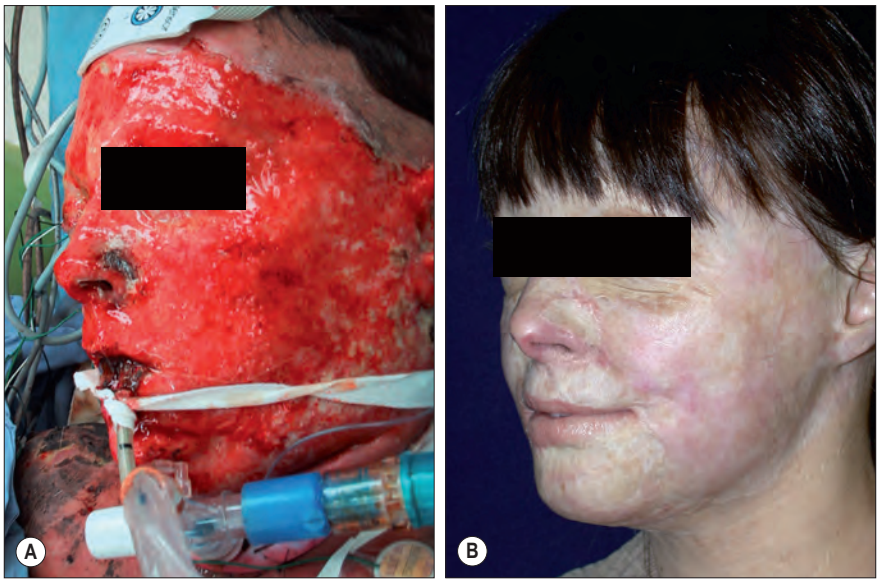

Fig. 50.3 **(A)** Ungrafted facial burn injury 30 days following 85% burn in a 34-year-old electrician. Wound closure was obtained with split-thickness grafts at 5 weeks. **(B)** Four years following burn injury. Lower lids and alar lobules have been released and grafted.

myriad ancillary techniques currently available to favorably influence the healing of facial burns such as pressure, silicone, silicone-lined computer-generated facemasks, topical and intralesional steroids, vitamin E, massage, and treatment with pulsed dye lasers (PDLs) and ablative fractional CO_2 lasers. Impressive results have been obtained by advocates for early excision and grafting.[9] Very good outcomes, however, can also be achieved by being more conservative with this difficult group of patients (Fig. 50.3). The benefits in appearance and function of rehabilitated scars over early excision and grafting are dramatically demonstrated by the patients and accompanying videos in Figs. 50.4 and 50.5. Committing a patient to a grafted face should only be done when it is clearly the best alternative. The majority of acute facial burns are treated conservatively in most burn centers, with early excision and grafting limited to those cases where it is clear that a full-thickness burn injury has occurred.

Pathogenesis

Superficial-thickness, second-degree burns usually heal without scarring or pigmentary changes. Medium-thickness, second-degree burns that epithelialize in 10–14 days usually heal without scarring, although there can be

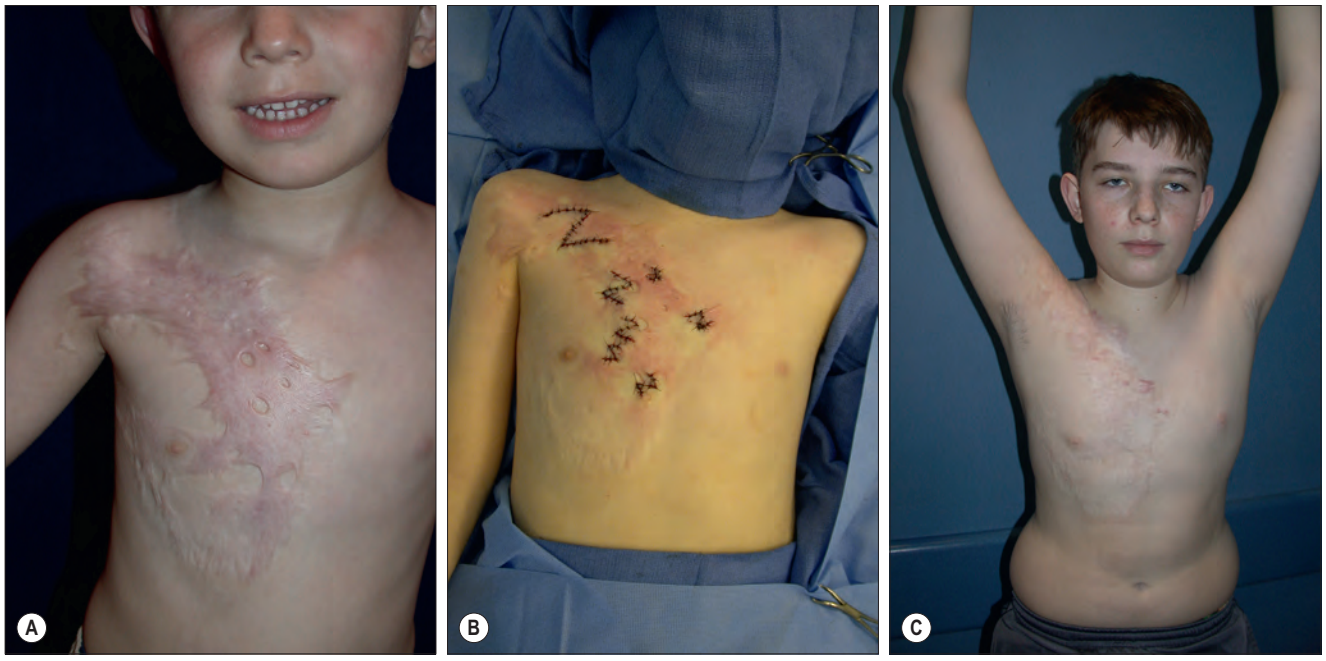

Fig. 50.4 (A) Four-year-old male 2 years after a mixed second- and third-degree scald burn from hot coffee. Parents refused excision and grafting. Scars are hypertrophic and inelastic with a significant contracture across the deltopectoral groove. **(B)** Multiple Z-plasties separated the scars into smaller, discreet areas with focal reductions in tension. Pulsed dye laser therapy was initiated at his first Z-plasty procedure. **(C)** Seven years later, after two small Z-plasty procedures and 21 laser treatments using both pulsed dye laser and fractional ablative CO_2, his chest scars are flat, soft, thin, inconspicuous, and elastic. **(D)** Video demonstrating the function of the scars after treatment.

Fig. 50.5 (A) Eighteen-month-old female after a hot liquid scald burn following excision and grafting 2 weeks following the injury. **(B)** Appearance of the skin grafts at age 12. **(C)** Appearance of the grafts after 8 treatments with the fractional ablative CO_2 laser. **(D)** Video demonstrating the function of the grafts after treatment.

Fig. 50.6 **(A)** One month following a flash burn, the right cheek is epithelialized. **(B)** Ten months later, there is massive hypertrophy despite conservative therapy with pressure.

long-term changes in skin texture and pigmentation. Deep-thickness, second-degree burns that epithelialize after 21 days or longer are unpredictable and must be carefully managed because they have a propensity to develop severe late hypertrophic scarring (Fig. 50.6). These patients should be closely monitored after initial healing and, at the first sign of hypertrophy, must be managed with all available ancillary treatment modalities. Pressure garments have been shown over several decades to be effective in suppressing and reversing hypertrophic scarring. Adding silicone to pressure therapy seems to increase its efficacy. Computer-generated clear face masks lined with silicone have improved the ability to deliver pressure to facial hypertrophic scars and are better tolerated by patients (Fig. 50.7). The vascular-specific PDL decreases hyperemia and seems to diminish hypertrophy. When tension plays a role in the development of early hypertrophic scarring, relief of the tension with either focal Z-plasty or judicious release and grafting can be very helpful. Ablative fractional CO_2 laser therapy can be used to decrease tension and also deliver corticosteroids into the hypertrophic scars with encouraging results. Definite full-thickness facial burns should usually be excised and grafted unless focal and small.

Fig. 50.7 Computer-generated clear silicone-lined masks are well tolerated and more efficacious than previous devices.

Evaluation of Facial Burn Deformities

Facial burn reconstruction should be based on an overall strategy and a clear understanding of the fundamental problems. Many reconstructive techniques have been described in the literature and can result in improvement if the strategic goals are appropriate.[10–12] The new era of scar rehabilitation has changed older strategies, and where this will eventuate is unclear at this time. It seems likely that scar excision and replacement with other parts of the patient's body will be less common in the future. The best reconstructive plan for the facial scar tissue will be scar rehabilitation using all available modalities to preserve its unique advantages as much as possible. Improved outcomes will be achieved with a judicious combination of contracture releases by Z-plasty, grafts, and flaps, followed by appropriate scar revision and laser therapy. Laser therapy *preceding* scar revision improves scar quality and facilitates surgery. Extensive scar excisions in aesthetic units and replacement

Fig. 50.8 **(A)** Three weeks following a deep second-degree burn with essentially normal facial features and proportions. **(B)** Six months later, contraction and hypertrophy have created facial burn stigmata.

Box 50.1 Stigmata of Facial Burns

- Short retruded upper lip
- Lower lip eversion
- Lower lip inferior displacement
- Flat facial features
- Loss of jawline definition

Box 50.2 Facial Burn Categories

Type I
Essentially normal facies with focal or diffuse burn scarring with or without contractures

Type II
Pan-facial burn deformities with some or all of the stigmata of facial burns

with microvascular free tissue transfer from distant sites will likely become less frequent. The role of face transplantation in burn reconstruction of the head and neck is unclear at this time.

Deep second- and third-degree burns heal by contraction and epithelialization. The more severe the burn injury, the more contraction takes place during the healing process. The changes in facial appearance following a deep second-degree burn injury are dramatically demonstrated in Fig. 50.8. Three weeks following a deep second-degree burn, the patient's facial features and proportions remain essentially normal. Six months later, contractile forces have deformed the facies in a pattern that is repeated to a variable degree in virtually all severe facial burns. These changes make up the stigmata of facial burn injury and are listed in Box 50.1. The eyelids are distorted with ectropion, the nose is foreshortened with ala flaring, the upper lip is shortened and retruded with loss of philtral contour, the lower lip is everted and inferiorly displaced, the lower lip is wider than the upper lip in anterior view. The tissues of the face and neck are drawn into the same plane with loss of jawline definition. The severity of these changes is proportional to the severity of the injury.

Fortunately the majority of facial burn injuries are not severe and do not involve the entire face. A relatively small number of patients sustain injuries that deeply involve the entire face, such as shown in Fig. 50.8. It can be helpful to separate patients with facial burn deformities into two fundamentally different categories, as described in Box 50.2. Type I deformities consist of essentially normal faces that have focal or diffuse scarring from their burns and may have associated contractures. Type II deformities make up a much smaller number of patients who have "pan-facial" burn deformities with some or even all of the facial burn stigmata. Although these categories are not rigidly defined, and there are some patients who do not fit neatly into one or the other, understanding the fundamental difference between these two groups of patients can help define treatment goals. It can also aid in selecting the most appropriate methods for reconstructive surgery.

Patients with type I deformities have an essentially normal facial appearance despite scars from their burns. In these patients, one must be certain that surgical intervention does not adversely alter normal facial features or create distortion from iatrogenically induced tension. Overall facial appearance should not be sacrificed in an effort to "excise scars" (Fig. 50.9). The best reconstructive options today for patients with type I facial burn deformities are

Fig. 50.9 **(A)** Five-year-old male with normal facial appearance and focal hypertrophic scarring without contractures. **(B)** After serial scar excision, he has a grotesque facial deformity from an extrinsic contracture. **(C)** Twelve-year-old female with a normal facial appearance and mildly erythematous, hypertrophic scarring. There was great pressure from patient and family to "remove scars." **(D)** After scar excision and cervicopectoral flap transposition she has a sad facial expression and loss of jaw line definition.

laser therapy combined with scar release and revision with Z-plasties when indicated or tissue rearrangement with local flaps. The PDL was the first laser to have demonstrated efficacy in the treatment of hypertrophic and contracted facial burn scars[13] and can be helpful for decreasing post-burn erythema and treating persistently erythematous burn scars. Z-plasties in combination with the PDL can be a powerful scar-improving combination[14] (Fig. 50.10). Full-thickness skin grafts are excellent for focal contractures. Excision of scars and resurfacing operations in aesthetic units and major flap transpositions, with or without tissue expansion, are rarely indicated.

The much less frequently encountered group of patients with type II facial burn deformities presents a completely different clinical situation. Examples of patients falling into the type II category are shown in Fig. 50.11. The surgical goals for this group of patients should be the restoration of normal facial proportion and, as much as possible, the restoration of the position and shape of normal facial features. The intrinsic and extrinsic contractures that exist in these patients require large amounts of skin. The correction of these contractures should be carried out in a carefully planned and staged fashion. The best sequence of operations is usually the following: eyelids, lower lip and chin, upper lip, cheeks, nose, and then other residual deformities. As each area is reconstructed, the addition of skin results in the relief of tension, which benefits other areas of the face. Excision of normal skin or elastic healed second-degree burned skin is almost *never* indicated. After facial proportion has been achieved and facial features have been

Fig. 50.10 **(A)** Hypertrophic scarring of both cheeks, lips, and chin 6 months following flame burn. **(B)** Multiple Z-plasties release tension on facial scars. **(C)** Pulsed-dye laser therapy can be used to decrease erythema. **(D)** Improved appearance 3 years following burn. No scars have been excised.

Fig. 50.12 (A,B) A 29-year-old firefighter with "pan-facial" burn deformity causing facial burn stigmata. **(C,D)** Seven years later, following the reconstructive sequence outlined in the text. Facial features and proportion have been restored. Note philtral reconstruction with composite graft from ear triangular fossa.

restored to their normal location and shape without tension, scar revision can be carried out to smooth and blend the remaining junctional scars (Fig. 50.12).

Normal faces are a mosaic of colors, textures, wrinkles, and irregularities. In a face that has undergone major burn injury, a mosaic appearance of scars, grafts, pigmentary abnormalities, and other flaws can be attractive as long as the facial features are restored to a normal location and are sufficiently loose and mobile for normal and appropriate facial expression. Laser therapy with vascular and fractional ablative CO_2 devices further blends, obscures, thins, and softens scars, enhancing facial expression and a more natural appearance (Fig. 50.13). Cosmetics can be useful for blending and camouflaging areas of pigmentary and textural abnormality, particularly in females.

Fundamental Principles and Techniques

CONTRACTURES

Burn injuries result in open wounds that either heal by contraction and epithelialization or are closed by skin grafting. Contractures result from both of these forms of wound healing. Contractures are either intrinsic or extrinsic. Intrinsic contractures result from loss of tissue in the injured area with subsequent distortion of the involved anatomic part. Extrinsic contractures are those in which the loss of tissue is at a distance from the affected area but the distorted structures, such as eyelids or lips, are not injured themselves.

Fig. 50.13 (A,B) Eleven-year-old female from Kosovo 18 months after a flash burn to her face with diffuse, erythematous, ulcerated, contracted, and hypertrophic scars. **(C)** Z-plasties separate broad areas of scarring, relieving tension, and immediately flattening and improving the appearance of the scars. **(D,E)** Six years later, after three additional small Z-plasty procedures performed at the same time as laser treatments. She has only had a total of nine pulsed dye laser treatments and six ablative fractional laser treatments because she lives in Kosovo. No scars were excised.

Corrective measures should be directed at the cause of the contracture in order to provide optimal benefit and prevent iatrogenic deformities. It is helpful to minimize the amount of skin and scar excised when correcting facial contractures. When tension is released, many scars will mature favorably and become inconspicuous. Even long-standing scars will respond to a change in their environment. Healed second-degree burns under tension may be unattractive but when restored to a tension-free state can be superior in function and appearance to any replacement tissue. Minimizing excision also decreases the amount of new skin that must be provided in the reconstruction. Every effort should be made to relieve tension from the face when performing burn reconstruction. Tight faces are never attractive. Tight scars are always hypertrophic and erythematous. Relaxed scars are happy scars. The fractional ablative laser has created a new paradigm for the management of tight, hypertrophic, erythematous, and even ulcerated pan-facial scarring with contractures. It is a clearly more powerful and efficacious treatment modality than the PDL. The patient shown in Fig. 50.13 is a perfect example of this beneficial change in the management of facial burn scars. Her scars were more diffuse and severe than those of the patients shown in Fig. 50.9 who were severely deformed by scar excision surgery. Her face is essentially normal after the rehabilitation of her "original equipment."

AESTHETIC UNITS

The concept of facial aesthetic units has profoundly affected plastic surgical thinking since its introduction by Gonzalez-Ulloa.[15] Initially conceived as the ideal approach for resurfacing the face following burn injury, this important concept has been emphasized in virtually all subsequent writings about facial burns. It is important to keep facial aesthetic units in mind during burn reconstruction, but the desire to adhere to this concept should not supersede common sense. When small, unburned, and unimportant islands of skin are in an aesthetic unit that is being resurfaced, they can be sacrificed. Otherwise the excision of normal facial skin is rarely indicated in burn reconstruction. All burned faces to some degree are mosaic. Scar revision with Z-plasties is an excellent technique to camouflage scars in a burned face. Mosaic faces that are proportional, tension free, and normally expressive appear much better in real life than they do in images. Lasers, as noted previously, also aid in obscuring marginal scars and add to the camouflage effect.

Z-PLASTY

The Z-plasty operation is a powerful tool in the surgeon's armamentarium for facial burn reconstruction. The Z-plasty has been used for more than 150 years to lengthen linear scars by recruiting lax adjacent lateral tissue.[16] Z-plasty can also cause a profound beneficial influence on the physiology of scar tissue when it is carried out within the scarred tissues rather than after excising them.[17] The physiology of this phenomenon is related to the immediate and continuing breakdown of collagen that occurs in hypertrophic scars following the relief of tension.[18–20] Z-plasty also narrows scars at the same time that it lengthens them. In addition, the Z-plasty adds to scar camouflage by making the borders of the scar more irregular. In order for Z-plasties to lengthen a burn scar and restore elasticity, the lateral limbs of the Z-plasty must extend beyond the margins of the scar. The improvement in the appearance of facial scars following Z-plasty and without any scar excision can be dramatic, particularly when combined with PDLs and fractional ablative laser treatments (Figs. 50.1, 50.10, 50.13, 50.19).

LASER THERAPY

Hypertrophic scarring is a frequent complication after partial-thickness facial burn injuries that take longer than 3 weeks to completely epithelialize.[21] Despite conservative management and close monitoring, hypertrophic scarring can become severe during the first 2 years after the burn (Fig. 50.6).[22–24] The PDL has emerged as a successful treatment modality during this period of scar proliferation and is an effective alternative to scar excision in patients with hypertrophic facial burn scars.[14,25] Multiple studies have demonstrated its beneficial effect on scar erythema and hypertrophy.[26–30] The PDL also rapidly decreases pruritus and pain[26,27] and provides an additional, low-morbidity therapeutic intervention for patients and their families during the often prolonged period of scar maturation. Restoration of hypertrophic facial scars to their previous state of a flat, epithelialized surface is a superior outcome to surgical excision with its concomitant increase in facial tension.[14] The development of fractional ablative and nonablative laser therapy using various types of lasers, including CO_2 and erbium-YAG, offers promising new options for the management of facial burn scars in the future.[31]

GRAFTS

Skin grafts are an essential part of facial burn reconstruction. Surgical decisions regarding donor site selection, the use of split-thickness versus full-thickness grafts, the timing of intervention, and the postoperative management of grafts often determine the success or failure of facial burn reconstruction. Split-thickness skin grafts contract more than full-thickness grafts, wrinkle more, and always remain shiny, with a "glossy finish" look. Split-thickness skin grafts should be used primarily in the periphery of the face unless the limited availability of donor sites requires their use in more prominent areas. Split-thickness skin grafts can be excellent for upper eyelid releasing and resurfacing. Hyperpigmentation of split-thickness grafts on the face is a frequently occurring problem in dark-skinned patients, particularly those of African descent.

The full-thickness skin graft is a reliable workhorse in facial burn reconstruction. The broad, central, conspicuous areas of the face such as the cheeks, upper and lower lips, and dorsum of the nose are excellent sites for the use of full-thickness grafts. The missing or damaged parts in the vast majority of even severe facial thermal burns are the epidermis and the dermis, and that is what full-thickness skin grafts provide. After facial burns, the subcutaneous fat may be compressed or distorted by contractures but it is rare that it is injured or completely lost. Adequate skin must be provided when doing definitive resurfacing operations with full-thickness grafts. Contractures must be overcorrected, and postoperative management with conformers and pressure is essential. Full-thickness skin grafts are very reliable when used electively in the face for reconstruction after burns.[32]

FLAPS

Flaps can be useful for facial burn reconstruction, but they must be used judiciously and skillfully, recognizing their problems and limitations. The thickness of skin flaps from all distant donor sites is greater than that of the normal facial skin. The face is tight following burn injury, and flaps tend to contract when transferred. They can therefore compress or obscure underlying tissue contours. Transposing or advancing flaps from the neck and chest up to the face can easily create extrinsic contractures that adversely affect facial appearance. When flaps have been enlarged by tissue expansion, they are even more dangerous in this regard. Contractures with a downward vector create a "sad" facial appearance that is distressing to patients (Fig. 50.9). Cervicopectoral flaps provide the best color match in color and texture to facial skin. Distant flaps, whether transferred by traditional technique or microsurgery, share the common flaw of poor match in terms of color and texture.

TISSUE EXPANSION

Tissue expanders must be used with caution in the reconstruction of the head and neck. The underlying theme of almost all burn deformities is tension secondary to tissue deficiency. Stretching adjacent tissue in order to carry out scar excision can easily result in an increase in tension and therefore create iatrogenic contour abnormalities. The complication rate of tissue expansion following burn injury is high, especially in the neck area and the extremities.[33–35] The scalp is a privileged site, however, that tolerates tissue expansion quite well, even in the burn patient population.[36] As noted earlier, care must be taken when advancing or transposing expanded flaps from the cervicopectoral area to the face because this can create extrinsic contractures with a downward vector.

Timing of Reconstructive Surgery

The timing of reconstructive plastic surgery following facial burn injury falls into three separate phases: acute, intermediate, and late. Specialized burn centers create an ideal patient care environment where acute care and reconstructive surgery can be planned and carried out in optimal circumstances with collaboration among acute and reconstructive physicians and surgeons. The reconstruction of facial burn injuries to the head and neck should optimally begin with the acute care.

Acute reconstructive surgery occurs during the first months following the burn injury and includes urgent procedures that are required to facilitate patient care or to prevent acute contractures from causing permanent secondary damage. Acute reconstructive intervention is most frequently indicated in the eyelid, perioral, and cervical areas. Intermediate reconstructive surgery takes place during the months to years after wounds are closed and the scar maturation process is proceeding. During this phase of recovery, some patients will present to the reconstructive surgeon after having received their acute burn care at another facility. Timely intervention when indicated is important in this group of patients because it can positively influence further maturation of scars and grafts. Scar rehabilitation with lasers has emerged as probably the most effective treatment modality in this intermediate phase of facial burn deformity reconstruction. Late-phase reconstructive patients present to the reconstructive surgeon with established facial burn deformities many years following their acute injury. Careful scar analysis and judicious use of the right techniques is essential during this period. It is the responsibility of the treating surgeon to weigh all the options and select the best combination of treatments to maximize the patient's own healing capabilities.

ACUTE-PHASE RECONSTRUCTION

Eyelids

Upper and lower eyelid ectropion can occur from burn injuries to the periorbital region (intrinsic contracture) or may arise secondarily as a result of the contracture of open wounds and skin grafts at more distant sites (extrinsic contracture). With severe ectropion, such as shown in Fig. 50.14A, early intervention is mandatory in order to prevent irreversible injury to the cornea. Conservative measures to protect the cornea, such as temporary sutures or contact lenses, are often ineffective. Tarsorrhaphy can cause irreversible iatrogenic injury and should not be used unless absolutely necessary. The best treatment is early intervention with release of contracture and resurfacing with split-thickness skin grafts (Fig. 50.14B). Release of even extreme contractures with grafting can be done in the presence of open wounds and effectively restores protective eyelid function.

Perioral Deformities

Microstomia occurs from circumferential scarring at the junction between lips and cheek. Perioral scarring from either open wounds or contraction of skin graft suture lines can act as a pursestring, resulting in diminished oral opening (Fig. 50.15). This can compromise alimentation and airway access. Microstomia is best addressed by the

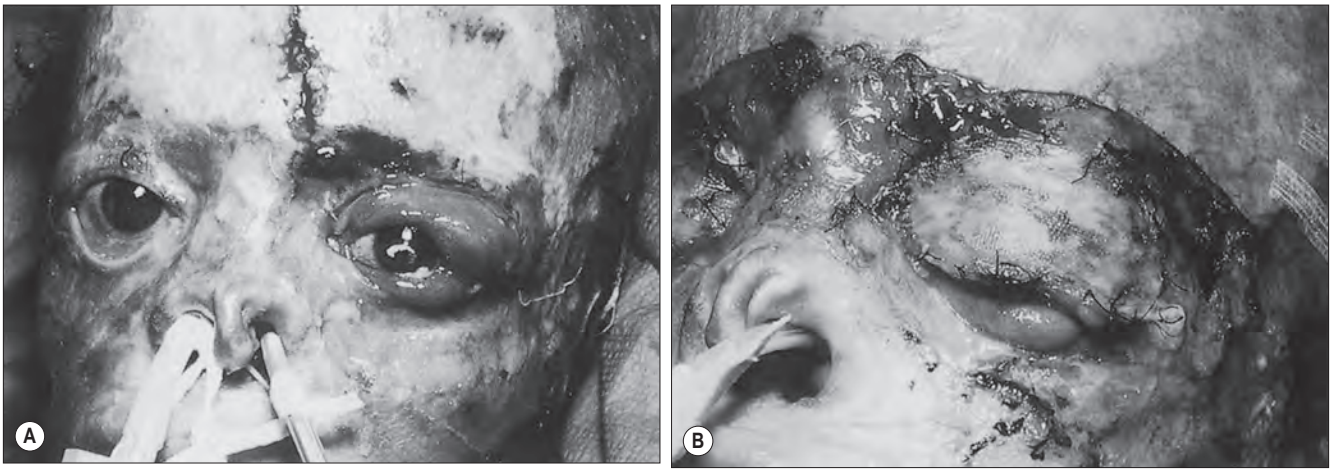

Fig. 50.14 (A) Extreme eyelid ectropion during early acute phase. **(B)** Successful correction of ectropion with release and graft despite operative wounds.

Fig. 50.15 Microstomia during acute phase as a result of circumoral contracture.

Fig. 50.16 Macrostomia secondary to contracture of open wounds and grafts with lip eversion and loss of oral competence.

acute release of the oral commissures, taking care to avoid extensive transverse releasing incisions in the aesthetic units of the cheek. Overcorrection can easily result in macrostomia. As soon as adequate oral opening is achieved for feeding and airway access, definitive reconstruction is best left for the postacute period.

Macrostomia is caused by rapid contraction of open wounds or grafts in the cheek and perioral region, resulting in eversion of the upper and lower lips and lateral movement of the oral commissures (Fig. 50.16). The loss of an effective oral sphincter causes drooling and desiccation of the oral mucosa and can result in irreversible damage to the dentition. Early intervention with release and grafting of the lower and/or upper lips should be carried out as soon as possible. Definitive reconstruction is best carried out at a later period.

Cervical Deformities

Anterior neck contractures in the acute period are best prevented by aggressive splinting and incisional releases and grafting when indicated.[37] When severe anterior neck flexion contractures occur, early release and grafting are necessary to allow for adequate airway access and to minimize hypertrophic scarring as a result of excessive and persistent tension (Fig. 50.17). Although secondary releases and grafts are often necessary, permanent correction of neck contractures with split-thickness skin grafts is frequently possible when postoperative management includes proper splinting and pressure (Fig. 50.17).[37]

INTERMEDIATE-PHASE RECONSTRUCTION

The intermediate phase of plastic surgical intervention consists of scar modification designed to favorably influence the healing process in the early months to years following acute wound closure. The treatment options during this period are multifaceted and are continuing to evolve. Significant progress is being made with these types of interventions.

It is often recommended that definitive reconstructive surgery be carried out after facial scars and skin grafts are mature, soft, and supple. This process takes at least a year and frequently takes many years to fully occur. The maturation of facial burn scars takes much longer than is generally appreciated by patients and reconstructive surgeons alike. If scars are continuing to improve, it is usually best to allow them to continue to mature. If scars are not maturing favorably or are improving very slowly, well-timed and well-conceived surgical intervention to favorably influence the clinical progress can be beneficial. The scar maturation process after facial burns is influenced by multiple factors. The most important factor, other than the initial severity of the injury, is the amount of tension present in the face and acting on the scars. Surgical procedures to decrease tension and to favorably alter the direction and contour of scars can achieve significant improvement in scar maturation for many years following a burn. Whenever healing burns cross concave surfaces, there is a tendency for hypertrophic scarring to develop. Examples in the face are the glabella, the nasojugal groove, the crus helicis of the ear, and the infracommissural folds. Relieving tension with Z-plasties without scar excision is very effective in correcting hypertrophy (Figs. 50.10 and 50.13). Steroids, both topically, intralesionally, and through ablative laser delivery, can be helpful during this period but must be used sparingly to avoid atrophy, telangiectasia, and erythema. In more severe cases, tension can also be relieved by judiciously placed releases and skin grafts (Fig. 50.18). The skin grafts can be of either split-thickness or full-thickness variety. Split-thickness skin grafts are best used where the location of the graft will be inconspicuous or where large amounts of skin are required to relieve the contractures. This is frequently indicated when there are associated neck contractures. Tension from the neck must be eliminated as much as

Fig. 50.17 (A,B) Extreme anterior cervical contracture secondary to burns of the entire chest and neck. **(C,D)** At 23 years post-burn, after release and split-thickness skin grafting. Two additional releases and grafts were required.

possible to allow for favorable maturation of facial burn scars. The use of full-thickness skin grafts during the intermediate phase of reconstruction should be rare and limited to circumstances where definitive repair is being carried out and there is little chance that further skin will be required in that region. The PDL is a proven adjunctive therapy that can decrease erythema and speed the rate of scar maturation (Fig. 50.10). Fractional ablative laser treatment is a paradigm-changing new intervention during this intermediate phase of recovery and reconstruction. It is an effective way to enhance the remarkable ability of scars to regenerate and remodel themselves. Every scar has the right to live, if it can be rehabilitated. The patient shown in Fig. 50.19 would certainly have achieved an even better result if vascular and ablative fractional lasers were available at the time of his reconstruction (Fig. 50.13). The result would also have been achieved more expeditiously, with fewer operations and less morbidity.

LATE-PHASE RECONSTRUCTION

Late-phase reconstructive surgery takes place when scars are mature and the patient's deformities are essentially stable. In some patients, scars will be soft and supple, but, in others, even long-standing scars may be hypertrophic and hyperemic many years following the burn injury because of persisting tension or unfavorable orientation. Scars can remain indurated and hyperemic for decades following a facial burn. Reorientation in this late phase with Z-plasties and treatment with the PDL can result in

Fig. 50.18 (A,B) Three-year-old male adopted from an orphanage in China 18 months after a severe house fire; he has pan-facial hypertrophic scars and contractures. **(C)** Pulsed dye laser therapy was initiated, and preauricular releases and split-thickness grafts were placed bilaterally. **(D)** Continuous scarring across the face was released lateral to each oral commissure with full-thickness grafts. **(e)** Z-plasties were performed to further release and flatten the now greatly improved linear scars. **(F,G)** Seven years later his rehabilitated scars are now soft and supple and his facial appearance and expression are acceptable. Fractionated ablative laser therapy is continuing.

Fig. 50.19 (A,B) Diffuse, hypertrophic scarring of cheeks, chin, and lips 8 months following flame burn injury. **(C,D)** At 12 years post-burn after treatment with pressure therapy, steroid injections, and multiple Z-plasties within the scar tissue. No scar tissue was excised.

remarkable improvement (Fig. 50.20). Fractional ablative lasers have also been shown to benefit facial burn scars many years after the injury. Scar excision can often be avoided, with its concomitant increase in facial skin tension and distortion of facial features.

Reconstruction of Specific Areas of the Head and Neck

SCALP

Scalp alopecia is seen in as many as 25% of children who suffer burn injuries of the head and neck.[38] McCauley et al. devised a system of classification for burn alopecia based on the pattern and extent of deformity.[39] They describe the pattern of alopecia as uniform, segmental, patchy, or total (types I–IV, respectively) and the extent of alopecia as 25% of the scalp, 25–50%, 50–75%, or more than 75% (subtypes A–D, respectively). Their system serves as both the means of description and an initial step in planning operative care. Previously described reconstruction techniques include serial excision, rotational scalp flaps, free hair follicle transplantation, and staged scalp tissue expansion.[40] Of patients with scalp injuries, associated adjacent burn deformities were commonly found involving the ear, nose, and eyebrow.[41] These injuries included ear deformity (46%), nasal deformity (27%), and eyebrow

Fig. 50.20 **(A)** A 16-year-old female 11 years following contact burn. Right cheek scar remains erythematous, indurated, and conspicuous. **(B)** Relaxation and reorientation of scar tissue with Z-plasty. **(C)** Five years later, after six treatments with the pulsed-dye laser.

deformity (46%). Therefore, in planning the surgical reconstruction for pediatric scalp alopecia, it is helpful to evaluate each patient for adjacent structure burn injuries requiring reconstruction. Therefore, as one plans the stages of tissue expansion procedures, one can plan concurrent reconstruction of associated burn injuries, sometimes taking advantage of the region of expected alopecia excision.

EYEBROWS

Eyebrow reconstruction following complete loss is an unsolved surgical problem. Composite grafts of hair-bearing scalp from carefully selected sites in the retroauricular area can satisfactorily transfer hair.[42–44] Unfortunately the hair is scalp hair that grows rapidly and is more projecting than the tangential delicate hair of the normal eyebrow. For complete eyebrow replacement, the technique of composite grafting as described by Brent[42] is most useful. For partial eyebrow loss, micro- and mini-grafting of scalp hair can be efficacious. Occasionally, borrowing composite grafts from a contralateral unburned eyebrow is appropriate. Temporal artery island flaps for eyelid or eyebrow reconstruction have been used for many years.[44–46] When used for eyebrow reconstruction, they can be bushy and conspicuous and should be used with caution, particularly when carrying out unilateral eyebrow reconstruction.

Burn injuries of the scalp and upper face often result in scars that distort the relative positions of the anterior hairline, eyebrows, and upper eyelid. Contour of the brow is distorted with exaggerated elevation of the central peak. Furthermore, scar contracture involving the upper eyelid can result in cicatricial ectropion associated with effacement of the supratarsal fold and corneal exposure. This stereotypic set of upper facial deformity can be treated with tissue expansion and antegrade forehead plasty.[47] In this technique, the scalp and forehead areas are tissue expanded. The tissue expander is removed and the scalp aponeurosis is advanced antegrade and loaded in redundant fashion over the brows at the level of the arcus marginalis. Accounting for the fourth dimension of time and tissue recoil, the brows are returned to a natural contour and improved position (Figs. 50.21 and 50.22).

EYELIDS

Correction of upper and lower eyelid contractures in the late reconstructive period can be a daunting and humbling challenge. The periorbital region is made up of complex three-dimensional anatomy and requires abundant skin to appropriately drape the contours of both the upper and lower eyelids. The slightest amount of excessive tension from either the eyelid skin itself or contractures in adjacent regions such as the forehead or cheek can profoundly and adversely affect eyelid function and appearance. Reconstructive goals should be restoration of a normally shaped palpebral fissure with appropriate orientation of upper and lower eyelashes at rest and in the open position whenever possible. This often requires extensive releasing incisions extending medial to the medial canthus and lateral to the lateral canthus in order to adequately release all the contracted tissues. When ectropion is the result of a distant contracture, the normal eyelid skin should always be returned to its normal location. Incisions should not be made at the eyelid margin, thereby separating the normal eyelid skin from the ciliary line and replacing it with a graft. When overlying scar is released, care must be taken to prevent injury to the underlying orbicularis oculi muscle. This is often rolled up and contracted and is rarely completely lost. It must be unfolded to its normal flat broad shape and the

Fig. 50.21 Tissue-expanded antegrade forehead plasty. This patient suffered flame burn injury to the scalp and forehead. The hyperpigmented skin graft on the scalp serves as a marker illustrating movement of the expanded scalp and forehead tissue. Before the forehead plasty, the patient suffered from upper lid ectropion and exposure of the left cornea. Note the overelevated eyebrows and effacement of the supratarsal fold in the left upper eyelid **(A)**. A tissue expander was placed **(B)**. Antegrade forehead plasty was performed, and forehead tissue was loaded in a redundant fashion above the brows, with overcorrection to account for tissue recoil **(C)**. At 1 month postoperation, note the extent of antegrade forehead movement, where the hyperpigmented skin graft is observed to move from the scalp to mid-forehead region. At 2 years following the operation, the forehead tissue has flattened out and the eyebrows are restored to an improved position over the orbital rims. Note the restoration of the supratarsal fold to the left upper eyelid and partial recoil of the hyperpigmented skin graft **(D)**.

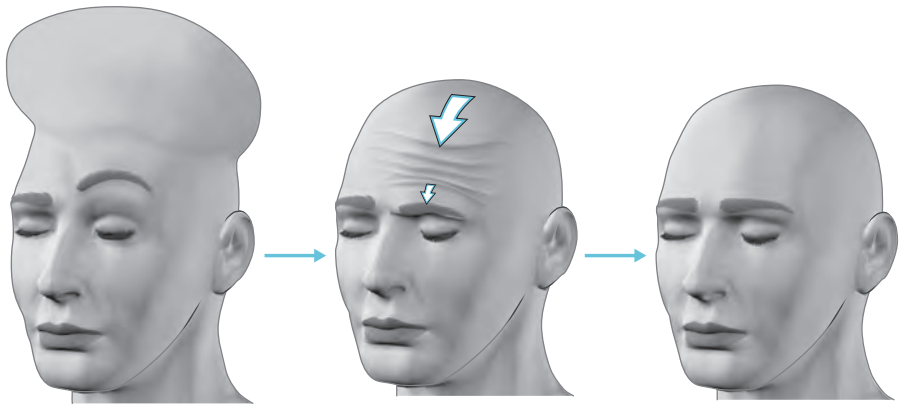

Fig. 50.22 Diagram illustrating tissue movements of antegrade forehead plasty. Scalp tissue is maximally expanded, with consequent further exaggeration of eyebrow elevation (left). Tissue expander is removed and the expanded scalp and forehead skin are advanced anteriorly, loaded in redundant fashion over the eyebrows (middle). Over time, the redundant skin recoils, restoring the eyebrows to a more natural position (right).

resulting defect resurfaced with abundant skin graft. Upper eyelid resurfacing is best carried out with split-thickness skin grafts from the best available donor site.[44] Full-thickness skin grafts in the upper eyelid usually transfer a thick dermal component that compromises the delicate contour of the supratarsal fold. Lower eyelid resurfacing may be done with either split-thickness skin grafts or appropriate full-thickness grafts when indicated. For minor contractures of either upper or lower eyelids, the perfect reconstructive material can be obtained from an unburned contralateral upper eyelid. Medial canthal folds are best corrected with Z-plasties when there is not a significant tissue deficiency.[48]

LOWER LIP AND CHIN

Deformities of the lower lip and chin usually occur in combination. Contracting forces result in inferior dislocation and eversion of the lower lip. In addition, there is compression of the soft-tissue contours of the chin prominence. Release should be carried out at the vermillion scar junction and the lower lip carefully unfurled, taking care to prevent iatrogenic injury to the underlying orbicularis oris muscle.[11] The resulting defect is then resurfaced with split-thickness skin grafts or full-thickness grafts when indicated. Restoration of chin contour can be improved with chin implants.

UPPER LIP DEFORMITIES

The upper lip is usually shortened and retruded by severe facial burn injuries. Releasing and grafting should be carried out, taking care not to overcorrect the deformity and create a long upper lip.[11] Full-thickness grafts from the best available donor sites are usually the best option for resurfacing. Reconstruction of the philtrum when indicated is best performed by the technique of Schmid,[49] using a composite graft from the triangular fossa of the ear (Figs. 50.12 and 50.23).

ELECTRICAL BURNS OF THE ORAL COMMISSURE

Electrical burns of the oral commissure constitute a unique and challenging burn injury to the head and neck. The injury occurs in small children and usually results from placing a live extension cord outlet in the mouth. Most of these injuries are minor and all should be treated conservatively in the acute period. If there has been minimal tissue loss, reconstructive surgery using local flaps can improve aesthetics.[50–52] When there has been extensive full-thickness loss of skin, vermillion, mucosa, and muscle, as shown in Fig. 50.24, reconstruction requires complete release of the contracture and replacement with adequate tissue of suitable quality.[53] A ventral tongue flap provides abundant mucosa and muscle and allows the lips and cheek to return to their proper location and shape. Normal facial appearance, mobility, and expression can be restored (Fig. 50.25).

NASAL DEFORMITIES

Burn injuries to the nose result in a broad range of deformities which can be focal and minor or can result in complete nasal amputation. Minor deformities are best dealt with by local scar revision, particularly with Z-plasties to relieve contractures, or releases in combination with full-thickness skin grafting. Shortening of the nose with flaring or partial loss of the alar rims is common in more severe facial burns. Local release of the alar lobules with full-thickness skin grafts is a useful technique for minor to moderate contractures. Complete excision of dorsal scar and graft in an aesthetic unit with a full-thickness skin graft is useful for more severe shortening. When the lower third of the nose has been amputated by the burn injury, inferiorly based, turn-down flaps of the dorsal nasal tissues can provide satisfactory lengthening and improved contour to the tip and alar lobules. More severe cases of nasal deformity can be treated by either dorsal turn-down flaps or other forms of total nasal reconstruction. The dorsal turn-down flap usually requires at least two stages but can be effective in even near total nasal amputation (Fig. 50.23). Forehead flaps are usually unavailable in patients who have sustained facial burns severe enough to result in total nasal amputation. Distant flaps can be used with either microsurgical transfer using a radial forearm flap or using the frequently unburned skin of the upper inner arm for a Tagliacozzi flap. If the face is otherwise composed of burn scar and graft, these distant flap nasal reconstructions have the disadvantage of appearing to be "stuck on" and stand out in the midst of the otherwise mosaic appearance of the face. When the face has required resurfacing with flaps, a nasal reconstruction with flap tissue is the best option (Fig. 50.26).

EAR DEFORMITIES

Improved care in the acute phase of burn injury has greatly decreased the incidence of helical chondritis and the resulting associated deformities of crumpled or lost cartilage. Minor ear deformities are often seen in patients with little or no hair loss and can easily be camouflaged. Larger defects can be treated by myriad local reconstructive techniques.[12,54–56] Subtotal ear amputation (Fig. 50.27) often lends itself to reconstruction with a conchal transposition flap and skin graft.[57] Complete ear loss can be masked by the use of a prosthesis. Fixation has been improved by the use of osteo-integrated implants, but cost and color changes remain problematic. Selected patients can be appropriate candidates for total ear reconstruction using autologous cartilage and soft-tissue coverage from either temporalis fascia flaps or expanded local tissue.[58] Alloplastic materials should not be used in the reconstruction of post-burn ear deformities due to an unacceptably high extrusion rate.[59]

Burn Neck Contractures

PREVENTION

Cervical contractures are a major problem in burns involving the chest, neck, and face. The anterior neck skin is thin, and the neck is a highly mobile flexion area easily prone to contracture. As noted previously, severe neck flexion neck contractures in the acute phase often require early reconstruction to aid in airway management. Neck contractures should usually be dealt with prior to carrying out facial burn reconstruction because the extrinsic contractile forces from the neck cause facial deformities and can adversely

Fig. 50.23 **(A)** A 3-year-old female 10 months following severe facial burn with subtotal nasal amputation. **(B)** Intraoperative design of a nasal turn-down flap. **(C)** Split-thickness skin grafting to nasal dorsum following turn-down flap and contracture releases. **(D)** At 16 years following turn-down flap after second release and graft.

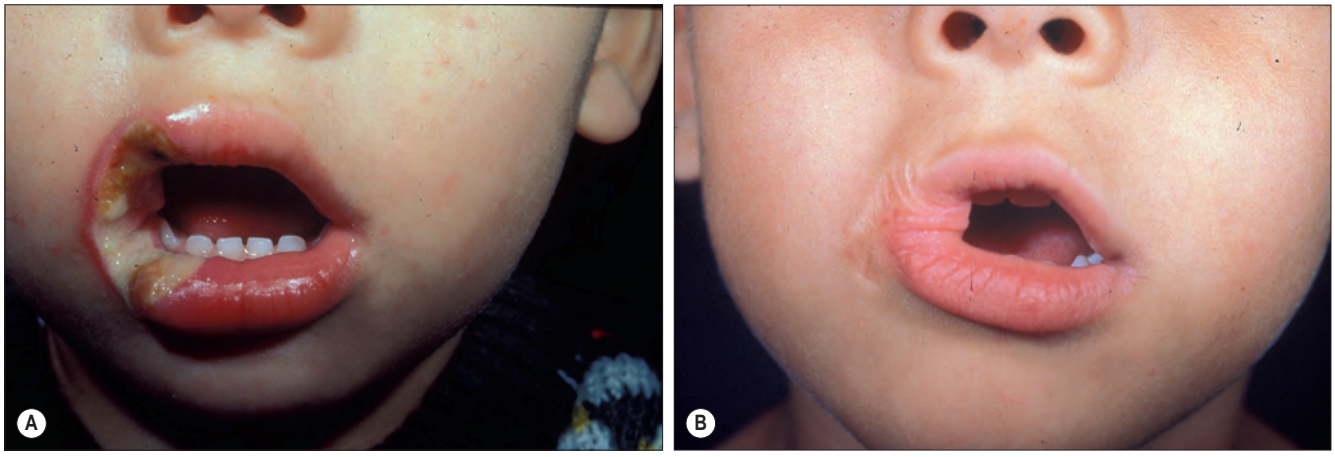

Fig. 50.24 **(A)** Severe oral commissure burns destroy vermillion, mucosa, muscle, and the skin of the lip and cheek. **(B)** Extensive contracture results with thickening of the leading edge of the commissure.

Fig. 50.25 (A) A 16-year-old male following devastating right oral commissure electrical burn. Some 40% of lip circumference is lost and the commissure is thick and immobile. **(B)** Following tongue flap reconstruction, the commissure is thin and mobile and facial expression is restored.

Cervicopectoral flap resurfacing was chosen for reconstruction of the cheeks and chin. **(C,D)** Nasal appearance following reconstruction with a Tagliacozzi flap. A scalp flap was used to reconstruct the upper lip and create a moustache.

Fig. 50.27 (A) Typical post-burn pattern of peripheral helical loss. **(B)** Reconstructed ear following expansion with conchal transposition flap and skin grafts.

Fig. 50.28 (A,B) Persistent anterior neck contracture following repeated inadequate split-thickness skin grafting. **(C,D)** Release and anterior neck resurfacing was carried out with bilateral shoulder flaps. Secondary midline Z-plasties improved the vertical release and created an aesthetic neck contour. Chin augmentation improved the patient's profile.

affect the maturation of scars on the face. Preventive methods to minimize cervical contractures during the acute period as burn scars and grafted areas contract include splinting, physical therapy, neck collars, and the use of a three-quarter mattress to encourage neck extension.

RELEASE AND GRAFTING

The majority of anterior neck contractures can be satisfactorily treated with release and skin grafting. Extensive contractures usually require split-thickness skin grafting. Focal contractures can be appropriate for full-thickness grafting, which will result in a superior outcome from both a functional and an aesthetic standpoint. When neck contractures are extensive, the lower face and chest are usually a combination of healed skin graft and scar. Split-thickness skin grafts represent "like tissue" and will blend into the area (Fig. 50.17).

LOCAL FLAP RECONSTRUCTION

When split-thickness skin grafting is unsuccessful because of recurrent contracture or does not provide a satisfactory aesthetic result, local flap reconstruction of the anterior neck is an excellent technique if there is available tissue. Flaps can either be unilateral or bilateral. When bilateral flaps are available, midline Z-plasties secondarily can help to improve neck contour (Fig. 50.28). Donor site morbidity is usually minimal because the upper chest in these patients has frequently been disfigured to some degree by the burn injury.

DISTANT FLAP RECONSTRUCTION

Free flaps have been advocated for the treatment of anterior neck contractures.[60] Excellent outcomes can be obtained but require microsurgical technique and create the possibility of complete flap loss. Another potential negative of free flaps to the anterior neck is that they can be thick and bulky, requiring multiple defattings and secondary revisions. The free flap can also appear to be an island in the midst of a broad area of healed graft and burn scar.

51 Management of Postburn Alopecia

RAJEEV B. AHUJA and PALLAB CHATTERJEE

Introduction

The importance of burn involvement of the scalp is due to its very visible location on the body. Deformities of the scalp may not always be easy to hide or camouflage, causing great distress to the individual. In large surface area burns, the scalp may be involved in 25–45% of cases.[1,2] Superficial burns of the scalp heal rapidly owing to the abundance of dermal epithelial structures. However in cases of deep dermal or full-thickness burns, the loss of dermal adnexa manifests as alopecia once healing is complete. As with anywhere else in the body, burns of the scalp that take more than 2 weeks to heal spontaneously are at a risk of developing increased scarring with accompanying cicatricial alopecia.[3]

Repeated split skin graft (SSG) harvesting from the scalp may also result in scalp alopecia. Although scalp, because of its thickness and high density of hair follicles, lends itself to reharvesting of SSG, Brou et al. reported a 61% incidence of alopecia if scalp was used to harvest skin grafts and had also sustained burns.[1] This is in contrast to only a 2.2% incidence of alopecia in patients without scalp burns who underwent harvesting of SSG from scalp.[4]

Spectrum of Postburn Alopecia

Burns of the scalp may purely involve the soft tissue or may also involve the underlying calvarium. While deeper partial-thickness burns may cause alopecia, full-thickness burns will inevitably lead to alopecia. A different dimension is added to the clinical problem if the calvarium also sustains burns, as is likely in an electrical injury. Optimal management of such an extensive injury has been a topic of discussion for a long time, with an evolving consensus for optimal management.

CLASSIFICATION OF SCALP BURNS

Harrison offered a classification to guide the treatment based on the depth of the injury:[5]

Type I: Total skin loss with intact pericranium
Type II: Total skin loss with involvement of pericranium
Type III: Total skin loss with involvement of outer table
Type IV: Total skin loss with involvement of both plates of the skull.

Patients with type I injuries typically require SSG for wound coverage in the acute stage, and later they present for alopecia reconstruction. Type II/III injuries require débridement until a vascular surface is reached, followed by immediate application of SSG; this may involve chiseling until reaching the underlying diploë. Alternatively, after soft tissue débridement multiple holes may be drilled in the outer cortex until reaching bleeding diploë. The wound is dressed for a few weeks until it is fully covered by healthy granulations and then split-skin grafted. Alopecia reconstruction is undertaken at 6–9 months after skin grafting. Immediate coverage with local flaps to obviate temporary alopecia is not warranted except in small wounds with normal surrounding scalp. In type IV injuries, because there is loss of calvarium, the exposed dura requires coverage with local flaps (for small defects) or a free flap.[6,7] Historically SSG has been applied directly to dura to cover defects in a strategy that is risky but may be the only option in a resource-constrained setting. The goal is to obtain an early wound closure and restore aesthetics as a secondary procedure. These patients may have more complex reconstructive needs other than simple alopecia reconstruction. It is not unusual in developing countries to see patients requesting coverage of exposed calvarium several months after the injury.

Surgical Correction of Alopecia

A whole gamut of reconstructive options is available to correct postburn alopecia. The surgical options include serial excision,[8] scalp reduction, bipedicle flaps, modified rotation flaps on a template design,[9,10] other local flaps (Juri flaps,[11–13] Elliot flaps,[14] or Orticochea flaps[15,16]), tissue expansion,[17] and hair grafting (micro- or minifollicles).[18] It is intuitive and expedient to surgically excise the alopecia patch (whether from scar, skin graft, or a nonhealing wound) and to close the defect directly or with a local flap. In practice, this approach works for small areas of involvement.[19,20] Scalp tissue characteristics and underlying galea make the skin less stretchable and therefore less amenable to direct closure. Large areas of alopecia need to take into account the size and location of the defect and the state of remaining scalp before planning any procedure.

SERIAL EXCISION

Huang et al., in 1977, proposed a classification of the extent of postburn alopecia to guide reconstruction.[8] They recommended that alopecia defects of less than 15% of entire hair-bearing scalp were suitable for excision and direct closure by two or three serial excisions.[8] Seemingly mathematical, it still is an empirical approach because such calculations are not exact guides to the extent that other stages of serial excision would be possible. For small to

Fig. 51.1 (**A**) An 11 × 3-cm postburn alopecia patch in the right parietal area of a 30-year-old male patient. A 2.5-cm central ellipse of the scar was excised and primarily closed. (**B**) Postoperative result at 4 months. A second stage of excision was not necessary because the surrounding hair covered the residual scarred patch.

Fig. 51.2 (**A**) Long-standing exposed calvarium on the vertex of a 20-year-old male who suffered electrical burns. The outer table of the skull has sequestered, and attempts were made at drilling holes to generate granulations. There was also a previous unsuccessful attempt at moving bipedicle flaps to cover the wound. (**B**) After removal of the remaining sequestered bone, the anterior triangular alopecic area was excised and the same bipedicle flaps were mobilized to be sutured in the midline. The lateral raw areas were split-skin grafted (SSG), showing completely healed wounds at 1 month after surgery. The bald patch that would have resulted at the vertex with SSG has been eliminated, and the lateral areas covered with SSG are narrow and will not be visible after the hair lengthens.

moderate defects, it is much simpler to design local flaps on the rotation template principle,[9] as described below. The elliptical excision of the alopecia leaves an incision not much shorter in extent than a corresponding design on a rotation flap template. However no more than 2.5 cm scar width should be excised in one stage, or primary closure would become difficult (Fig. 51.1A and B). The second stage should be planned after 6–9 months to allow the scalp to adequately stretch and relax to permit another stage. Typically the scar width excised in the second stage is less than that in the first stage.

BIPEDICLE FLAPS

Quite similar to the principle of serial excision is the use of bipedicle flaps in scalp. Relaxing incisions on either side of the defect allow a slightly larger area to be excised and closed primarily (Fig. 51.2A). The donor areas are split-skin grafted, and these linear scars of alopecia are easily covered by surrounding hair (Fig. 51.2B).

LOCAL FLAPS AND THE ROTATION FLAP TEMPLATE

Ultimately the best tissue match is provided if alopecia reconstruction can be achieved by locally available tissue, either by serial excision or by a flap that leaves no donor defect or an insignificant defect requiring SSG that can be camouflaged by surrounding hair. Of historical significance are classical rotation flaps[9] where the defect was triangulated and the base of the triangle was a segment in the hemispherical incision of the rotation flap. The size of the rotation flap was never specific, and very large rotation flaps had to be designed to achieve the desired closure in the inextensible skin of the scalp. Often, design inadequacies were compensated for by making "back cuts" along the flap

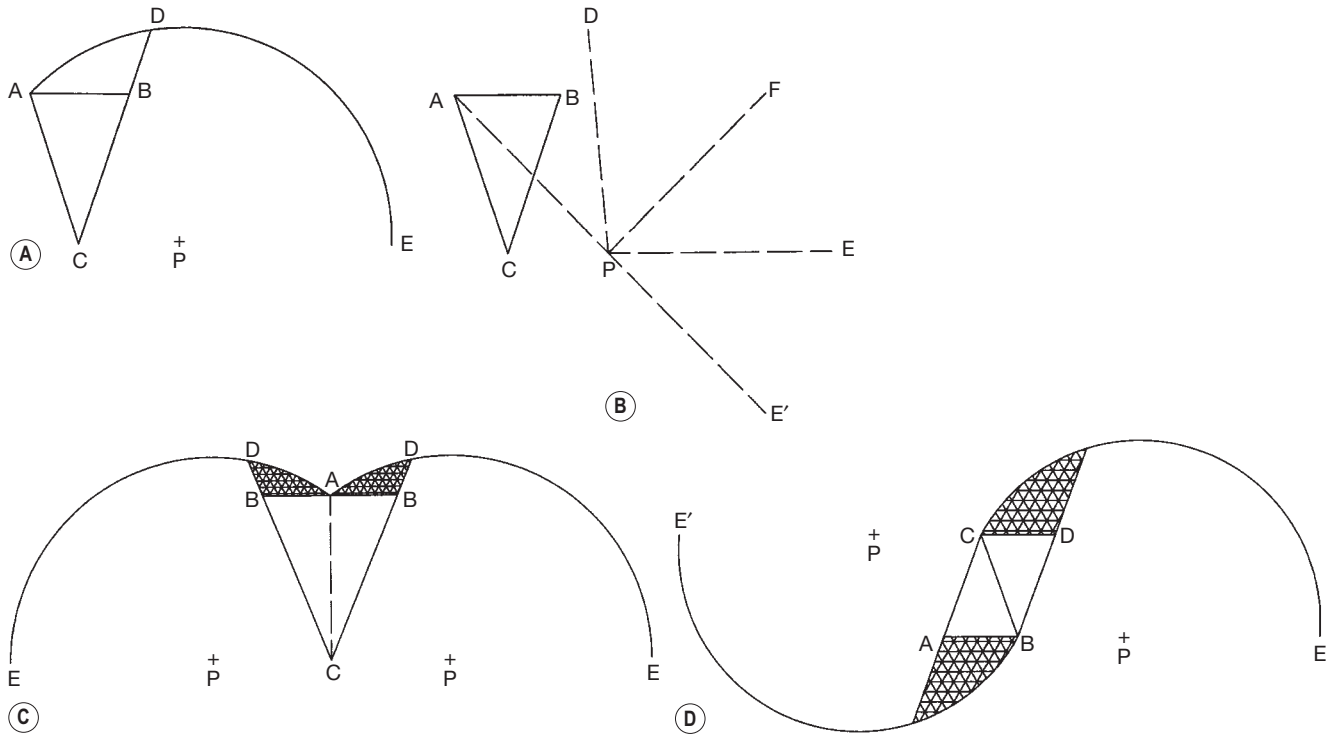

Fig. 51.3 (**A,B**) Line drawings to show the execution of a rotation flap template design for triangulated defects. An isosceles defect is created, with a less than 30-degree apical angle (A), and the pivot point (P) is selected so that CP is slightly longer than AB. With AP as the radius, an arc ADE is drawn. CDE is the rotation flap template. The incision can continue along the arc of rotation beyond E if CP = AB or slightly less due to anatomical constraints. This extension of incision beyond E is a design reserve and not a back-cut because it does not compromise the blood supply of the flap. The triangle ABD is geometrically shown to be excised, but only a small piece needs trimming after flap movement, and this helps in accommodating tension in large defects. (**B**) To design the arc ADE, strategic points can be marked using a thread, and these are joined in free hand. (**C,D**) Large defects may be excised maximally as an equilateral triangle that can be bisected to have a template flap on either side of the defect or as an appropriate rhomboid with flaps designed diagonally. Flap planning takes into account the available tissue, anatomic limitations, and minimal excision of normal tissue to fit a suitable geometry.

base to facilitate movement at the cost of compromising the blood supply. A paradigm change in geometry was proposed by Ahuja in 1988,[9] wherein a modified rotation flap was used clinically in scalp defects, and then subsequently a rotation flap template design was offered to logically explain the movement.[10] It became possible to primarily close moderate to large scalp defects in a single stage without "back cuts," thus obviating the requirement for serial excisions or tissue expansion in such cases. The technique has since been adopted in an algorithmic approach to scalp defects.[21] Rotation flaps planned on the template design can easily close defects up to 6.5 cm in width, something that was never possible using the classical rotation flap. Fig. 51.3(A–D) explains the execution of a rotation flap template design for triangulated defects. Figs. 51.4 to 51.6 illustrate clinical execution of a single template flap, bilateral template flaps, and two template flaps in an S-shaped design to cover large alopecia areas in a single stage.

To improve the extensibility of the scalp skin it is often useful to score the galea on the under surface of the flap perpendicular to the flap movement. Raposio et al. state that each galeatomy corresponds to a 40% reduction in scalp closing tension and a tissue gain of approximately 1.67 mm.[22] However this technique should always be a reserved move to lessen tension and should never be considered as a means to excise larger areas by making compromises in the design. Occasionally, at the limits of the flap design, if there is undue tension in flap closure it is better to place a small SSG at the extreme end of the donor area (Fig. 51.5D). Such small resultant defects generally are covered by surrounding hair but can also be excised after 9–12 months.

Quite often the alopecia patch is a large area of exposed calvarium. A dry, uninfected exposed calvarium need not be chiseled to create a bleeding surface because it will be well vascularized after a viable flap cover (Figs. 51.4 to 51.6). However if the outer table of calvarium is sequestered completely or partially, the complete outer table should be excised before flap coverage (Fig. 51.2). All flaps need to be provided suction drains for 3–4 days, even if the calvarium outer table has not been excised.

Although now of historic interest only for large vertex defects Orticochea introduced a four-flap technique[15] that was subsequently modified to a three-flap "banana peel" technique in 1971.[16] This was before the era of tissue expansion and the rotation template design. Although quite useful in the correction of moderately sized areas of alopecia, these techniques cause extensive blood loss and excessive scarring.

Juri et al.[11–13] and later Elliot[14] described a variety of innovative monopedicled scalp flaps to cover segmental areas of alopecia, especially to restore the frontal hairline and for the occipital region. However only small-sized alopecia segments that were located in favorable locations

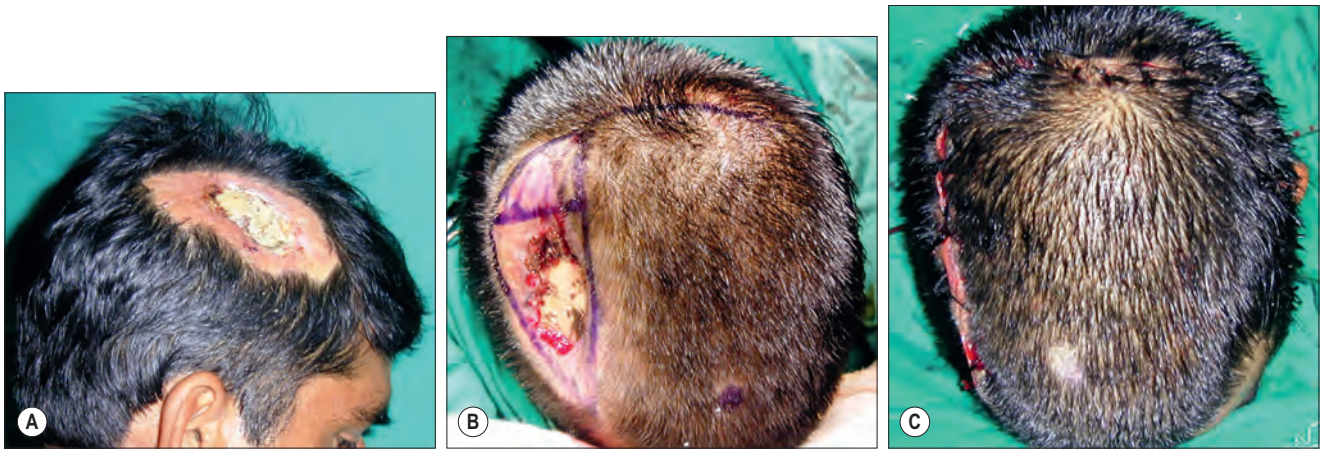

Fig. 51.4 (**A**) A 35-year-old patient with a 6 × 9.5-cm defect in the scalp following electrical injury. There is an alopecia patch with exposed calvarium. (**B**) Showing triangulation of the defect and markings for a rotation flap template. Note the area ABD has been marked in the defect that will be excised and not as a part of the triangulation. (**C**) Intraoperative picture showing primary closure of the large defect and complete correction of alopecia.

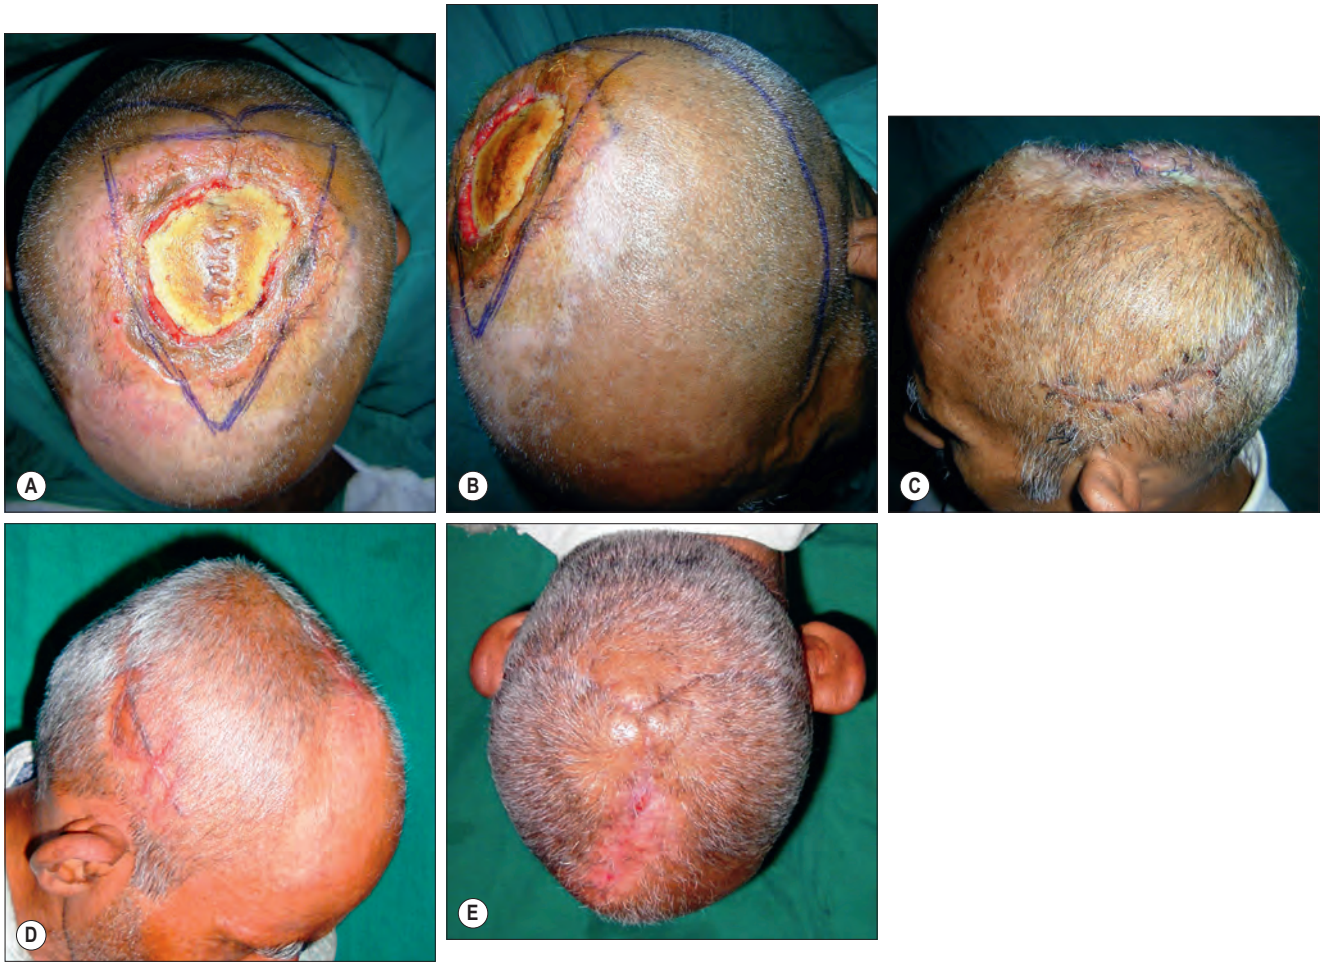

Fig. 51.5 (**A**) A 65-year-old patient with a long-standing defect on the scalp measuring 7 × 6 cm. Bilateral rotation flaps have been marked after proposed triangulation of the defect. (**B**) Left lateral view to show the extent of flap marking. (**C**) Left lateral view at the 10th postoperative day. The flaps were rotated over the exposed bone without chiseling of the outer cortex (bone was dry and noninfected). (**D**) Right lateral view at 6 weeks showing well-healed incisions. A small skin graft was placed to ease some tension because the defect was extremely large and closure was leading to some tension. (**E**) Showing primary healing of the flaps at midline with complete resurfacing and correction of alopecia.

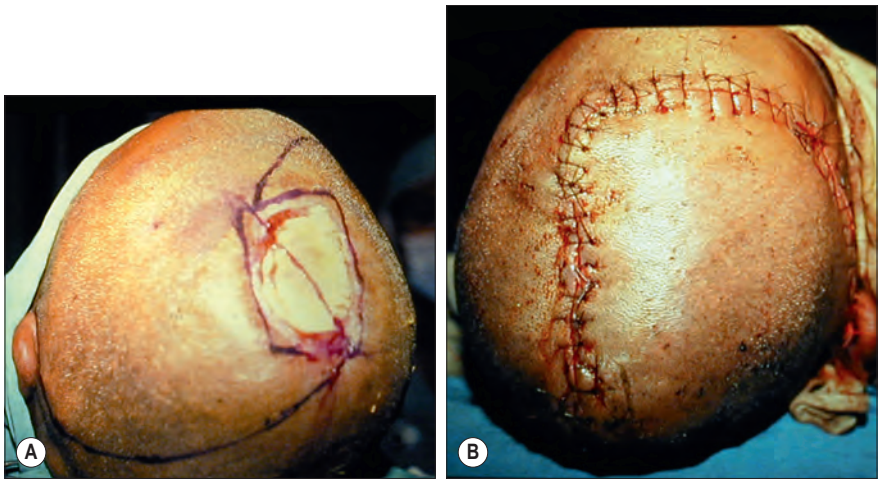

Fig. 51.6 (**A**) A 5.5 × 6.5-cm circular defect on the vertex of the scalp following electrical injury. Large rotation template flaps have been designed diagonally with proposed freshening of the defect as a rhomboid. (**B**) Immediate postoperative result showing complete closure of the scalp defect (as well as correction of alopecia).

could be corrected. Feldman increased coverage of patients with significant burn alopecia by combining horizontal scalp reduction with the Juri flap.[23]

TISSUE EXPANSION

Although the concept of soft tissue expansion using inflatable subcutaneous balloons was introduced in 1956 by Neuman,[24] Radovan is credited with its rediscovery and making it popular for clinical use in the 1980s.[25]

Briefly tissue expansion is the result of a constant mechanical stress load that leads to tissue regeneration.[26] The epidermis becomes thicker, with most of the mitotic activity occurring in the stratum spongiosum. The dermis thins out, with the greatest amount of thinning occurring in the papillary dermis.[27,28] The activation of a number of growth factors for epithelial and connective tissue growth may be responsible for this true tissue regeneration and not merely stretching of overlying tissue.[26]

McCauley et al. described the effective use of tissue expansion in the treatment of post-burn alopecia of the scalp in 1990.[17] This was at a time when the rotation flap template design was just introduced, so their classification of post-burn alopecia based on both pattern and extent of scalp involvement to guide treatment strategy included the option of tissue expansion only.[17] With our current approach, we propose a simplified treatment strategy to manage scalp alopecia by modifying the recommendation of McCauley et al. (Table 51.1). Despite the fact that tissue expansion has complication rates ranging from 15% to 20%[29–31] in scalp defects, it remains the best option and is the only option for defects of between 20% and 75% of hair-bearing scalp area. For defects larger than 75%, the only possibility is camouflage with a hairpiece.

Use of tissue expanders massively improved the outcomes for reconstruction of large alopecia patches. Losses between 50% and 75% will require placement of two expanders simultaneously or sequentially. Sequential expansion aims to achieve partial reconstruction from one expander; after a wait of several months, the second expander can be placed strategically to complete the reconstruction.

Table 51.1 Treatment Strategy Recommended for Alopecia Management

Alopecia Segment	Treatment Strategy
	SINGLE
<20% of the hair-bearing scalp	Rotation flap template
20–50% of the hair-bearing scalp	Single tissue expander
50–75% of the hair-bearing scalp	Two expanders placed simultaneously or sequential expansions
>75% of the hair-bearing scalp	Use hair piece (wig)
	TWO OR MORE
If amendable to tissue expansion	One/two expanders placed simultaneously or sequentially
Not amendable to tissue expansion	Use hair piece (wig)

Modified from McCauley RL, Oliphant JR, Robson MC. Tissue expansion in the correction of burn alopecia: classification and methods of correction. *Ann Plast Surg.* 1990;25:103–115.)

Tissue expansion generates a source of local skin that may be used as an advancement or a rotation template flap, and it permits direct closure of the donor site.[32] After proper planning of the desired flap movement following expansion, a suitably sized and shaped expander is chosen by measuring the dimensions of the recipient area. Although the literature is replete with several mathematical models in deciding the most appropriate size and shape of the expander,[33] the selection can be easily made clinically by recipient site requirements and the donor flap available for expansion. As a rule of thumb, the available donor skin before expansion should never be less than the recipient

Fig. 51.7 A 21-year-old girl with a 10 × 10 cm alopecia patch on the vertex following thermal burns. A 500-mL crescent tissue expander was inserted through an incision just parallel to the edge of the defect. (**A**) Showing full expansion achieved in 3 months. (**B**) Lateral view to show the posterior extent of expansion. (**C**) The alopecia patch was excised and the expanded flap advanced into the defect. Postoperative view at 10 days.

Fig. 51.8 (**A**) A laterally situated, extremely large alopecia patch on a 12-year-old boy following thermal burns. A single 800-mL, crescent-shaped expander was inserted and inflated over a 4-month period. The incision line gave way slightly after 3.5 months, but the expansion continued with an exposed implant for the next 10 days. (**B**) Five-year postoperative picture showing complete restoration of hair on the scalp by tissue expansion.

area for one-stage expansion. The minimum expander base should be a little more than the recipient area, although the largest expander possible should be selected. Expander volume is less of a clinical guide because overexpansion is always possible. Figs. 51.7 and 51.8 are illustrative clinical examples of tissue expansion for alopecia correction.

The inextensible skin of the scalp makes it a bit tougher to place the implant, and it is essential that an adequate pocket is created below the galea. It is hazardous to place tissue expanders above the galea in the subcutaneous tissue. A short incision parallel to the defect and about a centimeter into healthy skin is used for implant placement. The port of the expander is located at a short distance through another narrow pocket. Magnasite expanders are convenient but more expensive. They have an in-built port that can be detected under the skin with a magnet. The expansion is initiated 10–14 days after the insertion. Full expansion is achieved over 3–4 months, by weekly injections, as an outpatient procedure. The end point of injection is slight patient discomfort or blanching of the overlying skin, after which a few milliliters of fluid are withdrawn. The width of the expanded skin over the dome should at least equal two times the recipient area plus 30% (to allow for skin retraction). Hallock described the utility and safety of expander overexpansion very early in the evolving concept,[34] and nowadays overexpansion beyond the manufacturer's volume recommendations are routine. After complete expansion, the expander is removed through an incision that traces the proposed flap. Optimal mobilization of the flaps is accomplished by releasing the periphery of the capsule under the expanded tissue. Capsular scoring incisions should include galea, and they are made perpendicular to the direction of flap movement.[32]

Tissue expansion is painful and socially incapacitating for the patient during the expansion phase. In addition, it has a substantial complication rate from infection, exposure, or extrusion, ranging from 15% to 20%, which may require premature removal of the expander and abandonment of

the procedure.[30,31] Occasionally it may be possible to continue expansion with an exposed implant but only for a few days because each injection to inflate the implant also causes the skin gap to widen.

HAIR FOLLICLE GRAFTING

More recently Barrera has shown successful use of micro- and minigrafts in the correction of large alopecia segments in 32 burn patients.[18] Because of the small size of micrografts (1–2 hair follicles) and minigrafts (3–4 hair follicles), it is hypothesized that the metabolic demand is very low, thus allowing them to survive in scar tissue. This affords an important technique to provide coverage to irregular patches or to provide refinements to misaligned hairlines following various flap coverage techniques.

Conflict of Interest

None of the authors has any conflict of interest to report.

52 Trunk Deformity Reconstruction

PETER DZIEWULSKI and JORGE LEON VILLAPALOS

Introduction

Burn injuries to the trunk may have functional and cosmetic consequences.

The torso, abdomen, and back connect anatomically with the shoulder girdle and the axilla laterally, with the neck superiorly, and with the groin tissue and the lower limbs inferiorly. This means that burn injuries to the trunk may cause damage primarily to three areas:

a. Damage to soft tissue layers including skin, subcutaneous tissue, fascia, muscle, and internal organs
b. Damage to the trunk boundaries, causing potential contracture and functional deficit to the neck, axillae, and groin areas
c. Damage to specialized body parts within the trunk, specifically the breast.

Even though the initial acute management of any extensive burn injury is relatively universal and subjected to well-recognized protocols of trauma resuscitation, the extensive total body surface area (TBSA) that can potentially be involved when the whole of the trunk is injured—up to 36% TBSA—may have devastating consequences: skin, muscle and visceral damage, breast and nipple-areolar destruction, and potential development of life-changing burn scar contractures in the vicinity of the neck, axillae, and groin areas.

It is then easy to understand the potential complexity of the reconstructive challenges that trunk tissue damage may require. Superficial damage may leave minimal functional deficit and barely noticeable cosmetic embarrassment that may not need difficult or lengthy reconstruction, but deeper damage may require the use of multiple reconstructive procedures of ascending order of complexity in several subzones of the trunk: excision of scars, use of split-skin grafts (SSG) with or without the support of dermal matrices, full-thickness grafts, tissue rearrangement procedures based on the z-plasty principle, tissue expansion surgery, and local, regional, distant, or free flaps.

Complex reconstruction will require maximum complicity and collaboration of the burn patient with the multidisciplinary team, specifically with the scar management and physical rehabilitation teams to ensure restoration of anatomy and return of the patient to his normal life and society environment.

The impact of appropriate acute management in subsequent reconstruction cannot be understated. The principles of prompt trauma management, judicious resuscitation, early débridement with a dermal preservation approach and soft tissue cover, and a strong rehabilitation approach impact greatly on the subsequent approach to reconstruction.

Any deep damage to the tissues of the trunk at those levels may cause simultaneously deep soft tissue loss, damage that affects body parts such as the breast, or a burn scar contracture either primarily or secondarily by involvement of those important joint mobile areas.

Recently published International Society for Burn Injuries (ISBI) practice guidelines for burn care[1] supported by best evidence and research established recommendations for optimum acute management of the burn wound.

Those most relevant to successful reconstruction of the trunk are:

- Thermally injured patients should be evaluated using a systematic approach that first seeks to identify the greatest threat to life.
- Evaluation of burns should estimate TBSA utilizing a standardized method and delineate characteristics that require immediate attention from a designated burn center.
- Appropriate resuscitation should be initiated promptly and tailored based on patient parameters to avoid over- and underresuscitation.
- Adult patients with burns greater than 20% TBSA and pediatric patients with burns greater than 10% TBSA should be formally resuscitated with salt-containing fluids; requirements should be based on body weight and percentage burn.
- Abdominal escharotomy should be performed when circumferential or near circumferential eschar is associated with evidence of intraabdominal hypertension (IAH) or signs of abdominal compartment syndrome (ACS).
- Early surgery for small to moderate-sized deep burns (less than approximately 20% TBSA) speeds recovery, might improve outcome, and is cost-effective.
- Tangential excision is the standard method of burn wound excision. Fascial excision may be indicated in very deep burns and high-voltage electrical conduction injuries.
- Burn wound excision and grafting can be undertaken without undue blood loss by using some or all the following: subcutaneous infiltration of burn wound and donor site or topical application of epinephrine solutions, or both; tourniquets for limb surgery; fascial-type excision using electrocautery; other topical hemostatic agents such as thrombin and fibrinogen; prevention of hypothermia; compression dressings; limb elevation; and staged burn excision.
- After excision or débridement of the deep burn wound, it is essential that the wound is covered with autograft skin or an appropriate skin substitute.
- Deep dermal burns (wounds that heal in >3 weeks) require aggressive and monitored scar prevention

therapies augmented with appropriate pain relief and combined with early positioning regimens and physiotherapy for joint mobilization to prevent hypertrophic scarring and joint contractures.
- All extensive hypertrophic burn scars should receive pressure therapy with silicone therapy as the first line of treatment. Restraint should be applied in opting for the surgical modality before scar maturation unless the scar is functionally limiting because of a developing contracture.

Therefore, four clear burn care phases are ultimately considered:

- Initial evaluation and resuscitation
- Wound excision and initial skin cover
- Definitive skin closure and rehabilitation
- Reconstruction and reintegration to society.

Appropriate implementation of these recommendations in a staged fashion ensures the survivability of the burned patient, but also of the quality of the reconstruction.[2]

Reconstruction of the Trunk Soft Tissue Layers

Even though the late effects of burn injury in the tissue layers of the abdomen, torso, and back may be less problematic than in other anatomical areas, the consequences of abnormal scarring and tissue derangement may still cause functional problems such as pain, itching, limitations in activities of daily living, and cosmetic embarrassment.

The torso protects the thoracic cavity and upper abdomen and assists in the process of respiration. The abdominal wall, with its multilayered structure, protects the abdominal viscera and assists in position, breathing, and visceral function.[3] The clinical consequences of the burn injury to this part of the trunk in an acute setting may be relatively mild or utterly devastating if full-thickness soft tissue loss occurs.

ACUTE RECONSTRUCTIVE MANAGEMENT OF THE TRUNK SOFT TISSUE LAYERS

In the acute setting, superficial skin loss may be treated in a relatively conservative fashion with standard dressings or with the application of dermo-protective matrices such as Biobrane or Suprathel. A recent Cochrane review[4] aiming to assess the effects of burn wound dressings on partial-thickness burns suggested that dressing selection should be based on their effects on healing but that other parameters such as ease of application and removal, dressing change requirements, cost, and patient comfort should also be considered. Their conclusion was that, following analysis of a total of 30 randomized controlled trials (RCTs), traditional dressings containing silver sulfadiazine (SSD) were consistently associated with poorer healing outcomes than were biosynthetic (skin substitute) dressings, silver-containing dressings, and silicon-coated dressings.

Dermo-protective skin substitutes are characteristically used to aid reepithelialization in the acute management of partial-thickness burns until full healing occurs.[5] Biobrane is a bi-layered semi-permeable biosynthetic wound dressing with an outer silicone layer, a nylon-net in the middle layer, and an inner porcine collagen type I layer. Suprathel is a synthetic wound dressing consisting of a copolymer-foil of D,L-laktidtrimethylencarbonate and e-caprolakton.

A study comparing both dressings showed satisfying comparable clinical results in the use of both types of prosthetic material.[6]

In the acute setting, extensive burns and injudicious fluid resuscitation may lead to ACS, defined by the presence of organ dysfunction because of increased abdominal pressure or IAH.

Patients with severe burns are at risk for developing ACS due to the large volume of resuscitation fluid that is infused, abdominal wall compliance, and capillary leakage due to increased permeability.[7] This subsequently reduces blood flow to the abdominal viscera and may lead to bowel ischemia, multiorgan failure, and death if not properly addressed.[8]

When decompressive laparotomy is necessary, the complications due to an open abdomen add to those due to the extent of the burn.[9]

Decompressive laparotomy may help in the survival of burn patients, but the mortality can still be up to 50% and introduce a serious physiological and reconstructive challenge.[10]

Recently updated consensus definitions and clinical practice guidelines from the World Society of the Abdominal Compartment Syndrome state that decompressive laparotomy is the standard surgical method to treat severe IAH/ACS despite considerable potential mortality even after decompression.[11] Taking into consideration that the longer the abdomen remains open, the greater the potential complications, this forum of experts established several recommendations significant for the reconstructive strategies of the open abdomen following decompressive laparotomy for IAH:

- Prevent visceral adhesions, loss of soft tissue coverage, lateralization of the abdominal musculature and its fascia, malnutrition, and enteric fistulae.
- Aim to achieve same-hospital-stay closure of the open abdomen.
- Consider the use of negative pressure wound therapy (NPWT) for temporary abdominal closure after decompressive laparotomy.
- Consider component separation to facilitate early fascial closure of the open abdomen.
- Bioprosthetic meshes should not be routinely used in the early closure of the open abdomen compared to alternative strategies.

Several temporizing options using external devices have been suggested to aid the closure of the abdomen following decompressive laparotomy.[12,13]

The use of techniques that apply to the closure of large hernia defects can be used to close large decompressive laparotomy defects as well. The technique of component separation is not contraindicated in the burn patient, even in large burns with a deep pattern of injury.[14]

In this series, fascial access was obtained by raising burned skin flaps at the level of the costal margin from the anterior superior iliac spine inferiorly to the ribs superiorly. These skin flaps were then excised to facilitate grafting of

Fig. 52.1 Allograft cover of the back of an 80% total body surface area (TBSA) burn.

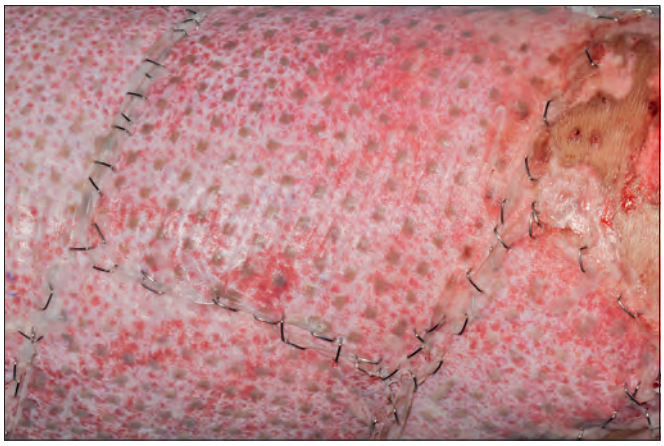

Fig. 52.2 Acute Meek autografting covering back skin following 80% total body surface area (TBSA) burn.

the abdominal wall. The fascial release that facilitated abdominal closure was made, in standard fashion, lateral to the rectus sheath through the aponeurosis of the external oblique muscle.

The acute reconstruction of trunk soft tissue loss related to the direct effects of the burn injury follows the steps applied to other parts of the body. Following stabilization, resuscitation, and débridement, acute soft tissue cover methods are decided based on the depth and extent of the burn, the availability of suitable donor sites, and the microbiology and nutritional status of the patient.

Extensive burns may destroy the skin layers and their blood supply to the extreme of making impossible self-healing and regeneration following a conservative approach. There are occasions in which the paucity of autologous skin or concerns regarding the infection control status of the recipient site recommends the use of temporizing techniques such as xenografts or allografts (Fig. 52.1) until definitive skin cover is achieved. Characteristically split-thickness autografting has been the standard method to address soft tissue loss during this period. A recent expert panel white paper on the surgical management of the burn wound and use of skin substitutes[15] clearly establishes the differences between skin substitute—a commercial biomaterial, engineered tissue, or combination of materials and cells or tissues that can be substituted for skin autograft or allograft in a clinical procedure—from a skin replacement, which is a tissue or graft that permanently replaces lost skin with healthy skin.

Skin grafts are usually meshed to a desired level of expansion; split-thickness grafts are frequently used if the wound bed exhibits appropriate vascularity and the donor skin is available in appropriate quantities. As every burns surgeon is aware, expansion of the SSG is associated with small areas of the wound healing by secondary intention and a poorer scar outcome.

In cases of extreme paucity of donor sites, the use of micrografting (Meek) techniques with or without dermal regeneration templates may represent a suitable form of reconstruction in the acute period[16,17] (Figs. 52.2 and 52.3).

Fig. 52.3 Healing of trunk burn wounds following Meek autografting.

Tissue engineering options have expanded the possibilities of reconstruction for the burned trunk. The ideal tissue engineering device needs to be rapidly available, autologous, site-matched, possess reliable wound adherence and express minimal donor site morbidity, be clinically manageable, improve the quality of scar, and be affordable.[18]

Some of the techniques currently available involve the use of dermal scaffolds such as Integra (Integra Life Sciences Corporation, Plainsboro, NJ), Matriderm (MedSkin Solutions, Dr. Suwelack, Germany), or Pelnac (Gunze Ltd., Japan) and the use of confluent and nonconfluent keratinocyte culture techniques such as Recell (Avita Medical, UK).

A deeper pattern of injury may require the use of more complex steps of the reconstructive ladder. The chest and abdomen, due to their anatomic proximity, are injured together frequently in flame, scald, or electrical injuries. In these situations, in which deep visceral structures may become exposed, the use of large flaps such as the omentum, latissimus dorsi, rectus abdominis, or deltopectoral may be indicated.[19–22]

Fig. 52.4 Hyperpigmented scar on the left side of the chest following electrical injury.

Fig. 52.5 Hypertrophic scar on the abdomen following flame burn.

LATE RECONSTRUCTIVE MANAGEMENT OF THE TRUNK SOFT TISSUE LAYERS

The late reconstruction of the soft tissue layers addresses the impact of abnormal scarring on the cosmetic and functional integrity of the trunk. Reconstruction due to scars in the boundaries of the trunk that alter the functionality of the neck, axillae, and groin area and reconstruction of specific body parts such as the breast will be addressed later in the chapter.

The reconstruction of the soft tissue layers of the trunk is simultaneous with recognized protocols of scar management such as massaging, moisturizing, and sun-protecting the scar; application of compression garments; and physical therapy. These are beyond the scope of this chapter and will not be addressed here.

The wise use of recognized surgical techniques in the acute phase of scar maturation diminishes the complexity of reconstructive needs. These include the use of darts in escharotomies when crossing joints, placing the seams of the skin grafts following skin tension lines, using sheet grafts when possible, placing grafts transversely over joints, applying early pressure therapy, and implementing an early ambulation and exercise regimen.[23]

The skin layers of the trunk may be affected by abnormal pigmentation, hypervascularity, hypertrophic and keloid scars, texture abnormalities in both the reconstructed and the donor site (Figs. 52.4 to 52.6), by the presence of contractures that can be well defined or diffuse, and by the presence of unstable tissue (Figs. 52.7 and 52.8) with a tendency to breaking down.[24] The approach to the management of these abnormalities is to always prioritize function over cosmesis, have a realistic approach to reconstruction, and appropriately time any surgical procedure to avoid interfering with the maturation of scars.

Selective scar resection and direct closure of the subsequent defect may be used in the trunk providing that sufficient skin laxity and tension-free closure exists.[25]

The skin of the abdomen, with its natural laxity and the possibility of redundant tissue, allows the use of recognized techniques of reconstruction such as abdominoplasty and liposuction to become valid options of soft tissue cover after scar excision.[26,27]

Fig. 52.8 Unstable scar on the center of the chest after flame burns treated conservatively. Close-up.

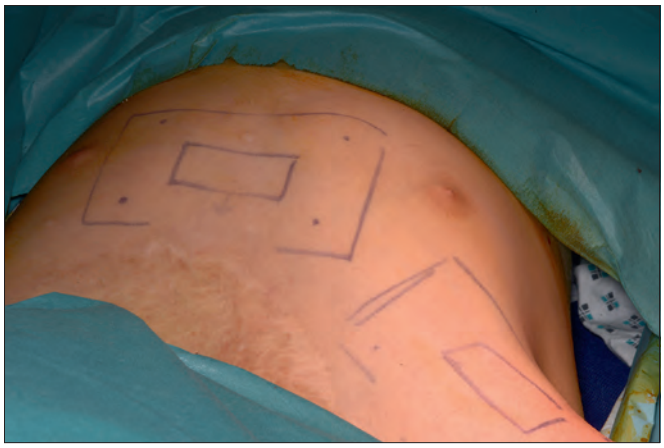

Fig. 52.9 Insertion of osmotic tissue expanders for reconstruction of chest burn scarring: skin markings.

The use of full-thickness grafts or dermal regeneration templates constitutes the next stage in the resurfacing and reconstruction of elective scar revision surgery. They provide the patient with a reconstruction of improved pliability[28,29] that has been proved to withstand even the natural skin tension resulting from a pregnancy.[30]

In cases of cosmetically disfiguring scars that exhibit lack of pliability, the use of tissue expansion techniques either on their own or combined with flap techniques[31] in the trunk offers the possibility of providing reconstruction with autologous skin following a two-stage procedure. The first stage introduces the expanders in a pocket near the scar. Once appropriate expansion has been achieved, including overexpansion,[32] the scar is excised and the subsequent defect covered with a flap of expanded skin usually using a technique of advancement, transposition, or rotation. It has been postulated that the insertion of the largest possible expander, a rectangular shape, and the method of advancement provides the largest amount of expanded tissue available.[33] Traditional tissue expanders are connected to a tubing system and a port that is placed usually over a bony prominence distant to the implant itself. Recently the use of osmotic tissue expanders has introduced a new option for reconstruction and resurfacing of defects after scar excision by avoiding the need for repeated injections. This is especially useful when dealing with pediatric patients.[34]

The insertion of osmotic tissue expanders requires careful dissection of an appropriately sized pocket to place the prosthesis. This is an important issue in the learning curve of the early user of this technique because the osmotic tissue expander tends to grow relatively quickly during the first 2 weeks of insertion.

Insertion of the expander too close to the scar to be reconstructed will increase the potential for implant extrusion. A sequence for the insertion of osmotic tissue expanders can be seen in Figs. 52.9 to 52.14. Following insertion, our protocol is to review the patient weekly for the first month post insertion to review the wound and assess for breakdown or dehiscence. We then follow the patient monthly until the second stage of reconstruction. This stage includes expander removal, scar excision, and reconstruction of the defect usually by advancement (Figs. 52.15 to 52.18).

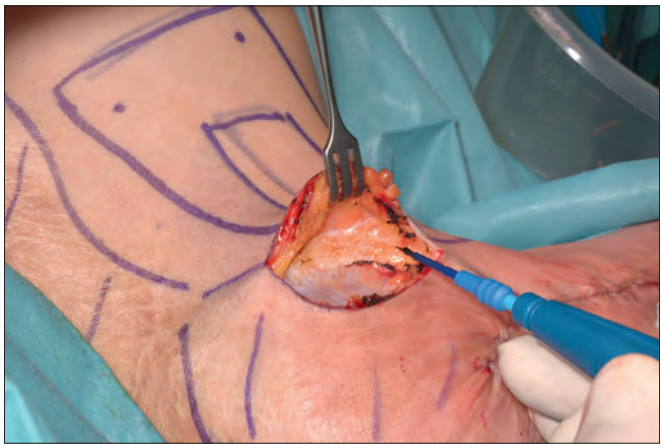

Fig. 52.10 Insertion of osmotic tissue expanders for reconstruction of chest burn scarring: pocket dissection.

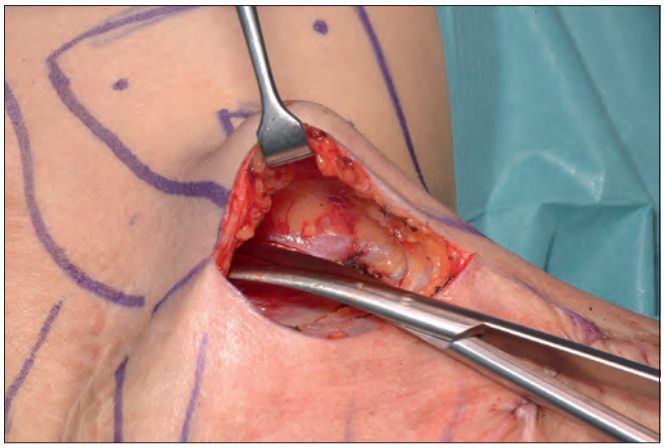

Fig. 52.11 Insertion of osmotic tissue expanders for reconstruction of chest burn scarring: pocket dissection.

Reconstruction of the Trunk Boundaries

Primary reconstruction of the neck, axillae, and groin areas will be described in a different chapter. Scarring in the trunk

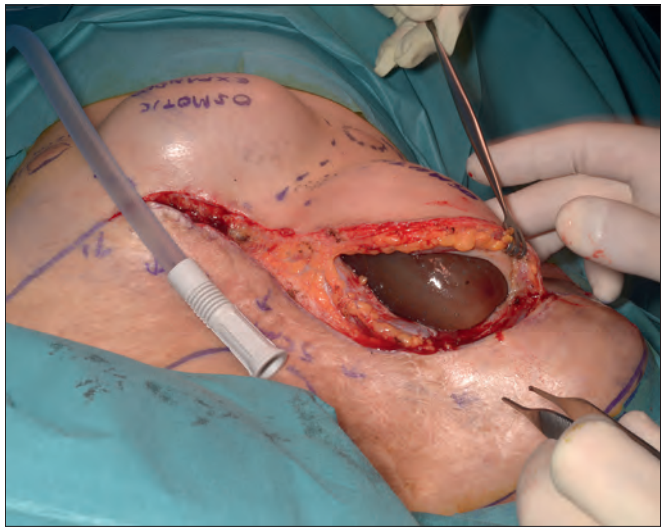

Fig. 52.16 Removal of expanders.

Fig. 52.17 Scar excision.

bordering these areas may cause contractures requiring reconstruction. The management of these involve the use of known principles of reconstruction, such as tissue rearrangement techniques like z-plasties or the introduction of additional tissue with skin grafts, dermal templates, or flaps.

The following clinical case illustrates these techniques. A 21-year-old who suffered 40% TBSA burns 4 years ago presented to our office complaining of tightness in the right flank, right axilla, and neck due to burns in the torso (Fig. 52.19).

Fig. 52.18 Expanded skin flap advancement, reconstruction and closure.

Fig. 52.19 Extensive chest scarring in a 40% total body surface area (TBSA) burned patient.

The scar contracture in the neck was addressed with the use of a dermal substitute (Matriderm) and a thin skin graft. An area of tightness in the right flank was treated with a long releasing z-plasty (Fig. 52.20). The tightness in the right axilla was addressed with a standard z-plasty for the anterior axillary fold and a five-flap plasty for the posterior shoulder area (Figs. 52.21 and 52.22).

The symptoms, once healing of the wounds was completed, were largely resolved by these procedures.

Reconstruction of the Breast

The management of the burned breast is a special and unique part of trunk reconstruction. The specific stages of the surgical techniques used to reconstruct the breast correspond to the distinct developmental stages it goes through. Due to this, reconstruction is particularly important in the prepubescent young girl because absence of a nipple is a noticeable concern.

Fig. 52.20 Z-plasty designed along right flank linear burn scar contracture.

Fig. 52.21 Z-plasty designed in right axillary linear burn scar contracture.

Once disfigurement and deformity are established, accurate assessment, characterization, and planning are crucial to timely and successful reconstruction.[35,36]

Abnormal burn scarring during puberty results in compromised breast growth and displacement of the nipple-areolar complex (NAC), the breast mound, and the inframammary fold.[37]

It is important to avoid excision of the breast bud in order to preserve the development of the breast in prepubescent girls.[38]

Burns during pregnancy and lactation are usually addressed with tangential excision and split-thickness skin grafts to facilitate healing of the wounds, allow breastfeeding, and reduce potential compromise to mother and fetus. The use of bromocriptine in the lactating woman ceases lactation and induces breast involution, allowing tissue cover as soon as possible.[39]

Fig. 52.22 Five-flap plasty designed in right posterior shoulder area.

Table 52.1 Classification of Postburn Breast Deformity

Location	Unilateral Bilateral
Extent	Total Subtotal
Anatomical	Breast mound NAC Inframammary fold
Deformity	Contracture: Intrinsic/extrinsic Hypoplasia Aplasia
Symmetry	

Postburn breast sequelae can be classified according to the descriptions in Table 52.1.

The burned breast can suffer scar contractures that can be intrinsic or extrinsic. Burn scars crossing the inframammary fold show both loss of definition and flattening of this area. When the breast mound is involved, breast growth can be compromised, and hypoplasia or aplasia ensues. The resulting asymmetry will cause distress and a perceived loss of femininity.

PRINCIPLES OF BREAST RECONSTRUCTION

Reconstruction of the burned prepubescent breast is best achieved once breast maturity is attained. Generally scar maturation is awaited, and reconstruction is performed during early adulthood. Appropriate timing of the contracture release is fundamental to avoid a hypoplastic-looking breast during postpubertal development. Staged reconstruction throughout puberty may be required to optimize the aesthetic result.

It is fundamental to document on examination the quality of the skin and scar, the type of scar contracture (intrinsic or extrinsic), the NAC position, the sternal notch to nipple distance, the breast base size, and any differences between the breasts in terms of symmetry, shape, and size. In addition it is important to note what tissues are left and what parts are missing.

It is also important to document what sort of donor sites are available: areas for harvesting both full- and split-thickness skin grafts, the back to examine the latissimus dorsi donor site, and all areas where potential flaps can be harvested for free tissue transfer such as the lower abdomen (deep inferior epigastric perforators [DIEP] flap), inner thigh (transverse upper gracilis [TUG] flap), and the buttock (superior gluteal artery perforator [SGAP] flap). In addition areas of fat deposition on flanks, buttocks, and upper abdomen must also be examined as potential sites of fat harvest for autologous fat transfer.

The reconstructive techniques to improve the burned breast appearance include the principles outlined earlier for reconstruction of the trunk such as skin grafts and tissue rearrangement techniques through z-plasties. Specific breast procedures include nipple reconstruction, implant-based breast augmentation, autologous fat transfer to improve breast volume, free tissue transfer, and reduction of the contralateral unburned breast to match the underdeveloped burned breast. The principles used to reconstruct the burned breast are described in Box 52.1.

Box 52.1 Principles of Postburn Breast Reconstruction

Release scar contracture
Resurface unsightly or painful scar
Replace missing parts including breast mound and NAC
Reestablish symmetry

RELEASE AND SCAR RESURFACING

This is addressed by contracture release to expand breast skin surface and split-thickness skin grafting combined or not with dermal regeneration templates, specifically at the inframammary fold, periareolar area, sternal area, and anterior axillary line. This helps to improve shape and volume (Fig. 52.23).

Expansion of breast skin may be achieved by standard tissue expansion or the use of distal or free flap tissue options.[40]

Reconstruction of the inframammary fold can also be performed by a release and advancement flap through expanded reverse abdominoplasty techniques.[41]

REPLACEMENT OF MISSING PARTS: BREAST MOUND RECONSTRUCTION

Volume replacement can be achieved by prosthetic implant-based reconstruction and autologous tissue reconstruction. The burn scar can be stretched to obtain volume, using tissue expanders inserted either in an open or endoscopic fashion (Fig. 52.24).[42]

Fig. 52.23 Breast contracture release. (Ai) Planned release of symmastia and inframammary fold contractures to release breast mound. (Aii) Following incisional release; note skin deficit. (Aiii) Resurfacing with dermal template. (Aiv) Use of topical negative pressure to secure dermal template and prevent shearing. (Av) Dermal template ready for autografting. (Avi) Second-stage resurfacing of dermal template with sheet autograft. (Bi–Biii) Preoperative views. (Biv–Bvi) Postoperative views following nipple-areolar complex reconstruction showing improvement in projection, cleavage, inframammary fold.

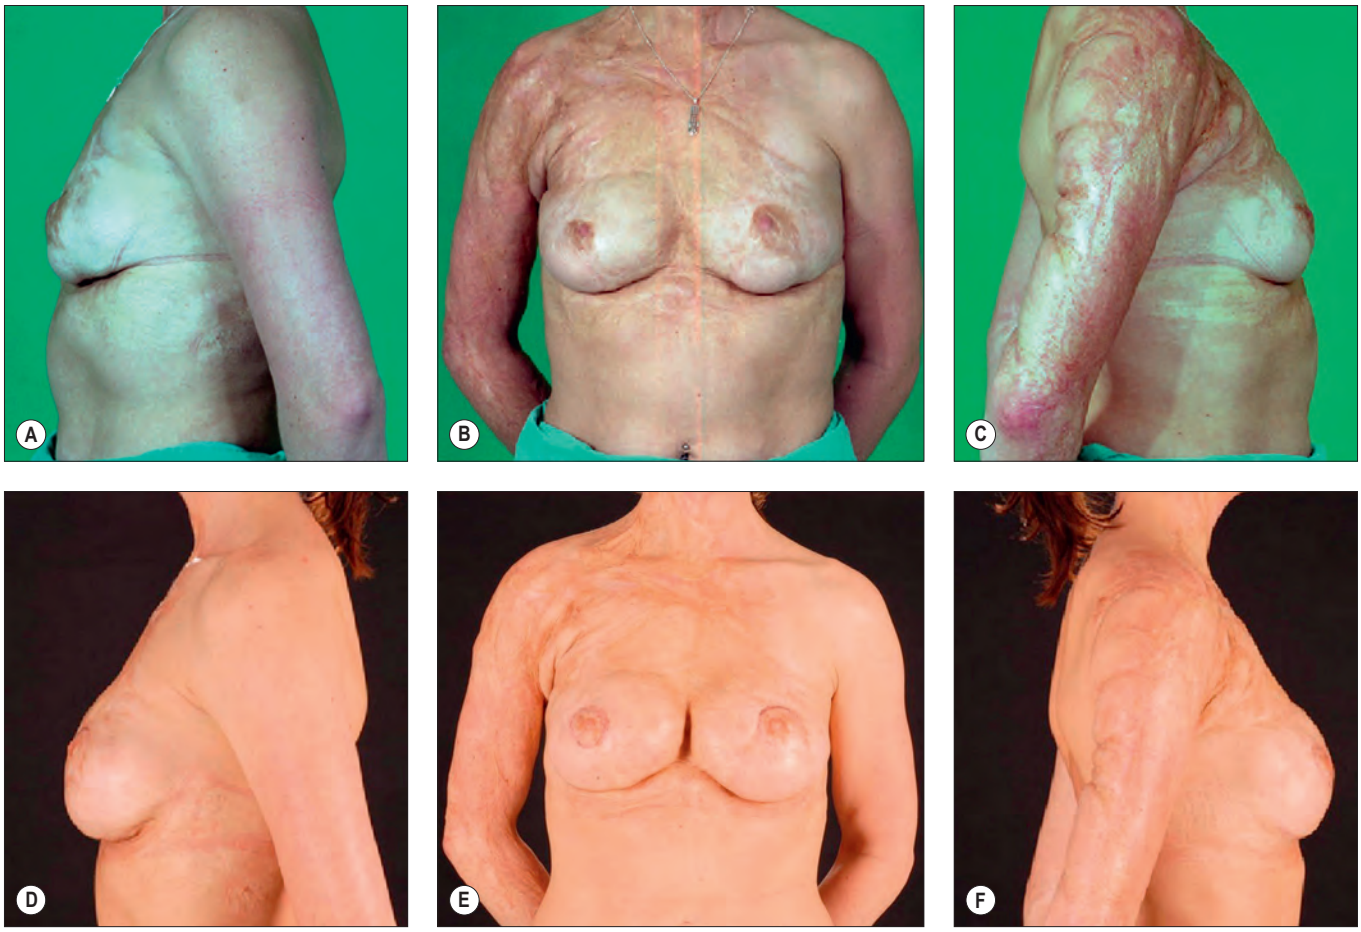

Fig. 52.24 Postburn breast mound reconstruction using tissue expanders. (A–C) Preoperative views showing characteristic flattening of breast, ptosis, and poor definition of cleavage. (D–F) Five-year postoperative insertion of bilateral tissue expanders showing improved projection, cleavage, and volume.

To prevent exposure and extrusion of the implant, submuscular placement and potential flap cover with a pedicle latissimus dorsi flap may be necessary.

Staged use of dermal templates (Integra) followed by tissue expansion appears to be a reliable technique to correct breast hypoplasia:[43]

- *First stage*: Scar release, expander submuscular insertion, and coverage of the anterior chest wall with Integra
- *Second stage, 1 month later*: Grafting of Integra, gradual expander overinflation
- *Third stage*: Expander removal and replacement with a permanent silicone implant.

Total breast reconstruction will be required in cases of breast aplasia. This is addressed with submuscular implants if the skin envelope is appropriate or with an array of flaps in cases of breast bud destruction. This will usually involve replacement of both skin and breast volume through submuscular tissue expansion, pedicle (latissimus dorsi) or free flap (DIEP, SGAP, TUG),[44,45] or a combination of both (Fig. 52.25).[46] Fat transfer provides options both for reconstruction and for scar modulation.[47,48]

NIPPLE-AREOLA COMPLEX RECONSTRUCTION

Reconstruction of the NAC is usually performed at a second stage once breast mound volume and shape have been addressed. The process can be divided into subtotal or total depending on how much of the NAC is preserved following burn injury. Subtotal reconstruction is usually addressed with release and skin grafting.

Total NAC reconstruction characteristically uses local flaps such as the skate or C-V flap but may be limited by the lack of pliability of scarred skin and by lack of projection of the reconstruction.

The areola can be reconstructed by using full-thickness skin grafts or tattooing techniques (Fig. 52.23 Bi–Bvi).

ASYMMETRY

Symmetrization procedures performed on the contralateral breast include breast augmentation or reduction and shaping using mastopexy/reduction techniques. Even though caution is warranted, concerns with reduction mammoplasty due to potential devascularization of the skin graft or NAC have proved warrantless because

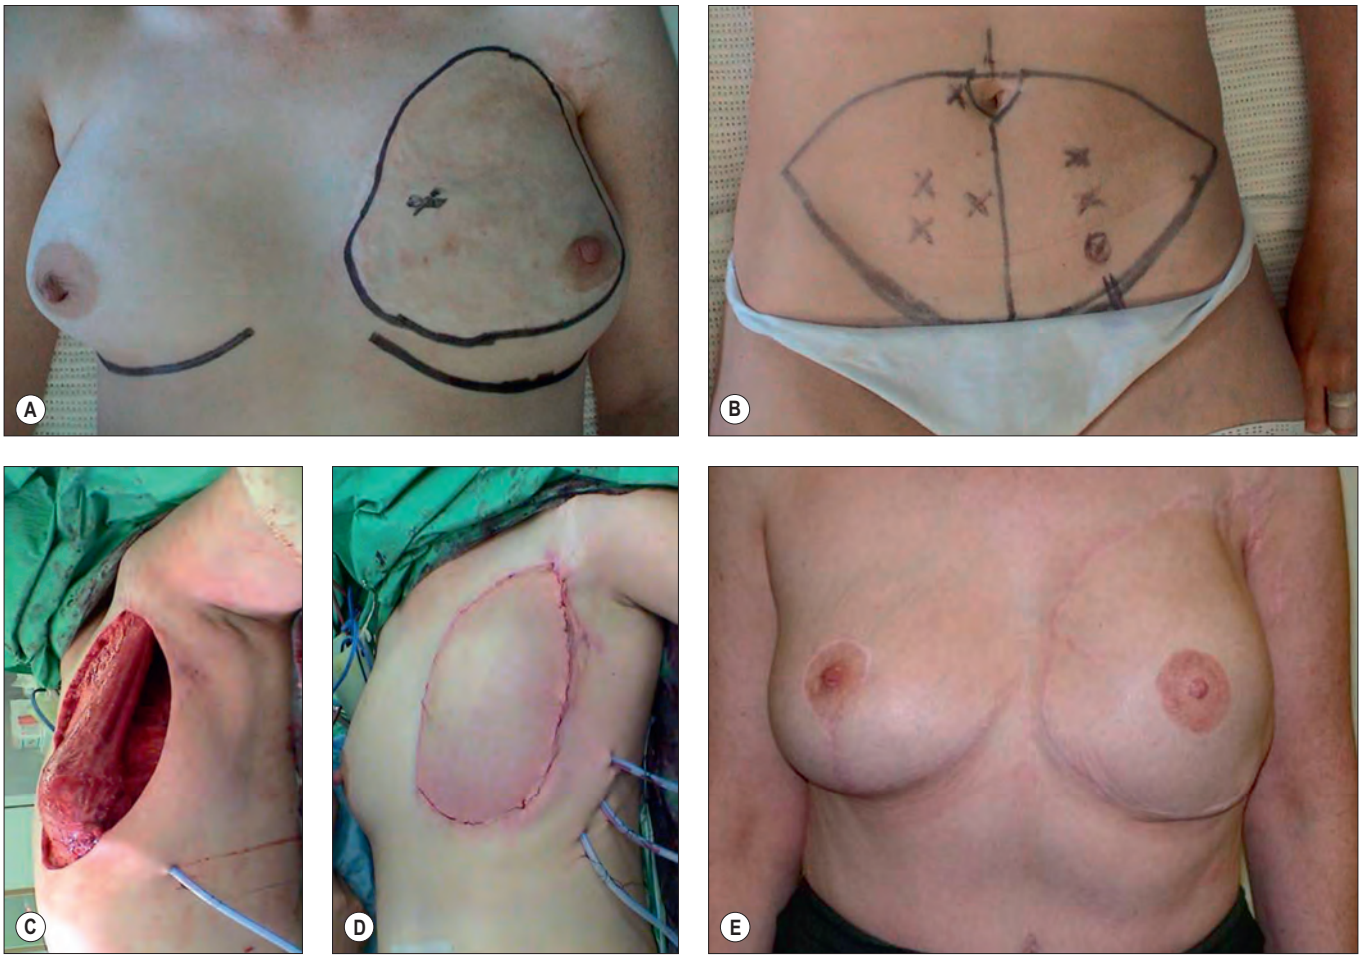

Fig. 52.25 Reconstruction of breast with DIEP flap. (A) Isolated burn scar on left breast in woman requiring mastectomy for breast cancer. (B) Markings for DIEP, including perforators. (C) Following mastectomy, subpectoral implant placement. (D) DIEP flap in place for skin cover. (E) Postoperative appearance following nipple-areolar complex reconstruction and contralateral mastopexy for symmetrization. (Case courtesy of Mr V Ramakrishnan FRCS [Plast] Consultant Plastic and Reconstructive Surgeon, St. Andrews Centre for Plastic Surgery, Chelmsford, Essex, UK.)

reduction mammoplasty in this group of patients is safe and carries minimal risk.

Conclusion

Initial care of the burned breast follows the general principles of burn management for the rest of the trunk, including resuscitation and judicious wound débridement with dermal and NAC preservation. This minimizes postburn deformity and maximizes reconstructive potential. Breast reconstruction principles include preservation and restoration of shape, volume symmetry, inframammary fold, NAC, and breast symmetry. Soft tissue cover applies reconstructive ladder principles of ascending complexity including symmetrization procedures.

53 Management of Contractural Deformities Involving the Shoulder (Axilla), Elbow, Hip, and Knee Joints in Burned Patients

KAREL D. CAPEK, RAMON ZAPATA-SIRVENT, and TED T. HUANG

Introduction

Burn injuries, regardless of the etiology, rarely involve a joint itself. However the joint function is often impaired because of burns. The joint problems and joint deformities noted in burn patients are mostly due to physical inactivity combined with limitation of joint movement because of scar contracture. The consequences of joint dysfunction are usually left for reconstruction later in the course of burn convalescence.

Contractural Deformities of the Shoulder (Axilla), Elbow, Hip, and Knee Observed in a Burned Patient

THE FACTORS LEADING TO FORMATION OF CONTRACTURAL DEFORMITIES

Folding bodily joints in flexion, a so-called posture of comfort, is a characteristic body posture seen commonly in a distressed individual. Although the exact reasons are not entirely clear, contraction of muscle fibers at rest and contractile force difference between the flexor muscle and the extensor muscle play an important role in the genesis of this body posture. The magnitude of joint flexion, furthermore, increases as an individual loses voluntary control of muscle movement, as frequently occurs in a burn victim (Fig. 53.1). A prolonged period of physical inactivity associated with burn treatment and scar tissue contraction around the joint structures as the recovery ensues further impedes joint mobility.

A subtype of joint problem seen with major burn injuries is heterotopic ossification. This may affect any joint, although the elbow is by far the most frequently affected. Its initial symptoms are markedly increased pain with motion and hyperemia/swelling. A high index of suspicion is needed to differentiate this problem from background post-burn pain.[1–3] The splinting and exercise/range-of-motion (ROM) care of patients with heterotopic ossification differ from standard burn rehabilitation, as noted later.

INCIDENCE OF BURN CONTRACTURE INVOLVING THE SHOULDER (AXILLA), ELBOW, AND KNEE JOINTS

Burn treatment that requires a long period of bed confinement and physical inactivity as well as restriction of joint movement will lead to joint dysfunction. Consequently every bodily joint (i.e., the vertebral, mandibular, shoulder, elbow, wrist, finger, hip, knee, ankle, and toe) is susceptible to changes. Of various bodily joints involved, the contractural deformities of the shoulder (axilla), elbow, hip, and knee are relatively common. Factors such as a wide range of joint movement and asynchronous muscular control are characteristic features of these joints, and, when combined with a high vulnerability to burn injuries, are the probable reasons accounting for the high incidence encountered. A review of the records of 1005 patients treated at the Shriners Burns Hospital in Galveston, Texas, over 25 years, indicated that the elbow was the joint most commonly affected. There were 397 patients with elbow joint deformity followed by 283 knee contractures. There were 248 axillary deformities. Hip joint contracture was the deformity least encountered and was noted in only 77 patients (Table 53.1).

EFFICACY OF SPLINTING IN CONTROLLING BURN CONTRACTURES OF SHOULDER (AXILLA), ELBOW, AND KNEE JOINTS

Although Cronin in 1955 demonstrated that the neck splint was effective in preventing recurrence of neck contracture following surgical release,[4] the routine use of splinting for burn patients did not become a part of the regimen of burn wound care in Galveston until 1968, when Larson, the former Surgeon-in-Chief and Willis, the former Chief Occupational Therapist at the Shriners Burns Institute, began to fabricate splints with thermoplastic materials to brace the neck and extremities.[5–8]

For more than three decades, a neck brace, a three-point extension splint, and a molded brace fabricated from thermoplastic materials—prototypes of devices used to splint the neck, elbow, and knee joints—were used in the management of burn patients at the Shriners Burns Hospital and

Table 53.1 The Distribution of Joint Deformities

Joint Involved	*n*
Shoulder (axilla)	248
Elbow	397
Hip	77
Knee	283
Total	1005

Fig. 53.1 The posture of comfort characterized by flexion of shoulder (axilla) and elbow joints, plus hip and knee joints, is assumed by patients under distress, as in burn patients.

the University of Texas Medical Branch Hospitals in Galveston, Texas. An "airplane splint" similarly made of thermoplastic materials was also used to splint the axilla when the use of other splinting and bracing techniques, such as a "figure-of-eight" bandage, were not feasible.

A study was conducted in 1977 to determine the efficacy of splinting across large joint structures such as the elbow, axilla, and knee by reviewing the records of 625 patients. There were 961 burns over these joints in this group of patients. Of these, 356 had involved the axillae, while 357 and 248 involved the elbow and knee joints, respectively. The incidence of axillary contractural deformities without splinting was 79%; with splinting this decreased to 26%. The subgroup able to wear splints for longer than 6 months had the lowest incidence of contracture at 15%, whereas discontinuation of splinting before 6 months identified a subgroup at high risk for splint failure, with 80% incidence (similar to a no-splint group). At the elbow, the incidence of contracture was 55% without splinting, decreasing to 12% with splinting, and further decreasing to 6% if splint usage was maintained for more than 6 months. At the knee, the incidence of contracture was 37% without splinting, decreasing to 3% with splinting, and further decreasing to 1% if splint usage was maintained for more than 6 months (Table 53.2). Although splinting and bracing were shown to be effective in minimizing joint contracture, it was not entirely clear if restriction of joint movement would affect the quality of scar tissues formed across the joint surface. The effects were assessed by determining the frequency of secondary surgery performed in this group of patients. More than 90% of 219 individuals who did not use splinting/bracing required reconstructive surgery. In contrast, the need for surgical reconstruction in individuals who wore splints was 25%.[9]

Knee			
Severe/moderate	26	4	2
Mild/none	45	16	155

Management During the Acute Phase of Recovery

It is believed that inadequate physical exercise and lack of joint splinting and bracing, although allowing a patient to assume the posture of comfort, are the main factors responsible for the genesis of contractural deformities seen in patients during the acute phase of recovery from burn injuries. The deformities, furthermore, are made worse because of skin involvement and burn scar contracture. To minimize this undesirable consequence of burn injuries, proper body positioning and splinting of the joint structures must be incorporated into the regimen of burn treatment. The treatment should be implemented as soon as the patient's condition allows.

BODY POSITIONING AND JOINT SPLINTING

Body Position

Although a supine position is preferred, the patient may be placed in a lateral decubitus position while confined in bed. The head should be placed in a neutral position with the neck slightly extended. For a patient placed in a supine position, neck extension is achieved by placing a small pad between the scapulae to facilitate scapular traction. A neck brace may be used if a patient is placed in other body positions.

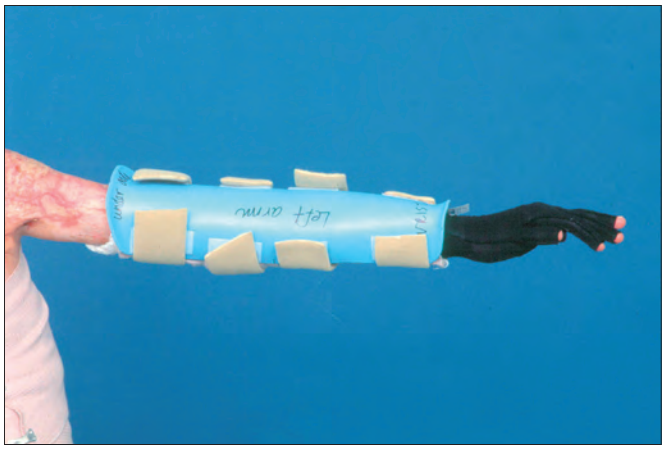

Fig. 53.2 A splint made of thermoplastic material is used to limit joint flexion.

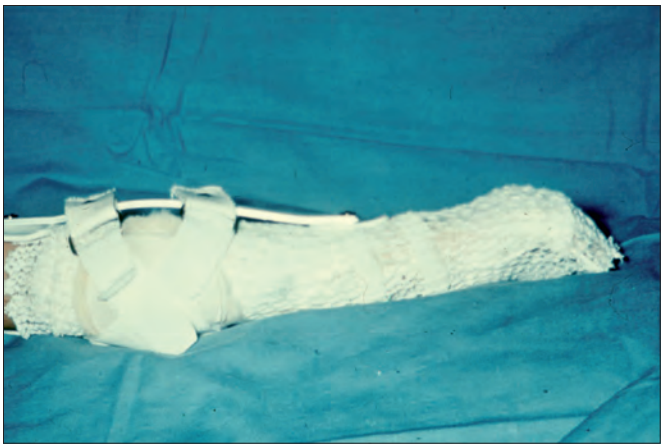

Fig. 53.3 A three-point extension splint manufactured similarly to an orthotic device is used either to extend a contracted elbow joint or immobilize the joint in full extension.

Shoulder (Axillary) Joint. The shoulder joint is kept at 90–120 degrees of abduction and 15–20 degrees of flexion. The position is not only useful in protecting the brachial plexus from traction injury but also effective in maintaining the stability of the glenohumeral joint. The position is best kept with the use of foam wedge, trough, and/or airplane splints. A figure-of-eight wrapping over a pad around the axilla, more frequently used for patients during the intermediate phase of recovery from injury, is effective in maintaining shoulder abduction. It is also useful in preventing excess shoulder flexion.

Elbow Joint. Elbow flexion is commonly seen in a distressed patient. Rigid flexion contracture of the elbow is a common sequela if the elbow is left unattended. With burns of the skin around the olecranon, exposure of the elbow joint is a common sequela if the elbow is allowed to contract freely. Maintaining the elbow in full extension therefore is essential. An extension brace (Fig. 53.2) or a three-point extension splint across the elbow joint is effective for this purpose (Fig. 53.3). If concern for heterotopic ossification develops, the elbow splint should be expediently changed to a functional position (around 90 degrees flexion) to avoid fusion of this joint in extension.

Wrist Joint. A contractural deformity involving a wrist joint is relatively common in individuals with hand burns that were not splinted properly. A cock-up hand splint should be applied to maintain a 30-degree wrist extension (Fig. 53.4).

Hip Joint. A contractural deformity of the hip is relatively uncommon unless the hip joint is allowed to remain flexed for a long period of time. Hip extension can be achieved by placing the patient in a prone position. In a supine position, 15–20 degrees of abduction is maintained with the use of a brace or anklet.

Knee Joint. Flexion of the knee is another posture commonly assumed by a burned victim. Similar to the elbow, uncontrolled flexion of the knee joint will lead to exposure of the joint structure, especially in instances where the injuries involved the patella surface. Maintenance of the knee in full extension is, in this sense, an essential component of therapeutic regimen. This is accomplished by means of a knee brace or a three-point extension splint to assure a full extension of the knee joint (Fig. 53.5).

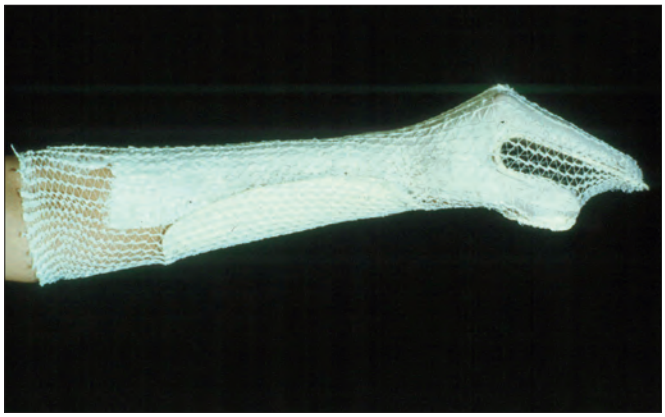

Fig. 53.4 A hand splint that will maintain the DIP-PIP joints at full extension and MCP joints at 70 degrees while keeping the wrist joint at 30 degrees extension (i.e., the hand in a position of "safety").

EXERCISE

Although exercising a burned victim is an integral part of burn therapy, it is seldom implemented until the resuscitative measures are completed and the condition of the patient is considered stable. The primary goal of exercise is to maintain the functional integrity of joint structures and muscle strength. This is attained by, in most instances, moving the joint manually and the muscles passively. Frequency and intensity of an exercise regimen, however, may vary depending on the magnitude of injury and the extent of joint involvement. The treatment, if possible, should be intensive and rendered as frequently as possible.

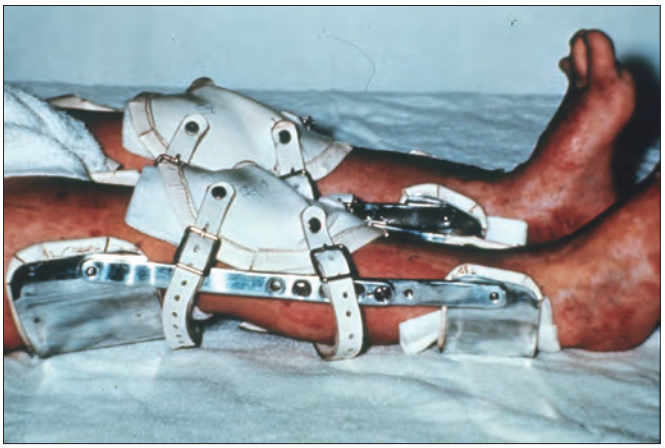

Fig. 53.5 A three-point extension splint can be also used to manage the flexion contractures of a knee joint.

Management During the Intermediate Phase of Recovery

A period starting from the second month following injury through the fourth month is considered the intermediate phase of recovery from burn injuries. The burn victims typically will have full recovery of physiologic functions with integument integrity restored. The cicatricial processes at the injured sites, on the other hand, are physiologically active, even though healing of the burned wound is considered satisfactory. This process is characterized by, in addition to a maximal rate of collagen synthesis, a steady increase in the myofibroblast fraction of the fibroblast population in the wound,[10,11] a cellular change believed to account for contraction of the scar tissues. Continuous use of splinting and pressure to support joints and burned sites is, in this sense, essential to control changes caused by ensuing scar tissue formation and scar contracture.

BODY POSITIONING AND JOINT SPLINTING

Joint splinting and body positioning are similar to the regimen used during the acute phase of burn recovery. That is, the shoulder is kept at 15–20 degrees of flexion and 80–120 degrees of abduction. A figure-of-eight wrapping over an axillary pad is used to maintain this shoulder joint position (Fig. 53.6). The elbow and knee joints are maintained in full extension by means of a three-point extension splint or brace. A pressure dressing or garment is incorporated into the splint. In instances where the use of figure-of-eight bandages or pressure dressings and/or garments is not feasible because of recent surgery, devices such as an airplane splint (Fig. 53.7) or a three-point extension splint may be used to splint the axilla, elbow, and knee joints.

PRESSURE DRESSING

A compression dressing, originally incorporated in the treatment of burned wounds of the upper and lower extremities at the Shriners Burns Hospital in 1968 as a means to provide mechanical support to healing wounds,

Fig. 53.6 An elasticized bandage is used to wrap around the shoulder (axilla) joints in a figure-of-eight fashion to extend and abduct the shoulder joints. An axillary pad is included in the wrapping to increase pressure upon the axillary fold.

Fig. 53.7 An airplane splint made of thermoplastic materials is used to maintain shoulder abduction. The angle of separation may be increased as the joint becomes more mobile.

is effective in reducing tissue swelling and in promoting softening of a burned scar. Compression of a burn wound even while healing is still in progress is most easily achieved by wrapping the extremity with an elasticized bandage. Wrapping of the extremity should begin at the hand or foot. The bandage is moved cephalad in a criss-cross fashion. The splint is reapplied over the bandage. It is important to rewrap the extremity three to four times daily. Wrapping an extremity with an elasticized bandage can produce a pressure gradient of 10–25 mm Hg.[6,12] The use of a pressure dressing should be continued for 12–18 months.

Management of Established Contractural Deformities

Contraction of the shoulder, elbow, hip, and knee joints can occur despite proper splinting and intensive physical therapy. Surgical reconstruction of contractural deformities, in this sense, remains an essential component of patient care and patient rehabilitation. The task of deciding the timing of surgical intervention, however, can be difficult and requires detailed evaluation of the patient and the deformity. The following are ascertained before surgery:

a. The causes of joint immobility
b. The extent and availability of nearby tissues that could be used for reconstruction
c. The extent of maturation of scar tissues that surround the joint.

PATIENT EVALUATION

Numerous factors will affect joint movements in burn patients. Although hypertrophy and contraction of scar tissues and/or contracted skin graft around a joint are the most common causes of joint impairment, changes in the ligamentous structures or the joint itself due to burn injuries could also limit joint mobility. Detailed examination that may include radiographic assessment of the joint structures is essential in order to formulate a definitive treatment plan.

NONOPERATIVE OR MINIMALLY INVASIVE APPROACH TO CORRECT A CONTRACTED AND/OR STIFF JOINT

Restoration of movements in a contracted and/or stiff joint may be attained by minimally invasive or nonsurgical means.[5–9,13] "Pushing" and "pulling" of an extremity that, in turn, stretches contracted scars and tissues around an affected joint is the principle behind this modality of managing a contracted and/or stiff joint. The treatment is found to be especially effective in mobilizing a contracted joint caused by a long period of physical inactivity and, in some instances, by scar contracture.

Although the morbidities associated with this modality of treatment are minimal, breakdown of the skin due to pressure and/or friction resulting from pushing and pulling can occur.

Shoulder (Axillary) Contracture

Tight scars formed across the shoulder joint, usually in the area along the axillary folds, often limit joint movement. The joint stiffness caused by scar contracture may be further aggravated by physical inactivity, especially if the patient is allowed to remain in the posture of comfort.

Two nonsurgical methods are commonly used to mobilize a contracted shoulder (axilla) joint. One is the figure-of-eight compression dressing technique and the other an airplane splinting technique.

Figure-of-Eight Compression Dressing. An elasticized bandage is wrapped over a pad placed in the axillary fold and around the shoulder joint in a figure-of-eight fashion to extend and abduct the shoulder. The dressing must be worn continuously, and it is removed only for cleansing. Continuous wearing of the dressing for a period of 3–6 months is necessary to obtain release. The mobility of the joint increases as the scar tissues across the axilla soften. The extent of release may be limited if the scar is thick and unyielding to pressure (Fig. 53.8).

Airplane Splint. This splint is fabricated with a thermoplastic material. The spreading angle of the splint is conformed to the extent of the shoulder (axilla) joint held at maximum abduction plus 10–15 degrees of extension. Abduction and extension of the joint (i.e., elevation of the arm) will be maintained by pushing the arm away from the upper thorax. Care is needed to protect the skin over the inner aspect of the arm and the side of the chest. The splint is changed regularly as the angle of joint abduction increases. To achieve the needed release, in most instances 1–3 months of continuous use of this device is usually necessary (Fig. 53.7).

Elbow and Knee Contracture

Flexion contracture is the most common deformity encountered in these two joints. The scar formed across the antecubital and the popliteal fossae frequently aggravates the magnitude of contractural problems in these joints. The following techniques are frequently utilized before surgery to obtain joint movement and joint extension.

Three-Point Extension Splint. The three-point extension splint is assembled similarly to a prosthetic/orthotic device. Two sidebars hinged at the middle are connected with a bracing trough at the end. A cap pad is attached at the mid-section of the sidebar to fit over the elbow or kneecap. The splint is placed across the antecubital fossa or popliteal fossa. Fitting of the splint is adjusted with Velcro straps (Figs. 53.2 and 53.3).

The amount of extension achieved by the joint is determined by the extent of preexisting joint stiffness. The angle of extension is initially determined by the angle of joint contracture. The magnitude of extension is controlled by tightening the olecranon or patellar pad. Extension is increased gradually as the joint gains its mobility. Problems encountered with the use of a three-point extension splint are uncommon; however breakdown of the skin can occur. Leverage attainable from three-point pressure application may be limited in a young individual because of short limb

Fig. 53.8 **(A)** A 6-year-old boy sustained burns to the right side of his body extending from the lower neck to the upper thorax that included the axillary crease. **(B)** He experienced difficulty in extending both the neck and the right arm because of ensuing contraction of scar tissues around the neck and the axilla. **(C)** A figure-of-eight dressing was used to maintain the shoulder extension and abduction. The dressing was used for 12 months. **(D)** He regained shoulder extension and mobility with the use of pressure dressing.

length. In such instances, the skeletal traction technique may be used.

Skeletal Traction Technique. Utilizing a skeletal traction technique to restore movements in a contracted joint typically requires percutaneous insertion of a Steinmann's pin through the radius for the elbow joint and the tibia for the knee joint. The pin is inserted through both cortices at the junction of the proximal two-thirds and the distal third of the radius or tibia. A contracted joint can be mobilized by continuous and constant "pull" on the long bone utilizing the gravitational force generated by 10–15 pounds of weight hung with a pulley device.

For a flexion deformity of the elbow, the patient is placed in supine position. The pulley traction device will provide a horizontal and then a vertically downward pull (Fig. 53.9).

Instead of a skeletal traction device, a weight placed around the ankle, with the patient placed in prone position, may be used to pull the foreleg to loosen a contracted knee. This technique is especially useful in treating individuals with a limited knee flexion contracture. Traction is continued for a period of time and is repeated several times a day (Fig. 53.10).

Although morbidities due to infection are uncommon, the continuous and constant force of pull can cause

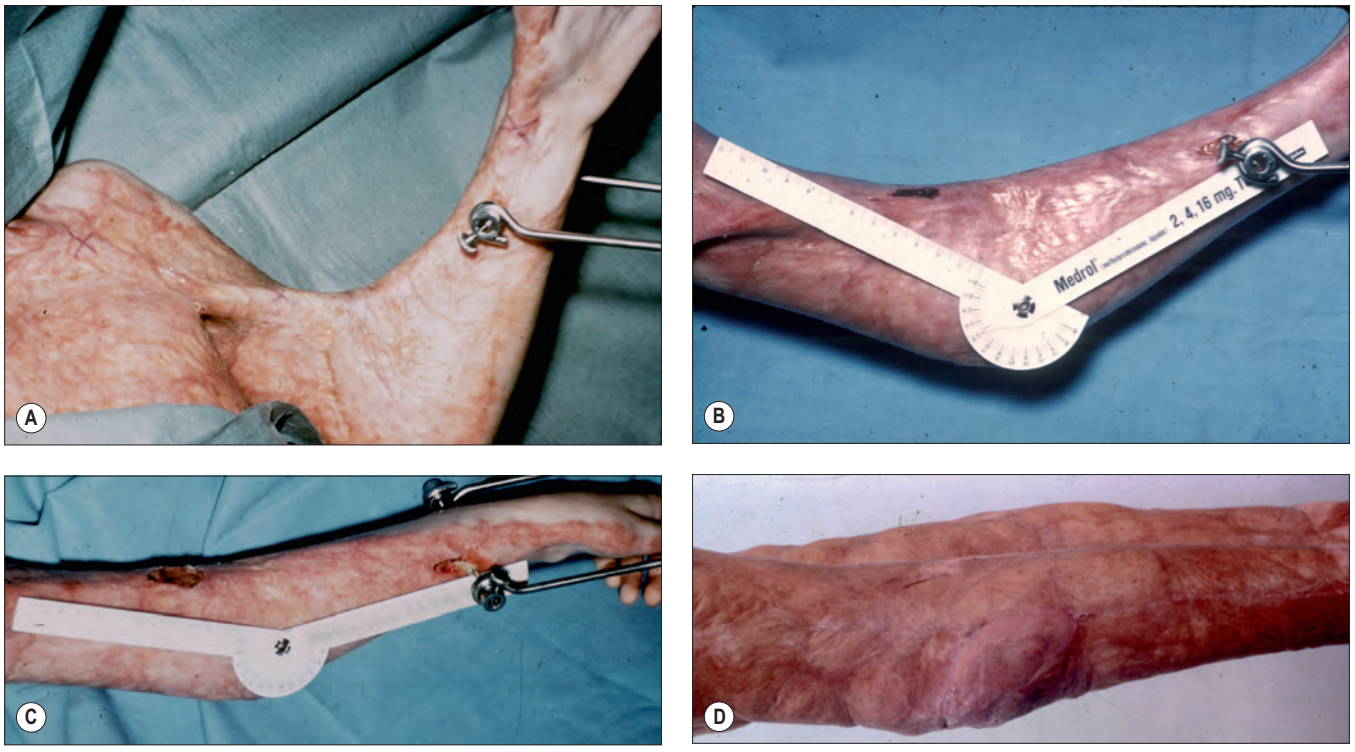

Fig. 53.9 A contractural deformity had developed involving the left elbow joint, even though there were no direct injuries involving the joint. A Steinmann's pin was inserted through the distal third of the radius for traction. A 500-g weight was used. A full extension of the contracted elbow joint was completed in 3–4 days.

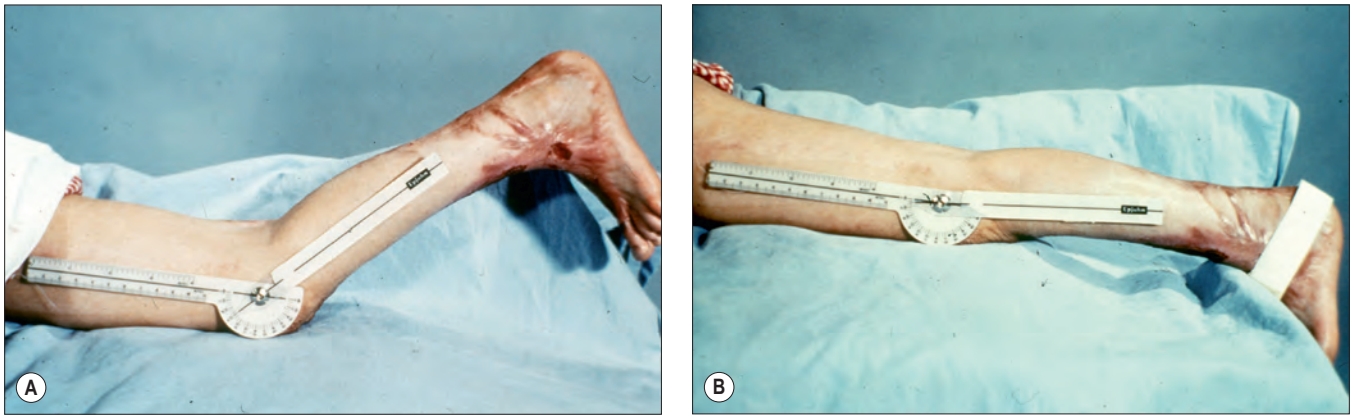

Fig. 53.10 A knee contracture developed in an 8-year-old boy due to improper positioning and immobilization of the knee joint. There were no direct injuries involving the knee area. With the patient being placed in a prone position, the ankle was strapped with a 10- to 15-pound weight. The flexion contracture was relieved in 3 days.

breakdown of the skin, typically located in the area across the joint surface. The wound can be temporarily covered with a surgical or biological dressing. Closure of the wound is contemplated once the joint contracture is fully corrected.

SURGICAL TREATMENT OF A CONTRACTED JOINT

Surgical treatment of a contracted joint is contemplated in individuals in whom the use of nonsurgical treatment is ineffective and where functional integrity of a joint is at jeopardy.

Presurgical Evaluation

The patient is seen and the involved joint is examined before surgery. The following features are assessed:

- *The extent of joint contracture* is determined and the passive and active range of joint motion is assessed. Radiographic evaluation may be obtained to delineate the structural integrity of the joint.

- *The magnitude of scarring and scar thickness* is assessed. The scar is usually thickest across the joint surface.
- *The location and size of uninjured skin* are delineated. The availability of uninjured skin frequently determines the technique of reconstruction. Skin graft and skin flap donor sites are also ascertained.
- *The point and axis of joint rotation* are located. The line of incisional release is in alignment with the axis of joint movement.

Techniques of Joint Contracture Release

Despite detailed examination before surgery, the exact cause of joint stiffness can only be delineated with surgery. In practice, contraction of the scar tissues across the joint structure is the most common cause of contractural joint deformities.

Release of Joint Contracture by Incising the Scarred Tissue. A contracted joint is freed by making an incision in the scar across the joint surface. The incision is placed in line with the axis of joint rotation. The incision is confined within the width of the scar initially and is lengthened as necessary to achieve the intended release. Prior infiltration of the area with lidocaine containing epinephrine in 1 : 400 000 concentration is useful in obtaining hemostasis and later pain control. The incision must be made with caution to avoid injuring major vessels and nerves. This is achieved by using a pushing instead of a slicing motion with a surgical blade to free the scarred tissues. The extent of release is assessed by the improvement of joint motion gained as the scarred tissue is severed.

In rare instances, cicatricial changes could involve the joint capsule. Then, reconstruction of the capsular structure will be necessary.

Z-Plasty Technique. A contracted area can be lengthened by use of the z-plasty technique.[9] The technique utilizes the principle that a contracted wound is lengthened by interposing two triangular skin flaps mobilized from an unburned area immediately adjacent to the area of release. The lengthening of the wound is maximally attained by interposing two triangular flaps of 60-degree angles. While the z-plasty technique is an excellent means to ameliorate the problem of wound contracture, it is not feasible if the amount of uninjured skin adjacent to the wound is limited.

Wound Coverage

There are six basic techniques of wound coverage. Namely:

a. Primary closure of the wound
b. A full-thickness or partial-thickness skin graft
c. An interposition skin flap mobilized from the area adjacent
d. Combination of an interposition skin flap and skin grafting
e. A muscle or skin-muscle flap mobilized from the adjacent area
f. A free skin or skin-muscle flap harvested from a distant site and transferred via a microsurgical technique.

Primary Closure of the Wound. Wound closure *per primum* following burn scar excision is difficult if not entirely impossible. Inelasticity of the skin surrounding the wound and an inadequate amount of uninjured skin available for mobilization and closure preclude the use of this method of wound closure. Closure of a resultant wound following release, in practice, would defeat the original objective of contractural reconstruction.

Skin Grafting Technique. The use of a skin graft, full or partial thickness, to cover a wound is the most fundamental technique of wound coverage; it is technically simple and has minimal morbidities.

OPERATIVE TECHNIQUE. A *partial-thickness skin graft* of 15/1000th to 20/1000th inch in thickness is harvested from an unburned area using a dermatome. The scalp, lower abdomen, and the anterior surface of the upper thigh are common donor sites.

A *full-thickness skin graft* can be harvested from the lower abdomen, above the suprapubic or inguinal area, without leaving unsightly donor site defects. The subdermal fatty tissues are removed but attempts should be made to preserve the subdermal capillary plexus (Fig. 53.11). The donor defect is usually closed primarily.

The graft is cut to fit the defect and the edges are anchored with 3-0 silk sutures. The ends are left sufficiently long to tie over a bolster to immobilize the graft. Several anchoring mattress stitches using 4-0 or 5-0 chromic catgut sutures may be placed in the center of the graft to immobilize the skin graft against the base. Hemostasis around the recipient site is essential. Hematoma formed underneath the graft will hinder the "take" of the graft.

AFTER-CARE. The bolster is usually removed 4–5 days after the procedure. Bodily fluid or blood elements accumulated underneath the graft (i.e., seroma and/or hematoma) are evacuated. This is achieved by making a small nick in the graft with a pair of surgical scissors. The fluid is "rolled" out with a cotton tip applicator. The joint is immobilized immediately, and a pressure dressing is used to minimize the consequence of contracture. Physical exercise is resumed 3 weeks after the surgery.

Interposition Flap Technique. This technique, known by various names such as the three-quarter z-plasty technique or the banner flap interposition technique, is the most useful method of wound coverage following a releasing procedure for a contracted joint. The technique is based on the principle that an open wound consequential to surgical release may be covered with a skin flap mobilized from an adjacent area. While the flap design is technically simple, it requires an area of movable tissue containing as little scar as possible adjacent to the released wound. Smaller defects can be treated with flaps of skin and subcutaneous tissue, although most functionally significant contractures require adjunctive measures to provide effective and durable release. We have found that an interposition flap, with its width tapering at its distal extent, can be fabricated with a length-to-width ratio as high as 5 : 1 by carrying the subjacent fascia with the rotation flap; this flap is the mainstay of our treatment of axillary contractures.[14,15]

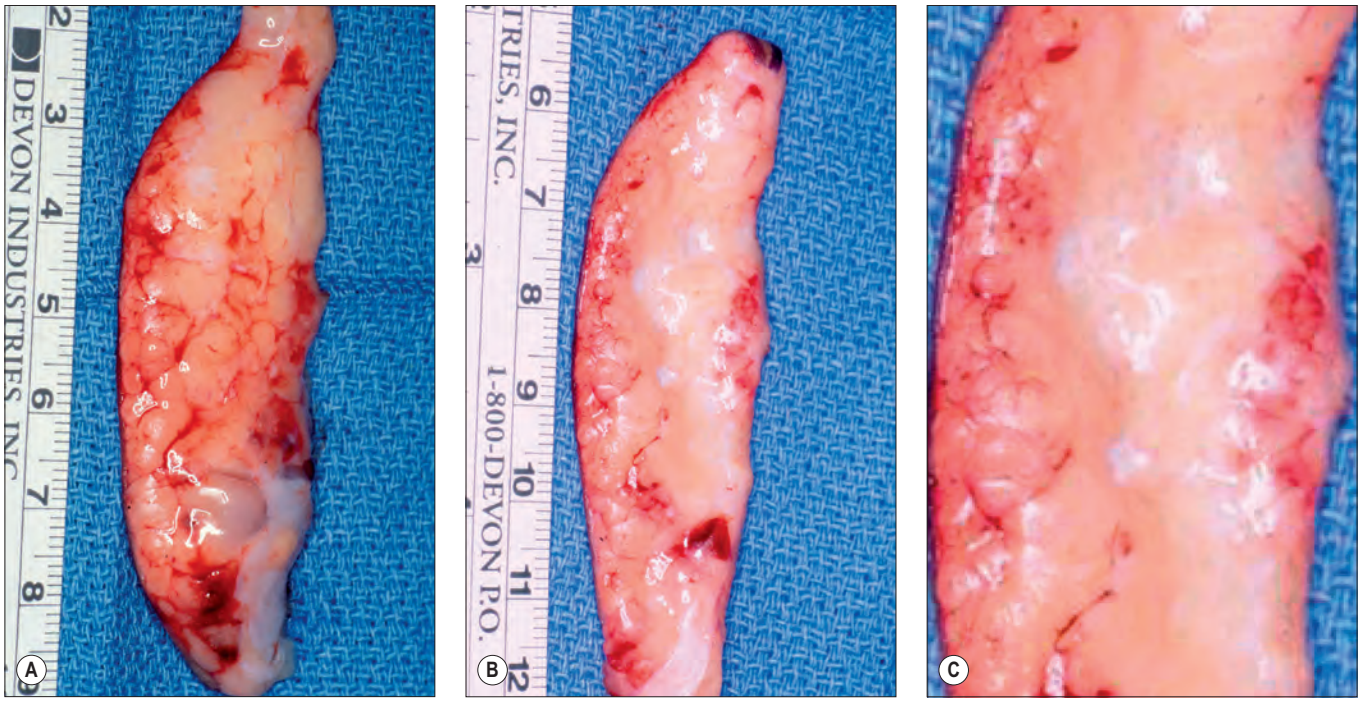

Fig. 53.11 **(A)** A piece of skin with subcutaneous tissues is removed from the abdomen and will be used as a full-thickness skin graft. **(B)** The subcutaneous fatty tissues were sharply removed with a pair of fine scissors. The capillaries were left undisturbed. **(C)** A close-up view to show the capillaries that are left in the graft.

OPERATIVE TECHNIQUE. A triangular skin flap is designed in an unburned area adjacent to the wound following release. A vertical limb of the flap begun at the end of released wound edge is set at a 90-degree angle to the end of the wound. The limb length is equal to the wound length. A triangular flap is formed by making the width of flaps at mid-section the same as the wound width. The flap can be based either proximally or distally depending on the direction of the triangular flap designed. The flap is dissected out and rotated 90 degrees to cover the defect. The flap donor defect is closed primarily. Healing of the wound is usually uneventful (Fig. 53.12).

The width of flap may be narrow in instances where the size of unburned skin is not enough to fabricate a triangular skin flap sufficiently wide to cover the wound. The flap, in such an instance, is anchored in the middle of the wound. The two sides not covered by the flap are closed with a skin graft (Fig. 53.13). For larger or wider defects requiring longer flaps, a fasciocutaneous flap is employed. This flap is designed as above, but the tissue to be mobilized is sharply dissected free "straight-down" to incorporate the outer leaf of the subjacent fascia. It is important to preserve the microcirculatory connections between the fascia and the skin. Occasionally we place a temporary suture between the edge of the fascia and its skin edge above while the flap is mobilized. A 5 : 1 or greater length-to-width ratio is possible using this technique. Superficial epidermolysis of the most distal aspect of the flap may occur but rarely is of clinical significance and resolves with local wound care over the course of 1–3 weeks.

AFTER-CARE. The wound edges are kept clean with antibiotic ointment. Sutures may be removed in 10 days. Splinting of the joint may be resumed within 4–5 days and joint exercise in 10–14 days.

Muscle Flap or Skin-Muscle Flap Technique. The technique is utilized in instances where the resultant defect following release is so extensive that coverage of the wound with a skin flap or a skin graft is not feasible.

While the latissimus dorsi muscle harvested either as a muscle flap or as a musculocutaneous flap may be used to cover the axillary defect, the soleus muscle flap or the gastrocnemius muscle-skin flap may be used to cover the wound around the knee joint (Fig. 53.14). A fasciocutaneous flap may similarly be fabricated to cover a tissue defect consequential to surgical release of a contracted joint (Fig. 53.15).

Use of a Free Flap or Muscle Flap. Although most of the major joint deformities could be reconstructed with the techniques described, the use of microsurgical technique may be occasionally necessary to transfer a segment of soft tissue from a distant donor site.

Of the varieties of flap available, we prefer the use of an anterior lateral thigh (ALT) perforator flap.[16,17] The vascular supplies to the skin around the anterior section of the upper thigh are consistent, so preparation of a flap is therefore technically simple. While the morbidities attributable to flap harvest are generally minimal, the flap can be bulky; secondary procedures to thin down a flap are often necessary (Fig. 53.16). Instead, a muscle flap may be used. The tissue bulkiness may be curtailed by using a skin graft (Fig. 53.17).

Text continued on p. 586.

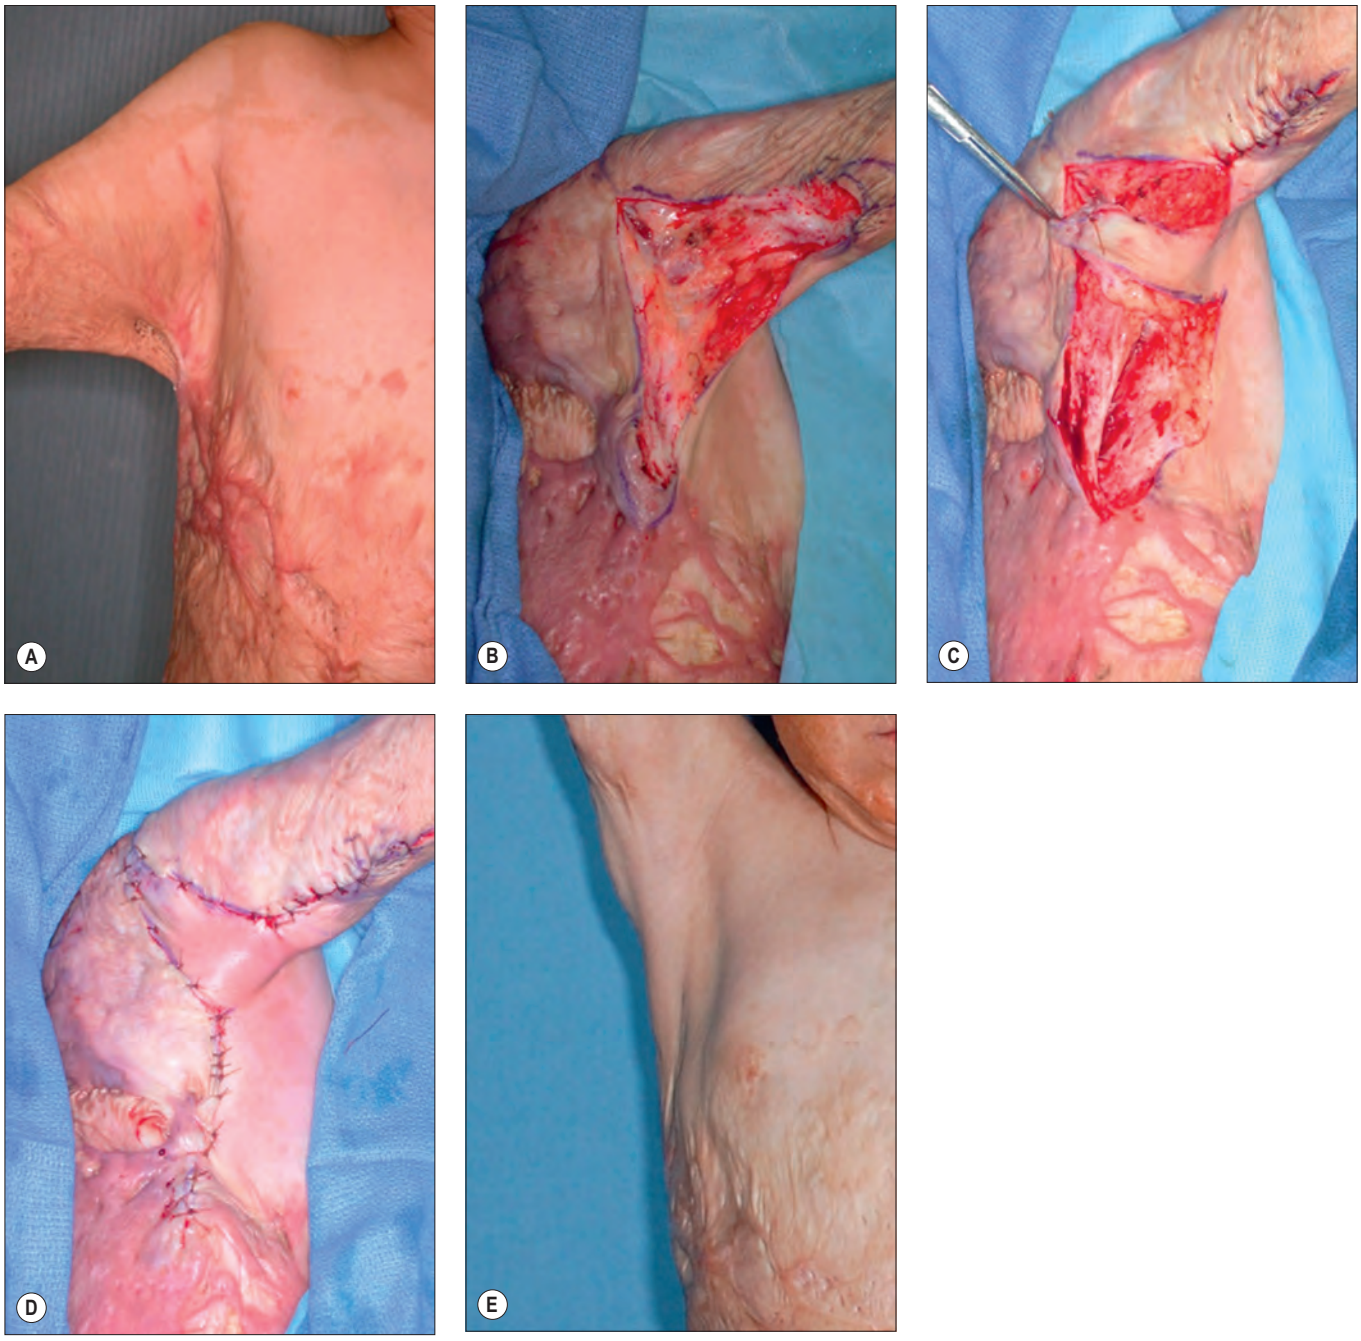

Fig. 53.12 **(A)** An interpositional skin flap technique (i.e., a modified z-plasty technique) is useful in reconstructing a flexion/adduction deformity around the joint, as seen in this 12-year-old individual who had sustained burn injuries around the right axilla. **(B)** An incision made across the area with maximal contraction resulted in a large tissue gap of 12 × 5–6 cm. **(C)** A triangular skin + fascia flap was mobilized from the lateral upper chest area and was rotated 90 degrees posteriorly to cover the wound. **(D)** The donor site was closed primarily. **(E)** The appearance of the wound 2 years following reconstruction.

Fig. 53.13 **(A)** An interpositional skin flap technique of wound closure may be modified, as in this 5-year-old girl who had sustained burns around the right axilla that caused contracture of the axillary joint. **(B)** The skin defect was so extensive that it could not be covered completely with a single flap. **(C)** The uninjured skin raised as a flap was transferred to the middle of the wound, leaving the areas proximal and distal to the flap to be covered with skin grafts. **(D)** The appearance of the wound 10 days following the surgery. **(E)** The appearance of the wound 10 years after surgery. The flap placed in the middle of the wound had increased in size because of body growth and stretching of the scar tissues.

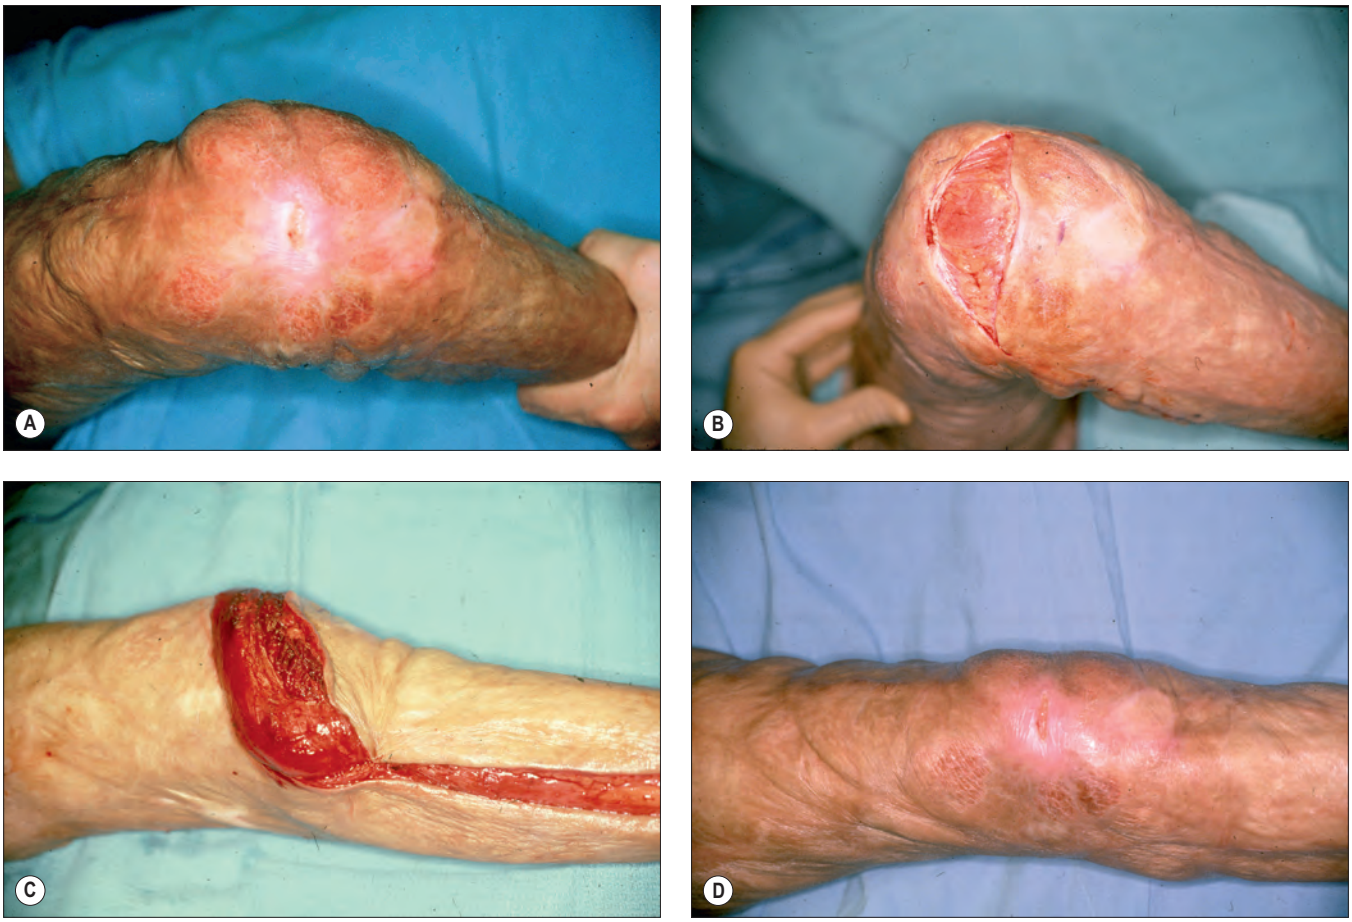

Fig. 53.14 (A) Flexion of the knee was limited because of tight scars around the patella. **(B)** An incisional release of the tight area across the patella provided relief of knee contracture. However, it resulted in an open wound of 4–5 cm in size. **(C)** A medial segment of the soleus muscle was used to cover the defect. **(D)** The appearance of the knee area 3 months following the procedure.

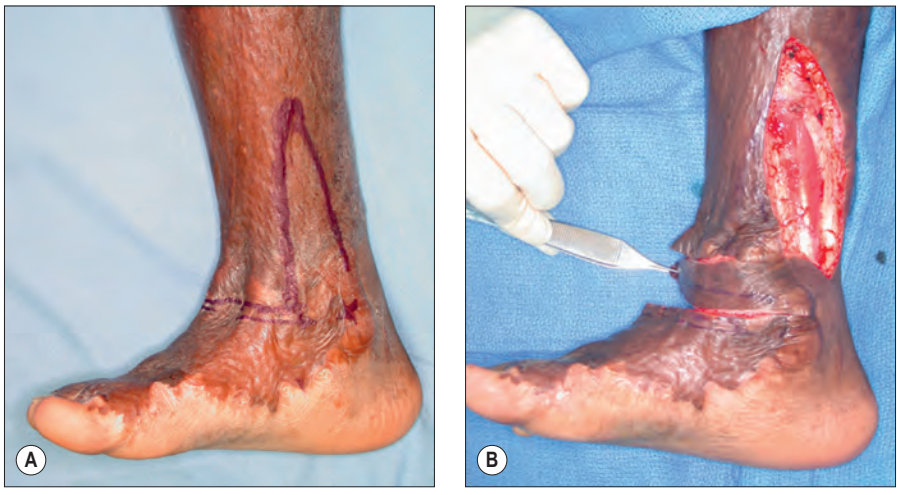

Fig. 53.15 (A) A moderate degree of dorsiflexion contracture involving the right ankle of a 6-year-old boy required release. A triangularly shaped skin + fascia flap was marked over the medial side of the lower leg. **(B)** A fasciocutaneous flap was fabricated and rotated 90 degrees anteriorly to cover a tissue defect consequential to contractural release.

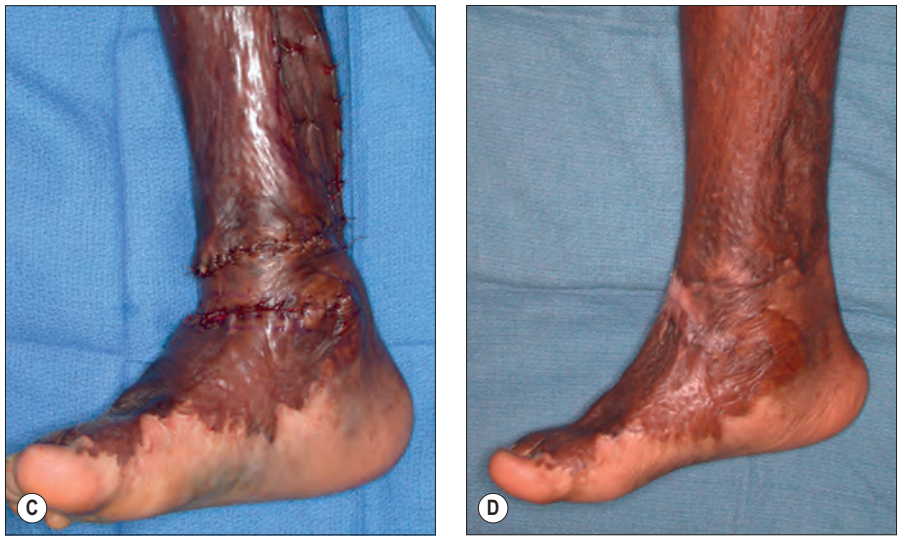

Fig. 53.15, con'd (C) The closure of the flap donor site required the use of a skin graft. Healing was uneventful. **(D)** The appearance of the right ankle area 18 months following surgery.

Fig. 53.16 (A) An anterior lateral thigh (ALT) perforator flap was used to reconstruct an ankle contracture deformity. **(B)** While wound coverage was achieved, the tissue was noted to be bulky, requiring secondary debulking procedures.

Fig. 53.17 **(A)** The patient had sustained electrical burns resulting in tissue loss over the right heel area. **(B)** Wound débridement resulted in a large soft tissue deficit exposing the Achilles tendon. A muscle flap was transferred via microsurgical means to cover the wound. The muscle was covered with a skin graft. **(C)** Healing was uneventful.

Conclusion

Contractural deformities of the shoulder (axilla), elbow, hip, and knee joints are commonly encountered after burn injuries. Although the injury involving limbs and joint structures could alone account for the deformities encountered, lack of proper positioning and inadequate physical exercise while recovering from injuries exacerbates these problems.

The use of braces, splinting, and pressure dressing is important in minimizing such an undesirable consequence of burn injuries. The treatment for an established joint deformity, on the other hand, requires surgical release of the contracted skin and scars. In this chapter, various methods of reconstruction have been described to manage the problems encountered and to outline the approach of managing contractural deformities involving the shoulder (axilla), elbow, hip, and knee joints. The interposition of an intact "integumentary functional unit" comprising epidermal, dermal, adipose, and fascial tissues with native nervous, vascular, and lymphatic connections allows release of the intrinsic tissue tension driving scar hypertrophy and contraction. Accumulating cellular evidence indicates that this mechanically transduced signal may lead to myofibroblast apoptosis and more rapid resolution of scar hypertrophy (Figs. 53.18 and 53.19).[18,19]

54 Acute and Reconstructive Care of the Burned Hand

DEREK M. CULNAN, KAREL D. CAPEK, TED HUANG, and WILLIAM LINEAWEAVER

Introduction

The hand is a primary means of communication, aesthetics, emotion, and sexuality. It exists at the core of our humanity. Particularly in the modern age of digital communication, the inability to interface with the digital world via hands is socially and intellectually isolating. Hands are injured in 80% of severe burns and are a primary American Burn Association referral criterion. Loss of hand function from burn injury frequently limits the patient's ability to work and requires evaluation for long-term disability, as discussed in Chapter 63. Functional recovery of the burned hand relies on quick and effective intervention by an experienced burn center.

Initial Assessment and First Aid

Successful restoration of hand function after burn injury begins with first aid, continues through acute care and occupational therapy (OT), and is augmented with reconstructive surgery. A careful history should be taken including the nature of the injury, but also of the patient's hand dominance, occupation, and special hand uses, such as playing a musical instrument.

Initial treatment is directed to prevent both further injury and conversion of the burn penumbra. First, the burning process must be stopped by removing the patient from the heat source and irrigating away any inciting chemicals. Historically, icing the burn had been advocated;[1] however, in modern burn care, maintaining the wound warm is now standard, and ice should be avoided. Blisters should be débrided both to allow assessment of the underlying burned dermis as well as to remove the cytotoxic mediators elaborated in the blister fluid, which can deepen the burn injury.[2]

The burn should be staged for depth at physical examination, and the patient should have an initial assessment of sensation, motor function, skeletal stability, and circulation (Fig. 54.1). The thin dorsal skin can easily suffer a third- or fourth-degree injury, whereas the thick glabrous palmar skin can often heal from even an apparently deep injury. Initial assessment is aimed at gross and limb-threatening injuries. Distracting injuries, pain, and fear can prevent an effective assessment of less obvious injuries, so patients should be followed up and reassessed.

Careful and repeated assessments must be made for compromised perfusion due to compartment syndromes and circumferential eschar constriction. These processes are limb threatening, and a high index of suspicion and prompt response must be maintained. Edema resulting from burn injury and burn resuscitation can cause a delayed appearance of compartment syndrome and eschar compression. Wound edema control is best accomplished with elevation. As discussed in Chapter 8, lymph pressures are typically in the 1–2 cm H_2O range, and this gradient can often be overcome with elevation by suspending the hand 50–100 cm above the phlebostatic axis, thereby creating a sufficient pressure gradient driving lymphatic drainage. Wounds should be dressed in a manner such that the burned hands can be monitored for neurovascular embarrassment and progression of the burned wounds (see Box 54.1).

Acute Care of the Burned Hand

The goals of acute management of hand burns include maintaining perfusion with resuscitation, neurovascular protection through the release of eschar compression and compartment syndromes, removal of necrotic burned tissue, early grafting, and early ROM. Resuscitation and hemodynamic support are critical because the heart is the organ that perfuses the hands. Should eschar compression or compartment syndrome develop, prompt decompression is critical for limb salvage. Clinical examination is usually sufficient to diagnose eschar compressions and compartment syndromes, including paresthesias, pain, passive resistance to extension, and loss of capillary refill in the nail beds.

Escharotomies are the mainstay of decompression in burn care. Incisions are made over the medial and lateral midaxial lines through the skin down to the fascia. The line of release extends both caudad and cephalad beyond the margin of tissue swelling to ensure complete release. Incisions on fingers are made along the midlateral line just dorsal to the digital neurovascular bundle between Grayson's and Cleland's ligaments.[3] Releasing incisions may be extended into the web spaces and to the dorsal surface of the hand to ensure the integrity of vascular supplies to the intrinsic musculatures of the hand. Many centers promote routine performance of escharotomies on both sides of fingers, and we advocate this approach. In a randomized control trial (RCT), a threefold increase in finger salvage was found with extended digital escharotomies.[4] Escharotomies should be carried out liberally because all full-thickness burns will eventually require excision and grafting, including resection of the escharotomy incisions, as seen in Fig. 54.2D, E.

Deep hand and arm burns may be insufficiently decompressed with escharotomies alone; release of fascial compartments will be required. Incisional releases may be carried out involving the forearm muscle compartment and

Fig. 54.1 Examples of burned hands. **(A)** A hand that has sustained a first- and second-degree, superficial partial-thickness burn with intact blisters. **(B)** Second-degree burn that is deep partial-thickness, typified by pallor mixed with erythematous changes (e.g., mottling). **(C)** Findings of skin anesthesia and vessel thrombosis suggest full-thickness, third-degree skin burn. **(D)** Carbonization suggests a complete destruction of the structures consistent with a deep, fourth-degree burn.

Box 54.1 Management Priorities of the Burned Hands

1. Evaluate burn and débride blisters
2. Decompression of compartment syndromes and eschar constrictions
3. Early therapy and splinting
4. Early excision and grafting
5. Early and aggressive range of motion (ROM) with occupational therapy
6. Secondary reconstruction of deformities

the carpal tunnel, as well as Guyon's canal (Fig. 54.2). The intrinsic muscles of the hand are particularly susceptible to elevated compartment pressures. These muscles infarct and contract, leading to an intrinsic-minus (claw) hand, discussed later. As such, care should be taken to release the interosseous compartments dorsally, the thenar and hypothenar compartments, and the palmar spaces as shown in Fig. 54.2C. The carpal tunnel and Guyon's canal should routinely be released as part of treatment of compartment syndromes of the hand.

The next goal of therapy is management of the skin injury. Partial-thickness burns to the dorsum of the hand are effectively treated with local care, skin substitutes, and immediate motion. If minimal superficial eschar is present, débridement can be achieved either operatively or with an enzymatic agent such as collagenase. Standard skin substitutes include homograft, xenograft, and ammonic membrane, which provide a durable covering, a wound matrix, growth factors to stimulate wound healing, and minimize chronic wound granulation tissue formation. In recent decades engineered skin substitutes (Integra, TransCyte, Hyalomatrix) provide a similar skin substitution covering and matrix in an acellular manner further discussed in

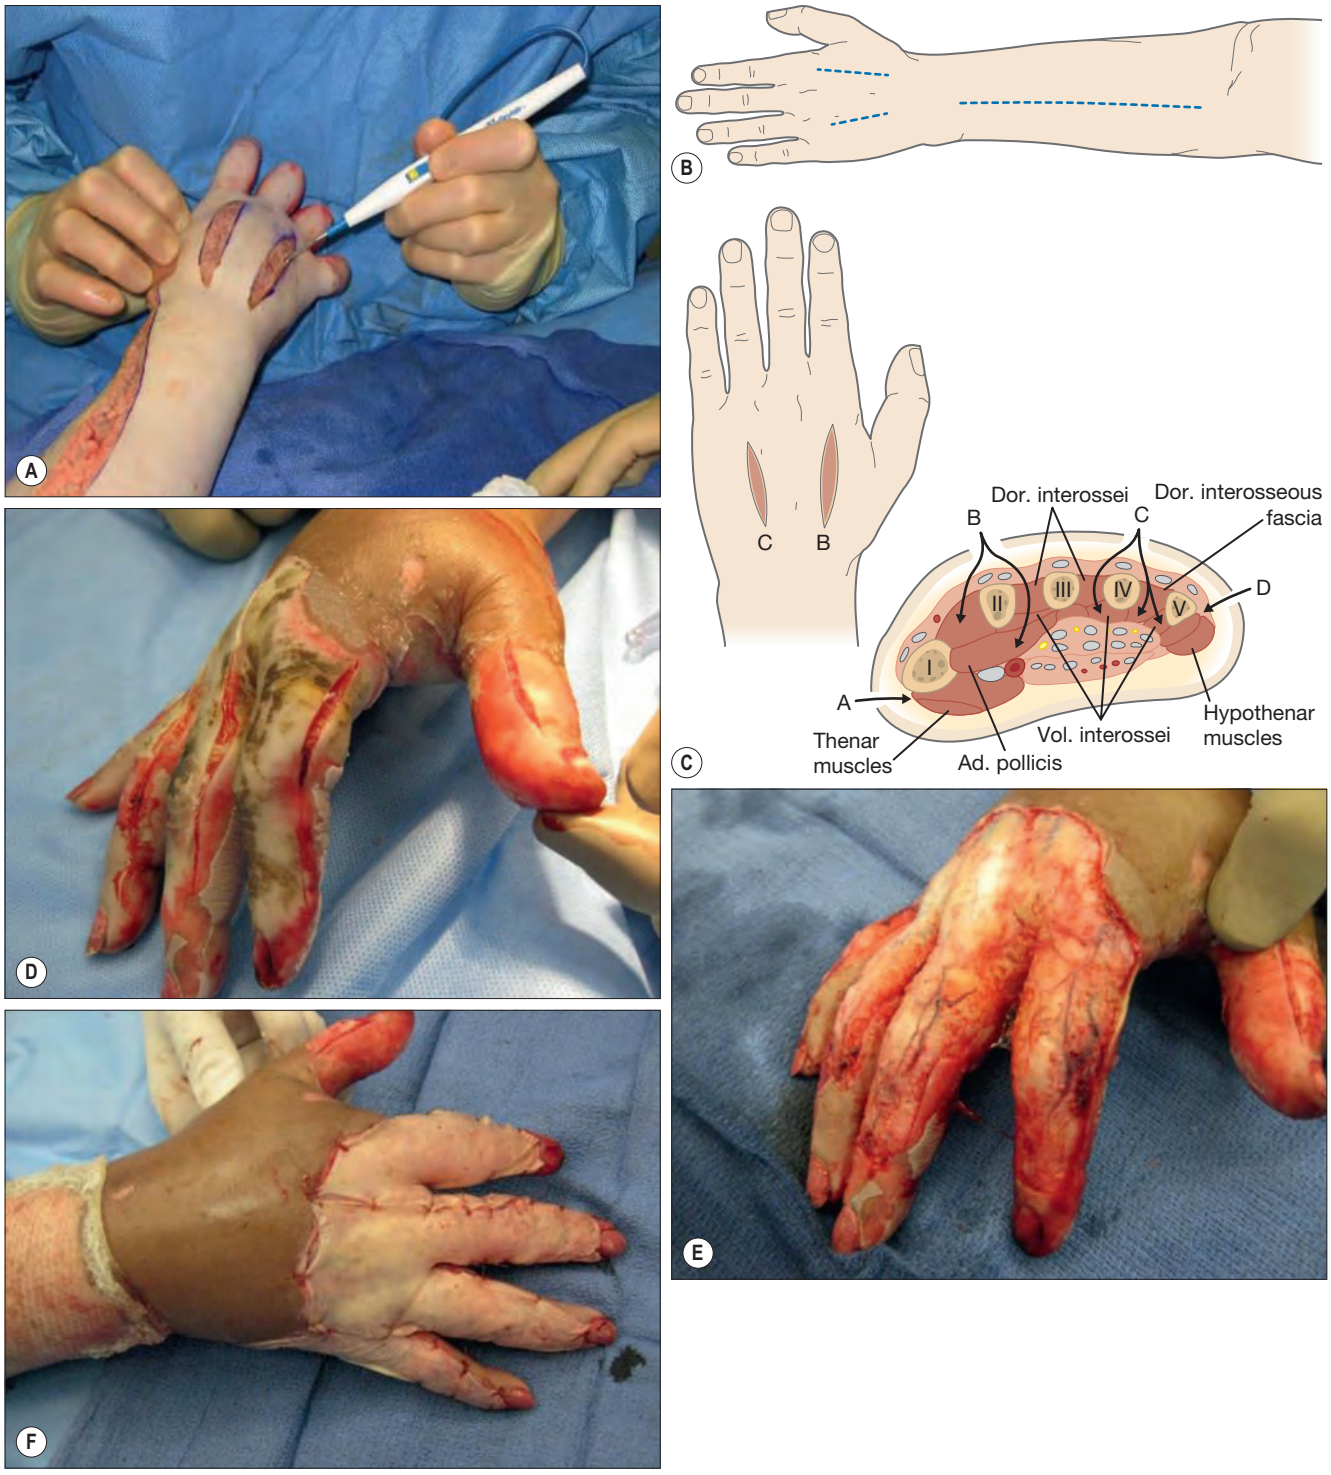

Fig. 54.2 Upper extremity escharotomies and fasciotomies. **(A)** A patient having completion of dorsal escharotomy incisions. **(B)** Drawing of dorsal fasciotomy locations. **(C)** Drawing of dorsal hand fasciotomy locations and a cross-section demonstrating the access to decompress all the compartments of the hand. Note the dorsal incisions decompressing the four dorsal interosseous compartments (incisions B and C), as well as accessing the adductor pollicis compartment via the second dorsal interosseous. The thenar muscles are decompressed via incision "A" volarly and radially, and the hypothenars are decompressed via incision "D" volarly and ulnarly. **(D)** Example of digital escharotomy incisions. **(E)** Subsequent escharotomy demonstrating that escharotomy incisions should be made liberally because all eschar will be subsequently resected. **(F)** Placement of homograft on escharotomized fingers, secured with sutures. (A, D, E, and F are courtesy of Dr. Lineaweaver; B and C are used with permission from Rowland S. Fasciotomy: the treatment of compartment syndrome. In: Green DP, ed. *Operative hand surgery*. vol. 1, 2 edn. New York: Churchill Livingstone; 1988: 678-679.)

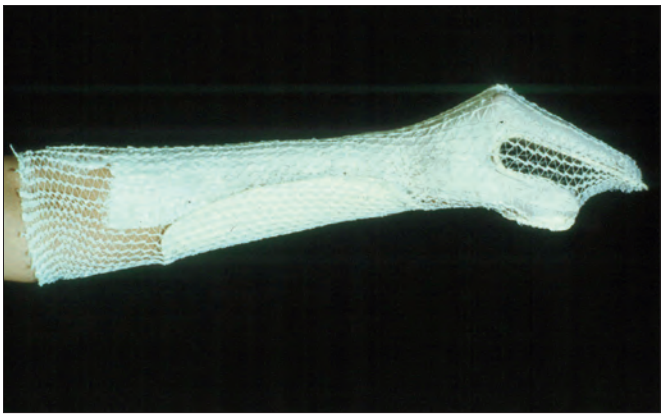

Fig. 54.3 Example of thermoplastic hand splinting. A hand splinted in intrinsic-plus position, also known as the "safe position." The distal interphalangeal–proximal interphalangeal (DIP-PIP) joints are maintained at full extension, metacarpophalangeal (MCP) joints at 70 degrees flexion, and the wrist at 30 degrees extension.

Chapter 15.[5] Other synthetic dressing materials such as nylon mesh with collagen matrix (Biobrane), polylactic acid (Suprathel), and silver ion-containing nonadherent long-term coverings (Mepilex or Acticoat) are used functionally as skin substitutes.[6] Collectively these materials function as skin substitutes, remaining in place, protecting the wound, providing a wound matrix, and allowing reepithelialization. However aggressive care and use of skin substitutes is advised to minimize scarring and fibrosis and maximize long-term hand function. Thermoplastic custom hand splints applied immediately play an important role in maintaining hand position while at rest (Fig. 54.3). Immediate ROM, however, is the most important intervention to maintain hand function. In cases where the wound is not superficial, delayed, or "conservative: burn wound treatment inevitably leads to delays, which can result in a poor outcome for the patient. Early removal of all eschar is at the core of modern burn care. In the setting of large burn wounds, definitive grafting of the hands may need to be delayed due to limitations of available grafts; hand wounds then need to be temporized with cadaveric skin. However grafting of the hands should be a high-priority limb-saving treatment, even in extensive burn injuries.

Deep burns to the dorsum of the hand are common because the skin is thin and the dorsum is exposed to injury in the protective reflex. Additionally, there is very little subcutaneous tissue so the extensor mechanism is susceptible to fourth-degree injury, particularly at the proximal interphalangeal (PIP) joint. The use of a split-thickness sheet skin graft is the preferred covering for the dorsum of the hand, providing the best scars and color match, although 1:1 meshing has similar outcomes.[3] The means of securing the graft, splinting, and the timing of therapy are areas of continuing controversy. Many groups now secure grafts with fibrin sealant or sutures and begin gentle active ROM in the first postoperative day.[7,8] Other groups continue to immobilize fingers in the intrinsic-plus position with K-wires for up to 6 weeks while reporting no permanent loss of ROM or articular surface damage.[9,10] Still other groups advocate immobilization of the hand during engraftment with splints for short periods of time. Finally some continue to argue for grafting the dorsum in the fist position because this increases the total skin length by 20% and mitigates some of the risk of extension contracture because split-thickness skin grafts (STSG) are known to contract up to 30–50% of the total graft area.[11,12] While there are data to support all of these grafting and splinting protocols, the primary goal is to begin hand therapy as soon as possible. In our experience, fibrin glues help achieve this goal effectively with initiation of motion on the first postoperative day (Fig. 54.4).

In cases where the paratenon of the extensor mechanism is compromised, skin grafts may not take well. In these cases the options are to allow granulation tissue to form on the tendons and cover with a skin graft, cover the tendons with an artificial dermal template and delayed skin grafting, or to use immediate flap coverage. Permitting the extensor mechanism to granulate with delayed skin grafting can compromise long-term hand function as the tendon becomes entrapped in scar. Such delayed treatments, however, become the treatment of choice in the setting where large burns and their threat to life are more pressing treatment priorities. Artificial dermal regeneration template materials can be effective in primary burn treatment, but these adjuncts are susceptible to infection in large or colonized burn wounds. In a well-selected patient these adjuncts have minimal complications, high engraftment, good cosmetic and functional outcomes similar to native skin,[5] and they demonstrate improved Vancouver scar scale, fingertip-to-palm score, and prehensile score.[13]

Early flap coverage of dorsal hand burns is an effective technique to cover and protect the extensor mechanism. Flap choice is often limited by the overall physiological state of the patient. The groin flap remains an option for expedience and reliability, although the bulky nature, prolonged inset, limited ROM, and obstruction to OT make it a flap to be used only when other regional or microvascular flaps are contraindicated. The merits of various flap techniques are discussed later in this chapter but are equally relevant to primary coverage. Both the posterior interosseous artery flap and the reversal radial artery flap can cover the majority of the hand. These flaps are reliable, technically straightforward, thin, and do not limit OT, making them practical options for coverage of the burned hand (Fig. 54.5).

Management of burns to the palm is most often expectant. The thick glabrous skin of the palm has deep reticular structures and appendages allowing skin regeneration with minimal sequelae in most burns. In the event that grafting is required, there is continuing controversy over the best graft source: STSG, full-thickness skin graft (FTSG), or medium-thickness glabrous skin graft (MTGSG). Herndon et al. reported that STSG functions as well as FTSG for palm burns.[14] Conversely Pham et al. have demonstrated that FTSG performed better for palm burns in children.[15] MTGSG is the best tissue match, with good graft take and low donor site morbidity.[16] In a 12-year experience with MTGSG, good sensation, color, and donor healing were reported.[17] Plantar glabrous skin also transfers Meissner's corpuscles and sweat glands, structures that may be important to the fine sensation and grip needed on the palms. We tend to use STSG but the appropriate patient can find good utility in all of these techniques.

Fig. 54.4 Example of excised and grafted dorsal hand burn. Occupational Therapy of the Burned Hand

Active motion is the means by which the hand maintains plasticity. The burned hand is predisposed to fibrosis because skin grafts and scars contract and deform the hand, while pain, edema, dressings, and splints limit hand mobility. As such, daily OT and a close working relationship between the surgeon and the therapist are critical to functional outcomes, reducing the need for secondary reconstruction to as low as 3.7% at 9 years according to Kreamer and Deitch.[18] A sufficient number of therapists should be available to treat each patient 1–2 times per day. A ratio of one therapist to seven patients is a good rule of thumb to allow for sufficient care. However the practicalities of early and aggressive OT are often limited by the particular practice scenario such as available personnel and other life-saving interventions, such as critical care or large burn wounds. Caring for hand burns requires extensive OT intervention and expertise in terms of physiotherapy and wound care usually only available at specialized centers.

The overall goals of OT are to maintain maximal hand movement, protect grafts, provide effective and well-fitting splints to maintain ligament length, and guide the patient's recovery toward maximum hand function. Intrinsic-plus splinting maximizes ligament and skin stretch in the position of function. The implication that the hand is safe in this position ignores the fact that the best position for the hand is in motion. No splinting should be considered as a resting substitute for active ROM.

OT can perform full ROM of all hand joints in the operating room prior to grafting to establish maximal mobility without pain and allowing the OT to be far more aggressive and expedient. This intervention can occur in parallel with other aspects of an operation thereby not increasing operative time. When fibrin glue or sutures are used to secure a sheet graft, therapists can take down the dressing on postoperative day 1, evaluate the graft, and evacuate any hematoma or seromas. If the graft is adherent to the wound bed, composite fist therapy should be initiated. Grafts are then dressed with functional compressive dressing and intrinsic-plus thermoplastic splints worn at night. Full range of hand motion can be achieved in 5 days with this protocol. Finally compression gloves should be manufactured to limit edema, hypertrophic scarring, and shearing of grafts.

Mobilization of the elbow is critical, and this joint should be kept extended to maintain maximal ligament length. Extension, however, is not a position of function, and, as such, elbow contractures in extension are debilitating because the patient is unable to reach hand to mouth. Therefore elbow ROM exercises are critical. The shoulder is

similarly best splinted in abduction to prevent axillary contractures. However abduction is not a position of function, and ROM therapy is again critical.

Management of Established Burned Hand Deformities

Long-term hand deformities can develop and cause progressive deformities and disabilities despite aggressive acute care. As discussed earlier, the best option to avoid reconstruction is assiduous acute care. Early excision and grafting of hand burns within 4–6 days of injury gives a fivefold reduction in the need for secondary correction of scars or of being debilitated.[19] When deformities occur refractory to OT, early reconstruction is advocated.[3] It is critical that both the surgeon and the patient have realistic expectations of the reconstruction and acknowledge that full premorbid restoration of hand function can rarely, if ever, be accomplished.

The most common pathophysiology of burn deformity is insufficient skin coverage from scar contracture. This primary skin contracture limits or deforms hand movement and leads to a fibrosis of the tendinous and ligamentous structures of the hand with progressive loss of function. Early establishment of durable, flexible, and sufficient soft tissue coverage is critical to preventive and secondary treatment of these deformities. Chronic wounds also occur commonly and require operative excision and closure. The loss of structures such as digits or extensor tendons is also common, and a reconstructive balance needs to be struck between the desire for definitive reconstruction and the patient's tolerance for additional surgery.

RECONSTRUCTIVE METHODS

It is important when reconstructing the hand to use the "reconstructive elevator" to determine the best solution for the patient and not move in a stepwise fashion through inadequate treatments. First, the contracture is incised or resected, the joints maximally stretched, and the entire extent of the tissue deficit made manifest (Fig. 54.6).

a. *Primary closure of the wound*: This technique is used to close a wound resulting from the excision of hypertrophic scar tissues. Primary closure should only be considered when adjacent skin permits tension-free, nondeforming repair.
b. *Grafting of a wound*: In situations where a skin contracture has occurred, if the contracture can be released leaving an adequate bed for additional skin grafts, then either STSG or FTSG can be considered a sufficient skin envelope.
c. *Skin flaps*: Often an adequate bed cannot be established for a skin graft because critical structures need to be covered or the recurrence of skin graft contracture is a major concern. In these cases a random pattern skin flap can be designed to close the wound. Classic flap designs, including z-plasty, modified three-quarters z-plasty transposition flap technique, rhomboids, rotations, and advancements, are all reasonable choices in the circumstances when adjacent tissue can be used for a flap (Fig. 54.7). The operating surgeon should not feel constrained to one type of tissue rearrangement and should choose the best surgery based on the defect and available adjacent tissue.
d. *Muscle flaps, musculocutaneous (MC) flaps, and fasciocutaneous (FC) flaps*: The vascular supplies to skin flap skin are enhanced by incorporating the muscle, fascia, or paratenon. The flap is mobilized to fill a defect resulting from scar release as a local, regional, or distant microsurgical flap (Fig. 57.16). In many cases early microsurgical reconstruction allows the best and most efficacious coverage of the wound and should be part of the armamentarium of surgeons treating these injuries. Muscle flaps bring a viable muscle to cover a wound, and the flaps themselves are covered with STSG (e.g., rectus flap). Musculocutaneous flaps bring a vascularized muscle with its overlying skin to cover a wound (e.g., latissimus dorsi flap). Fasciocutaneous flaps bring vascularized fascia with overlying skin to cover a defect (e.g., radial artery flap). Fascial flaps bring viable fascia and are subsequently covered with STSG (e.g., temporoparietal fascia flap). The best reconstruction technique depends on the patient's available donor tissue areas and overall health and tolerance for reconstruction and should not be constrained by the surgeon's

technical ability or knowledge. Regardless of the tissue donor chosen, care must be taken to limit bulk and allow the patient to move the intricate joints of the hand freely.

Reconstruction of Phalangeal Deformities

FLEXION CONTRACTURE DEFORMITIES

Flexion contractures usually occur from deep or full-thickness burns to the volar skin causing inadequate skin length. Joint and tendon sheath contractures can be contributing elements developing secondarily from the deformity and immobilization of the primary skin contracture. The contracted skin is released and a skin defect created by extending the contracted hand, as in Fig. 54.6. The resulting skin defect can then be closed by utilizing a transpositional skin flap technique (e.g., three-quarters z-plasty), pedicled flap, or skin graft, as in Fig. 54.6. Skin grafting is a viable option for closure of defects where no critical structures are exposed. As discussed in the acute burn section, there are controversies over the use of a dermal matrix, FTSG, STSG, or MTGSG should a volar graft be needed. If release of the contracture is inadequate, a capsular release of the affected joint may be needed.

In the setting of exposed critical structures (neurovascular bundles, tendons or bones), upon release of a volar contracture the best reconstruction depends on the available

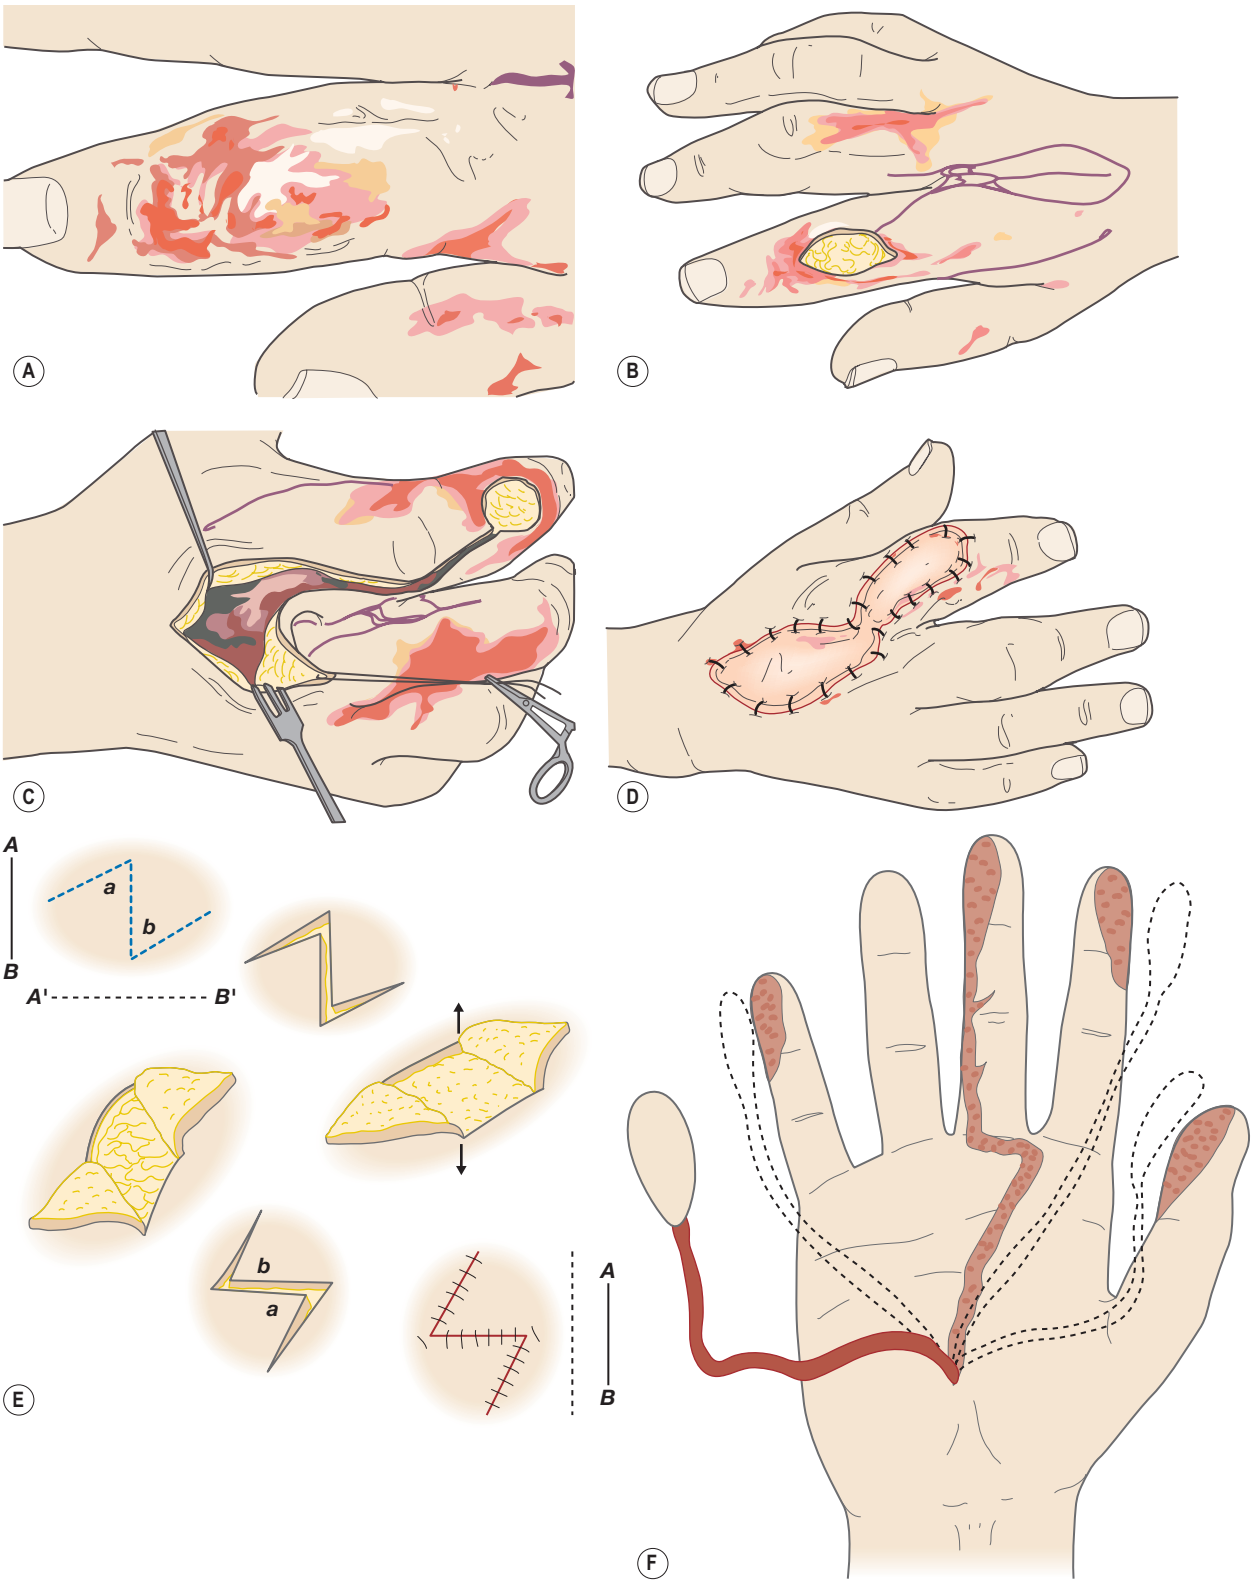

Fig. 54.7 Examples of local flaps for wound coverage in the hand. **(A–D)** Elevation and inset of dorsal interosseous artery flap. These exist in each web space and can be used to cover the finger out to the distal interphalangeal (DIP) joint with sensate tissue. **(E)** Line drawing of a z-plasty transposition flap. An incision is made along the contracture scar then flaps raised perpendicular at angles of 60 degrees. The flaps are then transposed, increasing the length of the scar. Typically flaps with tip angles of 60 degrees will increase in length of a contracture by 60% (75% by calculation). **(F)** Line drawings, elevation, and inset of neurovascular-island flap which can effectively cover the fingers, including the pad, with sensate glabrous tissue.

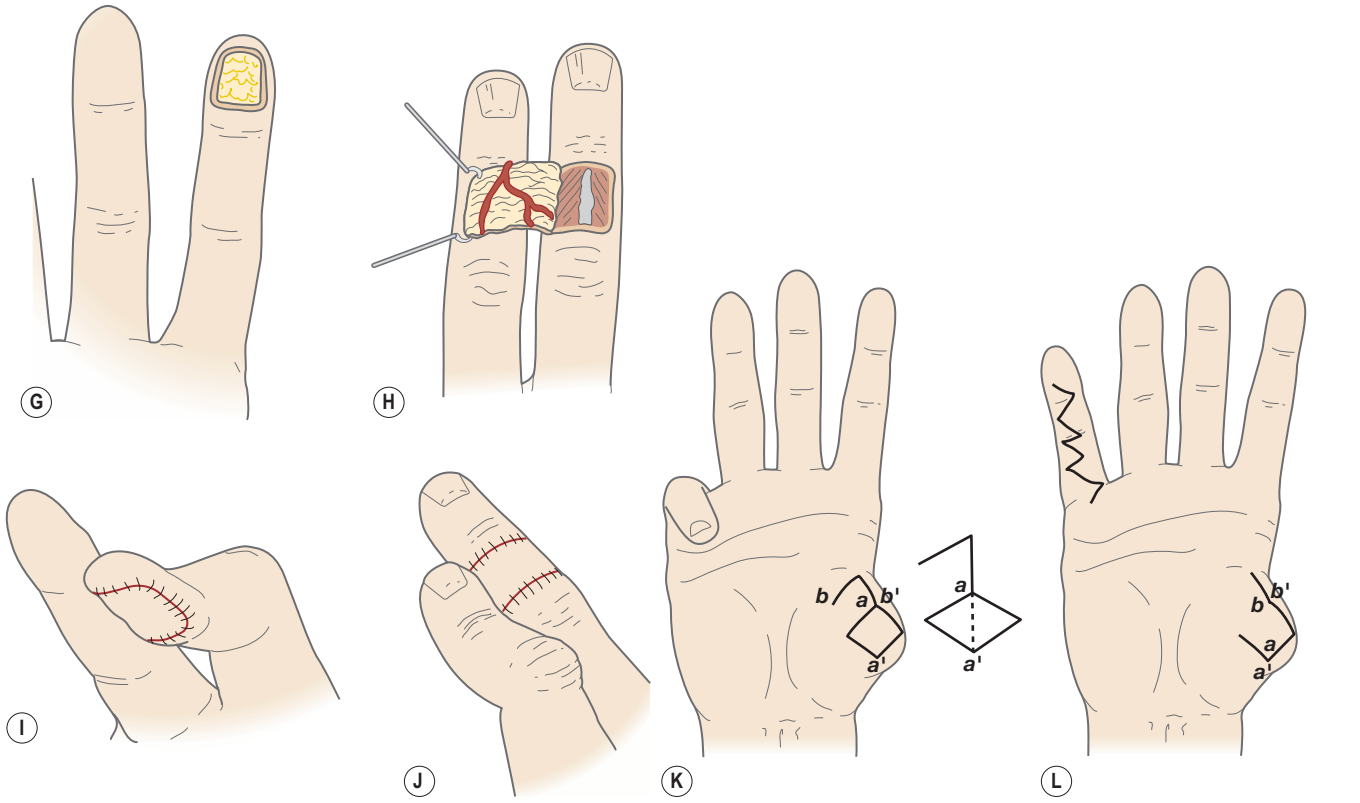

Fig. 54.7, cont'd (G–J) Line drawings, elevation, and inset of cross-finger flap which can effectively cover any part of the finger. **(K)** Line drawing of a hand with a flexion contracture of the small finger and an unstable thumb amputation wound marked with a Limberg (rhomboid) flap closure that will deepen the first web space and close the defect. The internal angles of the Limberg flap are 60 and 120 degrees, the width equals a to a' and the donor defect of b to b' must close primarily. **(L)** Line drawing showing the Limberg flap rotated into position as well as the flexion contracture of the small finger released by transposition of multiple z-plasty flaps. (A–D are used with permission from Agir H, Sen C, Alagoz S, Onyedi M, Isil E. Distally based posterior interosseous flap: primary role in soft-tissue reconstruction of the hand. *Ann Plast Surg*. 2007;59(3):291–296. E–K are used with permission from Lineaweaver WC, Buncke HJ. Flap reconstruction of the hand. In: Jupiter JB, ed. *Flynn's hand surgery*. 4 edn. Philadelphia: Williams & Wilkins; 1991: 607–625.)

donor tissue. The use of an axial lateral digital flap, a neurovascular island flap (Littler flap), a dorsal metacarpal artery flap, or a cross-finger flap may be necessary for a finger that has lost sensory supply to restore not only the soft tissue deficit but also the sensory supply (Fig. 54.7). When local flaps are inadequate, a dermal matrix may allow a staged reconstruction. The reconstructed finger is maintained at full extension by splinting. Alternatively a Kirschner wire placed intramedullary or underneath the flexor tendon sheath to maintain finger position for a period of 10–14 days can be effective.

EXTENSION CONTRACTURE DEFORMITIES

Burns to the dorsum of the hands are common, and these burns are often significant due to the thin skin and finely tuned extensor mechanism. Deformities here occur from insufficient skin envelope, exposed or compromised tendons and joints, tendon adhesion, and tendon disruptions (e.g., Boutonnières deformities). Surgical intervention is often needed to correct an established deformity refractory to OT interventions.

When there is insufficient skin on the dorsum of the hand, contractures can be released, constricting scar tissue resected, and the defect regrafted with STSG. STSG reconstruction can compromise tendon glide if the paratenon is compromised, although early motion protocols help maintain motion. For small defects, a three-quarters z-plasty transposition flap can be beneficial over the metacarpophalangeal (MCP) joint (Fig. 54.8). Often, for large deficits over the dorsum, a distant flap is needed, such as a distally based posterior interosseous flap, which can provide large-area durable coverage with good tendon glide.[20] This flap can be used when the donor area is burned and even in the acute burn setting when the donor area is recently skin grafted[21] (Fig. 54.5). Similarly propeller flaps can be constructed with reliability in the upper extremity.[22] Temporoparietal fascia free flaps can also provide excellent tendon glide, and microvascular flap coverage should be available to hand burn patients. Classically, large defects of the dorsum of the hand are covered with groin flaps, which are described later in the electrical burn section (Fig. 54.9). It is far preferable to use a flap that allows one-stage coverage and early motion, so groin flaps should only be employed in the rare circumstance where local, regional, and free flaps are contraindicated.

Extension contractures to the fingers are also common. They are released by incising the scar over the deformed finger joint(s) (i.e., the deformed distal interphalangeal [DIP], PIP, and MCP joints). If needed, the joint capsule is released. The resultant defect can be closed with the three-quarters z-plasty technique (Fig. 54.8). STSG can be used

Fig. 54.8 Examples of contractures treated with local transpositional three-quarters z-plasty. **(A)** Metacarpophalangeal (MCP) joint extension contracture with three-quarters z-plasty transposition flap marked. **(B)** MCP contracture released with transverse incision and transposition flap raised. **(C)** Three-quarters z-plasty flap rotated into position and flap donor area closed directly, **(D)** with follow-up at 3 years. **(E)** Release of flexion contracture of wrist with three-quarters z-plasty transposition flap marked. **(F)** Skin defect is manifest when the flexion contracture is released with a transverse incision.

Fig. 54.8, cont'd (G) Transposition flap raised in a fasciocutaneous manner and **(H)** rotated into the skin defect on the volar wrist. **(I)** Flap donor area closed with split-thickness skin graft, and **(J)** contracture release persists at 4-year follow-up.

for defects over the MCP joint. Dorsal metacarpal artery flaps allow coverage of the extensor hood out to the DIP joint. These flaps are elastic, durable, and sensate coverage for digits.[23] FTSG and cross-finger flaps also provide effective coverage options (Fig. 54.7).

The thin covering of the dorsum of the finger results in many central slip injuries and resultant Boutonniere deformities. PIP fusion or amputation is common because tenoplasty often fails in this setting of poor soft tissue coverage. Finally fat grafting can be used to repair contour deformities from severe contracture and burns to the hand.[24] Fat grafts may also improve tendon glide by elevating prior skin grafts off the extensors (Fig. 54.10). In a recently published series fat grafting was shown to significantly improve scar,

contour, and Michigan Hand Outcome Assessment compared to the unaffected hand.[25]

WEB SPACE CONTRACTURE

Narrowing of the web space is a common sequela of hand burns. Placement of unburned tissues in the dorsal aspect of the web space is the key to reconstruction. Reconstruction can be achieved through the use of a triangular skin flap mobilized from either the radial or ulnar side of the fingers and then rotated into a contracted web space, especially to the second, third, and fourth, to achieve the release. Z-plasty, advancement flaps, and V-Y advancements are also viable means of reconstruction. No additional physiotherapy is necessary. Unrestricted use of the hand daily will restore the web space and the movements of the fingers (Fig. 54.11).

First Web Space Contracture

First web space contracture is functionally significant because of limitations of thumb extension, abduction, and opposition. While conventional techniques, such as z-plasty and skin grafting, may be used to reconstruct the deformity, the technique combining two z-plasties with one central

Fig. 54.10 Fat grafting dorsal hand under split-thickness skin graft (STSG). Hand with dorsum extension contracture and contour defect treated with fat grafting. **(A)** Dorsally STSG hand with extension contracture. Note the sharp demarcation of the STSG's skin color and contour from the native skin at the level of the metacarpophalangeal (MCP) joint and wrist. **(B)** Six-month follow-up after a single fat grafting with a modest but significant increase in range of motion, scar quality, and hand outcome score in this preliminary study. Note the clear line demarcating the previously placed STSG at the level of the MCP and wrist, which now has improved contour and color. The authors postulate multiple graftings might have cumulative effects by releasing tethered skin and remodeling the subcutaneous layer in the hand. (From Byrne M, O'Donnell M, Fitzgerald L, Shelley OP. Early experience with fat grafting as an adjunct for secondary burn reconstruction in the hand: technique, hand function assessment and aesthetic outcomes. *Burns*. 2016;42(2):356–365.).

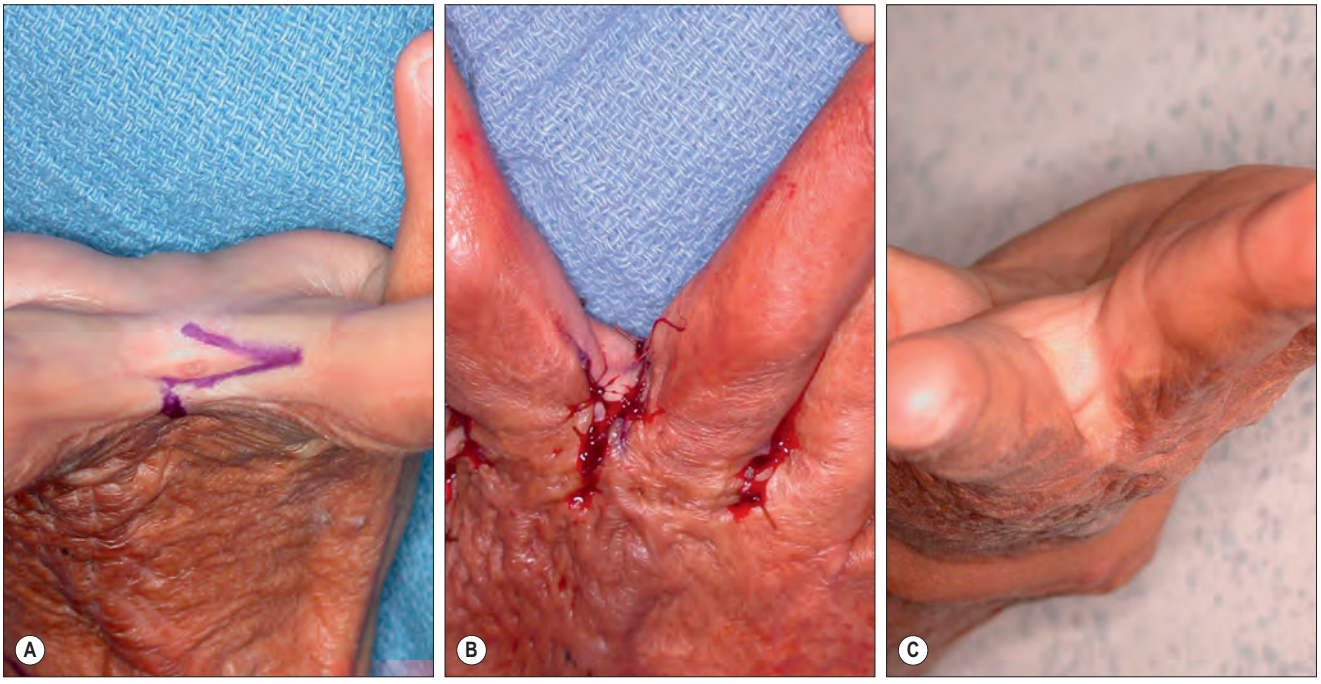

Fig. 54.11 Release of web space contracture. **(A)** Contracture of the right second web space with markings for three-quarters z-plasty transposition flap release. **(B)** The flap was rotated dorsally and the wound was closed primarily. **(C)** The appearance of the operative site 3 years following the release.

V-Y plasty, commonly known as the trident flap technique, the "jumping-man" technique, seagull-wing flap technique, or five-flap technique, is a simple and effective approach to providing the release. An approximately 30–40% increase in the first web space is obtainable using this release technique (Fig. 54.12).

RECONSTRUCTION OF A DEFORMED THUMB

It is estimated that 45–50% of hand function is forfeited with the loss of a thumb.[26] Reconstruction of the thumb should be offered to patients, and many techniques are available, from a toe-to-thumb transplantation to the creation of a

Fig. 54.12 Release of first web space contracture. **(A)** A moderate degree of web space contraction developed in the first web space 9 months following split-thickness skin graft (STSG). Skin markings were made for the "jumping-man" technique of contracture release, also know as the trident or five-flap technique. **(B)** Flaps transposed and inset. **(C)** An increase of 30–50% in the arc length of the web space with the "jumping-man" technique. **(D)** The appearance of the released web space 3 years later. **(E)** Line drawing of a hand with a first web space contracture and markings for the four flaps of the "jumping-man" and **(F)** the flaps transposed releasing the contracture. digital post. In many patients deepening the first web space provides an adequate post for grip and pinch.

The technique of stacking a remnant of the index finger to the thumb ray to elongate the thumb remnant and deepen the first web space has been used in Galveston for the past 30 years. Functionally this is a form of pollicization of the index finger. The remnant of the index finger is transected at the metacarpal or proximal phalanx level. The index finger is mobilized as a flap with its neurovascular bundle intact. The proximal bone margin of the index finger is fixed to the distal end of the thumb remnant. Resection of the index metacarpal deepens the first web space. The procedure carries low morbidities and could be performed in an outpatient surgical facility (Fig. 54.13).

Fig. 54.13 Index finger pollicization. **(A,B)** The skin drawing marked the skin edges of the index finger remnant. **(C,D)** The index finger remnant was fabricated as a composite island flap containing bony skeleton and the neurovascular bundles. The island flap was transferred to the remnant of the thumb. K-wires were used to anchor the flap. **(E)** The thumb remnant was lengthened by stacking the index finger remnant. The web space was deepened by removing the second metacarpal. **(F)** X-ray of a different hand following pollicization that demonstrates the bony changes associated with the procedure (F used with permission from Lineaweaver WC, Buncke HJ. Flap Reconstruction of the hand. In: Jupiter JB, ed. *Flynn's hand surgery*. 4 edn. Philadelphia: Williams & Wilkins; 1991: 607–625.)

Microvascular toe-to-thumb transfer has been demonstrated to lead to good functional outcomes.[27] The technique is beyond the scope of this chapter,[28] but it can provide very high satisfaction and result in a functional and sensate thumb.[29] Furthermore, multiple toes can be transferred to reconstruct function in the fingerless "metacarpal only" hand (Fig. 54.14).[30]

RECONSTRUCTION OF A CLAW HAND

The burned hand can develop a claw deformity from multiple etiologies. The classic claw hand, the intrinsic-minus hand familiar to all hand surgeons, can develop from ulnar nerve injuries either in the primary burn injury, compression at Guyon's canal, or compression at the cubital tunnel.

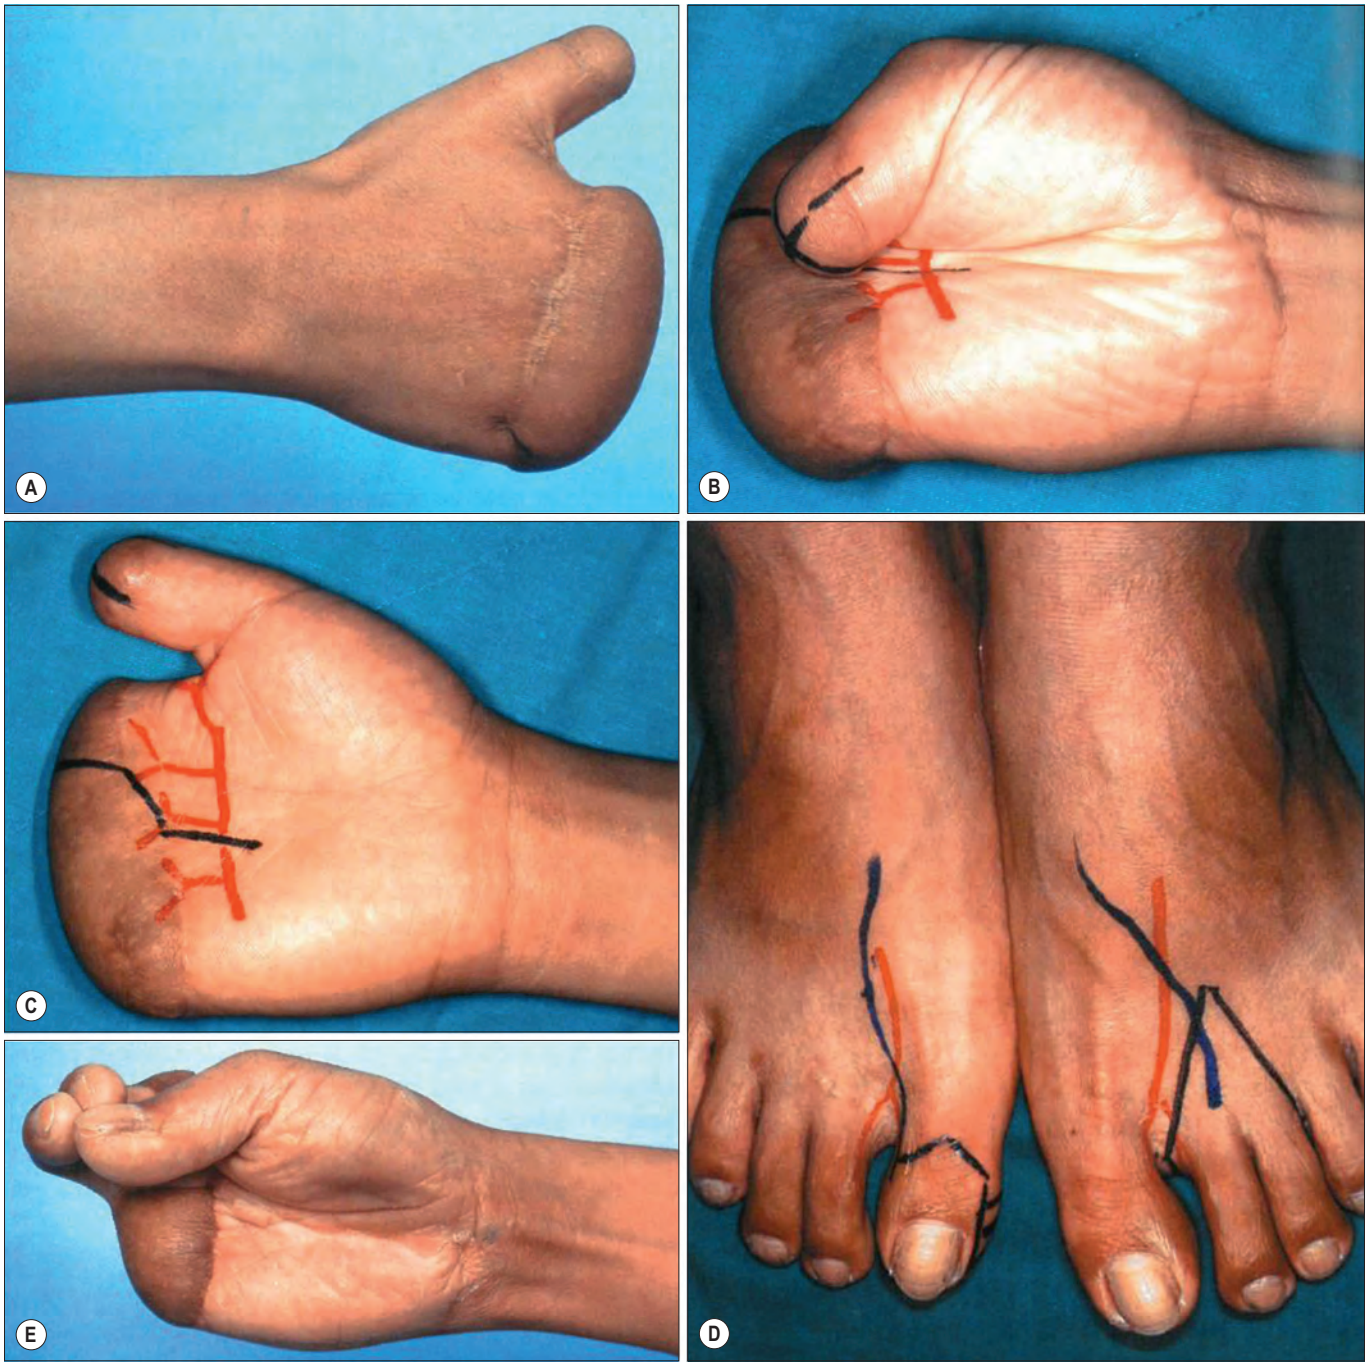

Fig. 54.14 Toe-to-hand transfer. **(A)** Metacarpal hand after closure with pedicled groin flap. **(B)** Thenar muscle function maintained. **(C)** Design of skin incision with recipient vessels marked. **(D)** Donor toes marked with right great toe and left combined second and third toes. **(E)** Tripod pinch present at 3-year follow-up. (From Vivek Jain F-CW. The metacarpal hand. In: Norman Weinzweig JW, ed. *The mutilated hand*. Lansing: University of Michigan/Elsevier Mosby; 2005: 280.)

In these cases ulnar nerve decompression can improve hand function.

A claw hand deformity can occur from necrosis of intrinsic hand musculature thereby creating an intrinsic-minus repose. In these cases ulnar nerve tendon transfers used to treat the intrinsic-minus hand from ulnar nerve injuries are not typically successful in the burned hand due to the overall soft tissue damage to the hand. Joint fusions in a position of function can improve overall hand function.

A claw-like deformity can also occur in burned hands with intact ulnar innervation and intrinsic musculature (Fig. 54.15). Scar contracture can create intrinsic-minus repose with MCP hyperextension and PIP contracture. This claw-like hand is treated by total scar excision and coverage with skin grafts or flaps. Early and aggressive OT is essential to regain intrinsic function.[31]

Fig. 54.15 Claw-like hand. *(A)* Classic presentation of the "claw-like hand" with metacarpophalangeal (MCP) joint hyperextension, interphalangeal (IP), proximal and interphalangeal (PIP) flexion, and thumb adduction. This intrinsic-minus repose appears identical to a claw hand from an ulnar nerve palsy but in this case is from a severe dorsal contracture. **(B)** Treatment consists of a transverse releasing incision proximal to the MCP (*arrows*) allowing MCP capsulotomy and flexion, then closure with a split-thickness skin graft (STSG). **(C)** Follow-up demonstrates composite grip and intrinsic function of the hand. Electrical Injuries Involving the Upper Limb

Electrical injuries are discussed in detail in Chapter 38 on electrical burns, but they are important to consider here because the upper extremity is a common contact point for electrical injury. Injuries often include the entire extremity (i.e., the shoulder to the hand). The damaged structures noted are mostly the muscles in the arm, neurovascular bundles, and the skin over contact points in the forearm and in the hand. The bones typically generate heat due to their high resistance and burn the tissue from the inside out. Thus a fourth-degree injury is common, and aggressive treatment is needed.

Various classification schemes have been described for electrical burns of the upper extremity but are clinically cumbersome and do not guide treatment. Treatment and diagnostic priorities are the same as all burn injuries: reestablishment of blood flow, débridement of necrotic tissue, decompression, early graft coverage, and early ROM. The incidence of extremity amputation in cases with deep, circumferential electrical burns can be in the range of 25–80%, attributable to vascular injuries. Assessment of vascular injuries and vascular compression in patients with electrical burns is, therefore, extremely important at the time of initial evaluation. The structural and functional integrity of the arteries is assessed with clinical exam, Doppler flow, magnetic resonance imaging (MRI), and angiography. Surgical exploration remains the definitive strategy for diagnosis and treatment. Patients sustaining electrical burns of the upper limb are frequently found to suffer other life-threatening injuries. Surgical débridement of burn wounds and wound exploration are planned as part of their overall stabilization.

Decompressive Escharotomy and Fasciotomy

Decompression to reestablish blood flow is particularly critical in electrical injuries. Tissue destruction particularly involving deep structures inevitably leads to interstitial extravasation of tissue fluid and tissue swelling. The release of muscle compartments is necessary in instances where the muscle compartments are swollen. Without releasing procedures, ischemia can cause muscle necrosis and nerve injury (Fig. 54.2). Deep muscles in contact with the bones, such as the pronator quadratus and rotator cuff muscles, are particularly at risk of necrosis and should be evaluated during decompressive surgery. Necrotic muscles should be removed as soon as possible to prevent systemic toxicity such as renal failure.

Early Débridement

In patients with obvious, deep burns to the arm and with life-threatening injuries, early proximal amputation should be considered. A proximal amputation can quickly remove extensive necrotic muscle, particularly when the rotator cuff muscles are infarcted. Prompt amputation of an

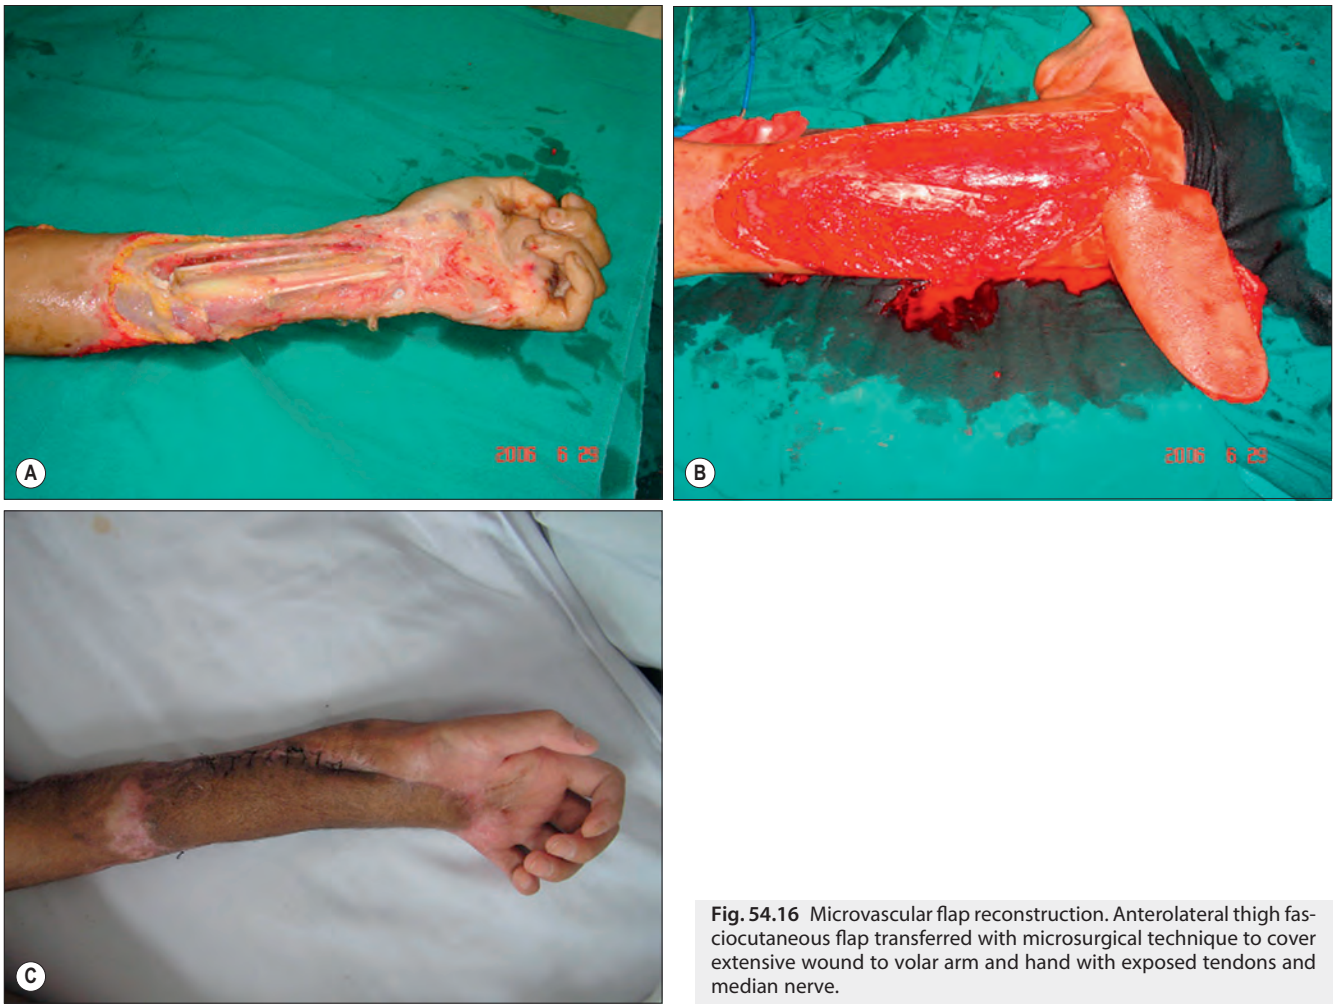

Fig. 54.16 Microvascular flap reconstruction. Anterolateral thigh fasciocutaneous flap transferred with microsurgical technique to cover extensive wound to volar arm and hand with exposed tendons and median nerve.

unsalvageable upper extremity can be a life-saving procedure that avoids hemorrhage and sepsis as well as the metabolic complications of multisystem organ failure from myonecrosis. This can be life-saving due to the risk of renal failure from rhabdomyolysis and the susceptibility of necrotic muscle to mold infection.

Complete débridement is advisable in the 1–2 days following injury. The procedures should include removal of all devitalized tissues, ascertaining the viability of intrinsic muscles and pronator and supinator muscles. Every effort should be made to preserve all forearm nerve structures unless nerve viability is clearly lost. Vascular continuity, in instances where the patency of both radial and ulnar arteries is compromised, may be restored by means of vein grafts, although often arterial thrombosis is a marker of severe necrosis and nonreconstructable disease.

Wound Management

The magnitude of tissue damage in high-voltage electrical burns is often so extensive that it involves muscles and blood vessels. Limb removal, in such instances, is the sole treatment option left to minimize lethal consequences of the injuries. The conventional regimen of a split-thickness skin graft for wound coverage is often not feasible because wound beds are devoid of vascular supplies and/or tissue loss is extensive (Fig. 54.16). Instead, local or distant flaps are used for wound coverage and protection of nerves, vessels, joints, and tendons. The pedicled abdominal flap has utility in this setting because the arm is within the zone of injury and local or regional flaps may have been compromised (Fig. 54.9).[32,33] However, even in the setting of electrical injuries, distant pedicled flaps should only be used in the rare instances where local, regional, and microvascular flaps are contraindicated or unavailable. An angiogram can clarify which regional flaps and microvascular recipient vessels are available.

FUNCTIONAL RECONSTRUCTION OF LIMB DEFORMITIES

Loss of limb function is not uncommon following electrical injuries. Insufficient vascular supply, extensive nerve and musculotendinous damage, and loss of muscle functions involving the shoulder girdle and the forearm, as well as loss of intrinsic musculatures of the hand are factors responsible for the difficulties encountered. Maintaining joint mobility and replacement of lost soft tissue in the forearm and hand are two key features necessary for functional reconstruction. Patients are encouraged to follow an OT regimen to maintain joint mobility, particularly of the finger joints.

Successful nerve grafting for sensory restoration and/or tendon transfer procedures for digital movements require prior skin flap procedures mobilized from an adjacent area or a free flap transferred via microsurgical means to restore the soft tissue coverage of the injured site. Restoration of the tendon activities is contemplated once these procedures are completed. At a minimum, the rehabilitative regimen in general takes 2–3 years to complete. Centers unable to offer the full range of reconstruction should refer patients to those more versed in limb salvage and hand surgery.

Conclusion

Effective hand reconstructive procedures rely not only on the surgeon's surgical judgment and skill but also on effective OT and the patient's compliance with rehabilitative treatment. As such it should only be attempted at centers with specialized surgical and therapeutic expertise. An experienced burn reconstructive hand surgeon can help move a patient toward even greater maximal medical improvement. A well-planned regimen is essential to restore these individuals to their former lives. This must be carried out in a multidisciplinary manner with an experienced surgeon and therapist.

55 Management of Burn Injuries of the Perineum

MOHAMED E. ISMAIL ALY and TED HUANG

Introduction

Burns of the perineal area are relatively uncommon despite the common involvement of the lower trunk and the lower extremities in burn injuries. The incidence of perineal burns was reported at around 12/1000 admissions more than 25 years ago.[1] While the occurrence of perineal burns has remained at around 1.0–1.5% at our institution, 35 children underwent genito-perineal reconstruction out of 1133 presenting with perineal burns between 2002 and 2009.

The continuous improvement in the survival rate following extensive burns of total body surface area (TBSA) more than 40% could account for the increase in the number of patients requiring secondary reconstruction.

Management During the Acute Phase of Injury

A conservative approach is usually the first line of management of perineal burns during the acute phase of admission.[1,2] The perineal area is cleansed daily with appropriate antiseptic and the wound is covered with antibiotic topical dressing. To avoid urine contamination of the burn area and the development of urethral strictures, the urethral tract is stented using an indwelling Foley catheter. The catheter is also used to decompress the urinary bladder and monitor urine output during the acute admission. The perineal area is neither splinted nor braced, the thighs are maintained at 15 degrees of abduction using a wedge splint to minimize hip contractures.

Other complications of perineal burns presenting during the acute injury phase include penile shaft necrosis, testicular necrosis, urethral stricture, and rectal prolapse. Although the Shriners Children Burns Hospital and the University of Texas Medical Branch Hospitals in Galveston, Texas, have adopted conservative management of perineal burns, the approach to wound care is, in practice, quite variable. The management plan is often modified depending on the anatomical structures involved in individual patients.

The burn is left to demarcate over time with the wound left to heal by secondary intention. Non healing wounds are reconstructed using partial-thickness or full-thickness skin grafts. On rare occasions, a local skin flap may be utilized from the adjacent normal skin to reconstruct full-thickness skin defects of the penile and scrotal areas.

BURNS OF THE PENIS

Burn injuries limited to the penis, although possible, are quite rare (Fig. 55.1). Concomitant involvement of the penis with burn injuries of the lower trunk and the perineal area, on the other hand, is quite common. Initial patient management, in addition to resuscitative measures, consists of wound care and urethral stenting. As mentioned earlier, an indwelling Foley catheter of appropriate size is inserted to stent the urethral tract and monitor urine output.

The catheter is removed once the swelling around the penile shaft has subsided and the wound status is delineated. No attempt is made to débride the burn wound early; the wound is left to demarcate and heal by secondary intention.

SKIN LOSS OVER THE PENILE SHAFT AND SCROTUM

Spontaneous healing is expected in most instances of burn injuries to the penis and scrotum since full-thickness injury of the penile and scrotal skin is relatively uncommon. Skin grafting, with a partial-thickness or full-thickness graft, could be used to cover the wound when healing is delayed (Fig. 55.2).

In rare instances, a skin flap is required to reconstruct structures such as the urethral tract and/or scrotal sac because of full-thickness skin loss. An inguino-pudendal skin flap mobilized from the inguinal crease area may be used if the use of a skin graft is judged not to be feasible.[3] The use of musculocutaneous flaps, such as a gracilis flap, is not recommended. The subsequent high tissue temperature developing in the skin paddle of the flap can potentially interfere with spermatogenesis.

BURNS OF LABIA MAJORA

Isolated burns of the labial area are rare, and such burns are often associated with injuries of surrounding areas such as the abdomen and inguinal folds. As in the management of burns of male genitalia, the injured areas are left to heal by secondary intention (Fig. 55.3).

Distortion of the labial structures mostly due to scar contraction in the pubic and inguinal areas is addressed by reconstruction at a later stage.

PERINEAL WOUND COVERAGE

An isolated burn injury of the perineal area is, as mentioned earlier, extremely rare; nevertheless the perineum

Fig. 55.1 An isolated burn injury of the penis is relatively uncommon. This was a 27-year-old man who sustained scald burns of the penis from accidentally spilling hot coffee onto his lap.

will be involved in extensive lower trunk/buttock burn injuries. The extent of scar contraction following wound healing will vary per the depth of burns. While the wound may heal spontaneously with residual minimal scarring, perineal contractures are a common sequela regardless of the methods used for wound care (Fig. 55.4).

The natural inclination of patients to adduct the thighs and hips while lying supine in bed during the recovery phase of acute burn injuries seems to aggravate scar contraction.

ANAL BURNS

Burns involving the anus are rare, although the area could be involved in extensive perineal burns. In the case of full-thickness skin loss around the anal opening, the use of a skin flap may be necessary to reduce the risk of stricture development. A skin flap mobilized from the adjacent area is required to reconstruct the perianal area. Wound coverage with a skin graft is technically difficult and will lead to the development of an anal stricture following graft contracture.

RECTAL PROLAPSE

Rectal prolapse can occur occasionally in young children with extensive burn injuries with or without perineal involvement. The pathophysiology of the development of rectal prolapse in infants with extensive burns remains unclear.

Redundant rectal mucosa; the structural relationship of the rectum to other pelvic organs such as the sacrum and coccyx, urinary bladder and uterus; and lack of muscular support provided by the pelvic musculature are anatomical features unique to infants 1–3 years old. All this could account for the development of rectal prolapse in this age group. A sudden increase in intraabdominal pressure, malnutrition, and constipation could conceivably aggravate the magnitude of the rectal mucosa descending through the anal opening.[4] Clinically, in addition to eversion of rectal mucosa, the presence of edematous swelling involving the buttocks and perianal area is quite common, despite the lack of burn injuries. The onset can be quite sudden without any obvious precipitating event; however, straining or the Valsalva maneuver can produce an eversion of the rectal canal through the anal opening.

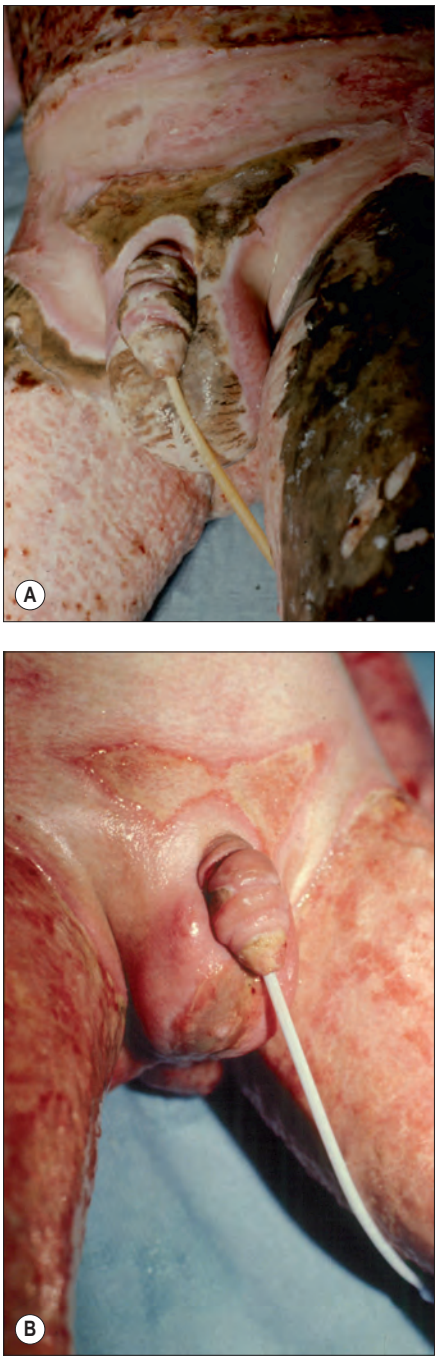

Fig. 55.2 **(A)** Burns of the penis are more commonly associated with injuries of the lower trunk and lower extremities. **(B)** Although skin grafts were used to achieve wound closure around the perineum, the major bulk of the penile wounds healed by secondary intention.

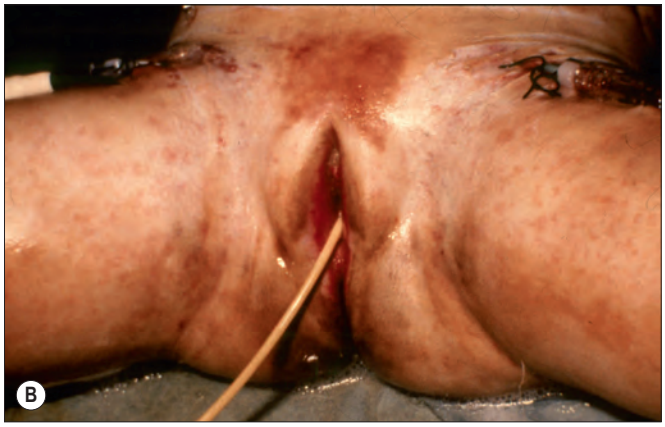

Fig. 55.3 **(A)** Burn injuries that involved the lower trunk and thighs, including the labia. While the lower abdomen and thighs required skin grafting, the labial injury was left to heal by secondary intention. **(B)** The appearance of the genitalia 5 years following the injury.

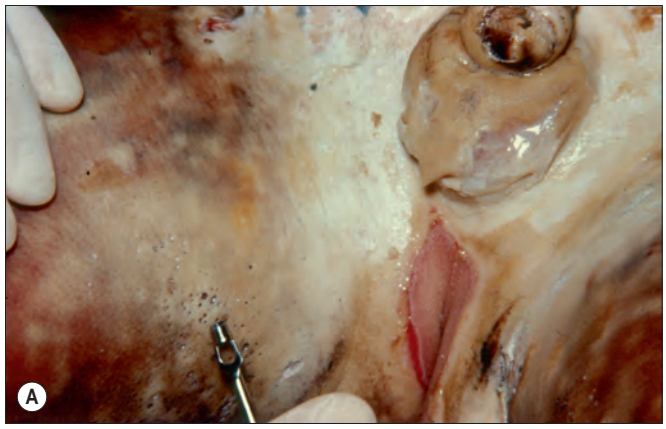
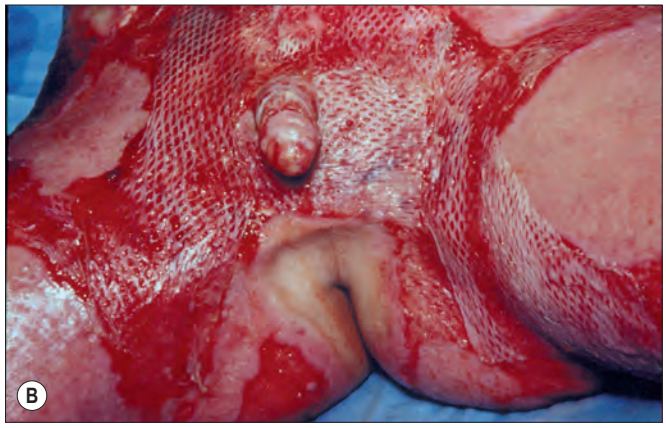
The treatment consists of rectal padding, daily cleansing of the perineal and perianal area, and a stool softener added to the dietary regimen to facilitate bowel movement. Spontaneous resolution of the rectal mucosa prolapse is likely as the nutritional status of the patient improves and tissue swelling subsides (Fig. 55.5). Surgical intervention, although in most instances unnecessary, is indicated if the prolapse is not readily reducible due to the development of anal sphincter dysfunction and/or intussusception.[4,5]

Reconstruction of Established Deformities of the Perineum and Perineal Structures

Cicatricial contractures around the perineum are the most common sequela of perineal burns.[1,6] The magnitude of the contracture is exaggerated as a result of burn scar contraction in the inguinal crease and inferior-medial gluteal folds. Other complications, although relatively uncommon, included complete loss of the penis, anal stenosis, and intractable rectal prolapse.

There are numerous reconstructive techniques available such as z-plasty scar release, interpositional skin flap technique, incisional release of scars and closure with local skin flaps, or skin grafts to reconstruct the deformities. In practice, the technique used to reconstruct perineal and genital deformities varies depending on the magnitude of scarring around the perineum and the extent of functional impediment encountered.





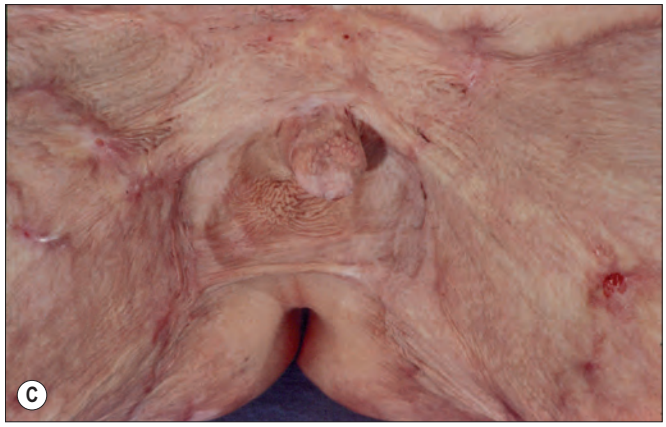


Fig. 55.4 **(A)** The patient was an 8-year-old child who sustained third-degree burn injuries of the trunk and lower extremities also involving the penis and the scrotum. **(B)** The wound including the scrotum was débrided, and skin was grafted using a meshed partial-thickness skin graft. **(C)** Scar hypertrophy and burn scar contractures developed at a later stage; tight scars across the perineum interfered with thigh movement.

RECONSTRUCTION OF PENILE DEFORMITY

The task of assessing the exact extent of penile deformities can be difficult. Distortion of the penile anatomy

Fig. 55.5 **(A)** This patient was a 2-year-old girl who had sustained 65–70% total body surface burns. **(B)** Prolapse of the rectum appeared 12 days following the injury and was managed conservatively. **(C)** The prolapse receded spontaneously 2 months later as she recovered from the burn injury.

attributable to scar contracture could be due to skin loss or a combination of skin and Buck's fascia involvement. In addition, scarring in the pubic area and/or the inguinal fold can further exaggerate the extent of penile deformity, as mentioned earlier.

Engorging the penile shaft is required to assess the extent of penile deformity because the gross appearance of a flaccid penis can be misleading. Artificial penile erection is created under anesthesia by placing a tourniquet at the base of the penis using a piece of quarter-inch Penrose drain and normal saline solution is injected into the corpus cavernosum sufficiently to induce congestion. The cause of shaft deformity whether attributable to skin loss and/or fascial loss will be delineated once the artificial erection is achieved.

The skin defect produced following incisional release of the scar is covered with a full-thickness skin graft if Buck's fascia is not involved in the burn injury. In rare instances, if Buck's fascia is involved, surgical release of the fascial deformity is required. A dermal graft harvested from the lower abdomen can be used to reconstruct the fascial defect. A skin flap mobilized from the area along the groin crease as an island pedicled skin flap could provide an alternative cover to reconstruct the skin defect.

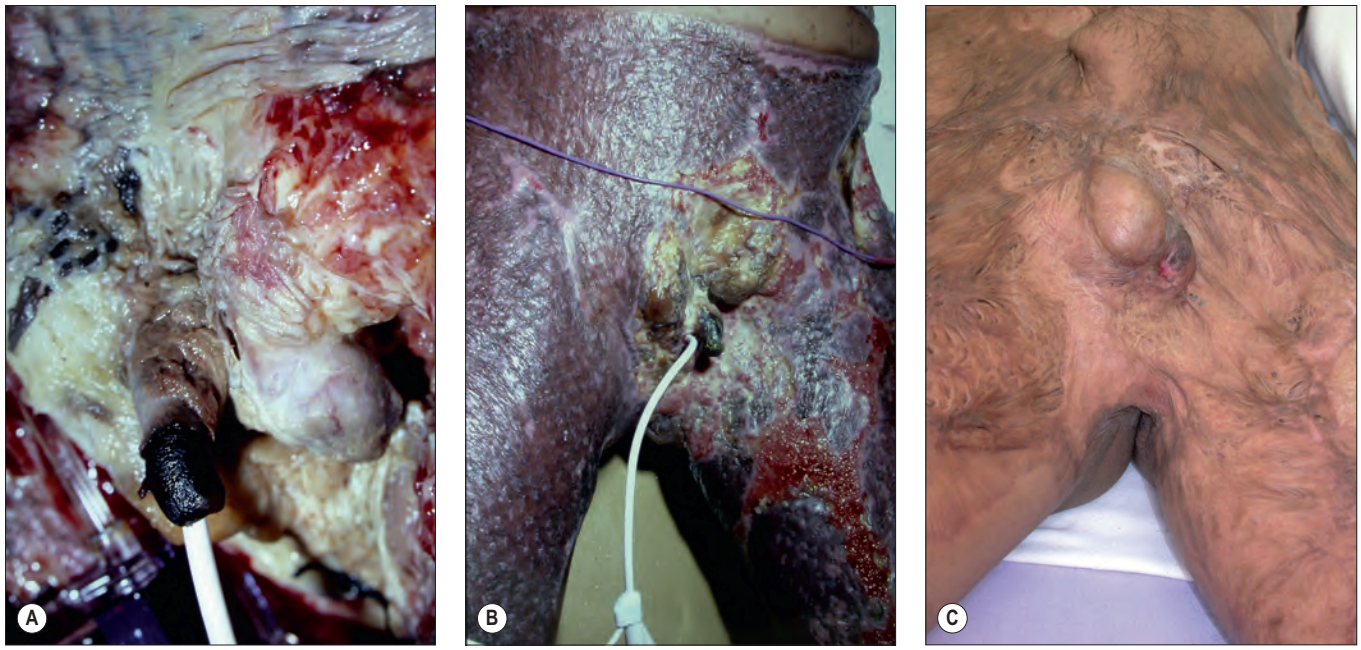

Fig. 55.6 **(A)** A full-thickness burn of the penis, although uncommon, can occur, and the outcome is devastating, as seen in this 10-year-old boy. No attempt was made to remove the penile tissue, even though it appeared grossly necrotic. Instead, the wound was left to demarcate, and an indwelling Foley catheter was used to stent the urethra. **(B)** The patient lost the phallus entirely. **(C)** The patient can urinate through a short remnant of the penis. Reconstruction of the penile shaft was planned for a later stage.

Complete loss of the penis, although devastating, is extremely rare (Fig. 55.6). If present, penile reconstruction is delayed until puberty. The delay is often necessary due to limited soft tissues that can be harvested for genital reconstruction soon after the burn injury.

There are several methods currently available to reconstruct a neo-phallus: a segment of rectus abdominis musculocutaneous flap, for instance, may be mobilized from the lower abdomen to form a neo-phallus. Although the appearance of a reconstructed phallus may be cosmetically acceptable, the structure usually lacks sensation; it serves as a urinary conduit at best.

The microsurgical tissue transfer of a combination of an innervated radial forearm osteocutaneous flap and big toe pulp has been described for penile reconstruction.[7] While the urethral tract was reconstructed utilizing a full-thickness skin graft or a tube-within-a-tube technique at the time of penile reconstruction using a radial forearm osteocutaneous flap, the pulp of the big toe was used to reconstruct a glans penis. The big toe pulp provided a structural contour resembling the glans, and cooptation of the digital nerve to the penile nerve restored sensory nerve functions (Fig. 55.7).

RECONSTRUCTION OF SCROTAL DEFORMITIES

Full-thickness burn injuries of the scrotum often result in scar encasement of testicular structures; reconstruction requires surgical release of the scarred areas. A thin skin flap such as the inguino-pudendal flap or a flap mobilized from the adjacent area is required to cover the resultant defect. A musculocutaneous flap such as a gracilis flap is not suitable for scrotal reconstruction because of the thickness of the flap and possible reduction in spermatogenesis due to high tissue temperature within the flap. Even though contracture deformity is likely to occur in the long term, a skin graft can be used to cover the defect following scar release.

RECONSTRUCTION OF LABIAL DEFORMITY

An isolated contour deformity of the labia majora is relatively uncommon; nevertheless scar contraction occurring in the suprapubic and pubic area, as well as the inguinal fold, could distort the normal configuration of the labia. Primary surgical release of the contracted scar tissues around the pubic and inguinal fold areas is an essential step to determine the extent of labial deformity and the reconstructive technique for the deformed labia.

To restore a contour deformity caused by skin and subcutaneous tissue loss, a skin flap may have to be mobilized from the adjacent area. To reconstruct a contour deformity due to parenchymal tissue loss, lipo-modeling (i.e., transfer of freshly harvested fat cells) could be useful. To inject free fat cells to augment the labial contour, the cells are aspirated from the lower abdomen using the inner cannula of a no. 14 Intracath needle attached to a 3-mL syringe. The fat is prepared and injected in the desired area as per the "Coleman" technique.[8]

RECONSTRUCTION OF BAND DEFORMITY AROUND THE PERINEUM

Scarring and scar contracture of the perineum is a common sequela of perineal burns, especially if they are left to heal by secondary intention. Although it seldom causes difficulties to the young patient, perineal scars could potentially

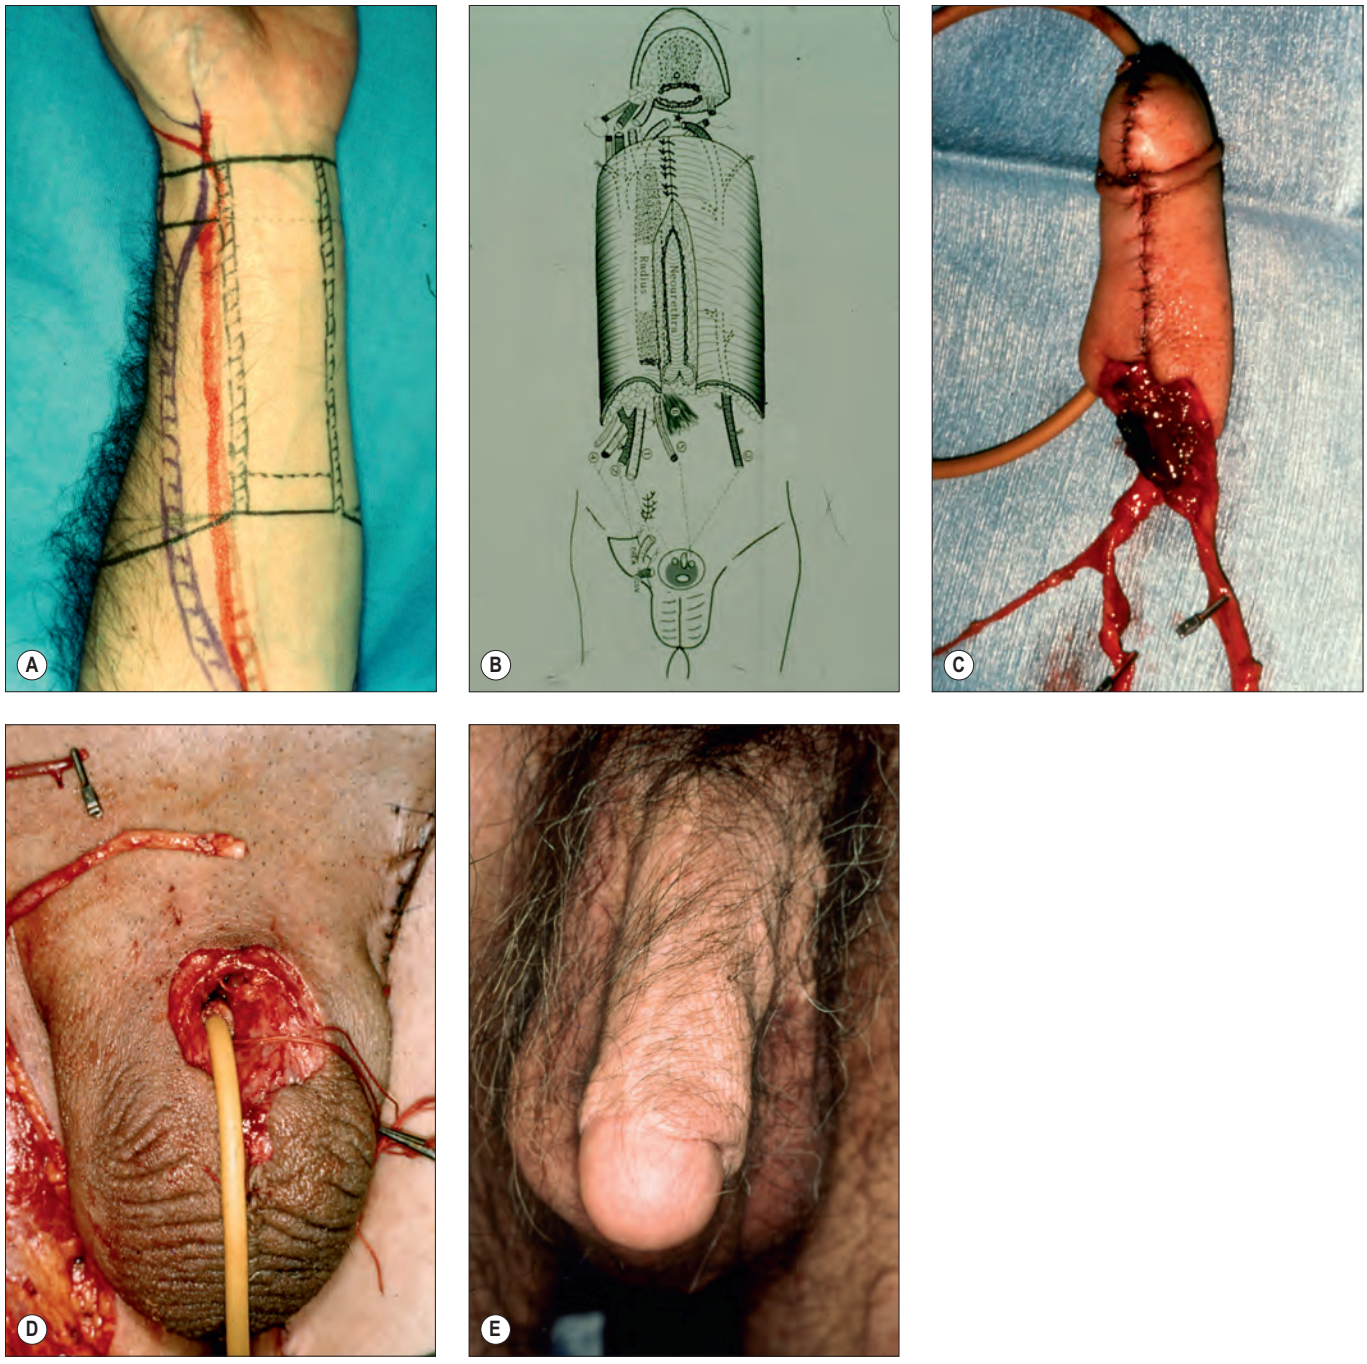

Fig. 55.7 (A) There are various techniques available for penile reconstruction; a radial forearm composite flap, one of the methods currently in use, was chosen to reconstruct a phallus structure for a 51-year-old man who lost his penis following tumor excision. **(B)** As shown in a schematic drawing, a section of the skin with radial artery attached is harvested from the volar surface of the forearm and utilized for penile reconstruction. A tube-inside-a-tube was used to reconstruct the urethral tract. In addition, the pulp from the big toe was also used to reconstruct the glans penis. **(C)** The tissues were assembled with vessels and nerve structures set for anastomosis. **(D)** The appearance of genitalia before reconstruction. **(E)** The appearance of the reconstructed penis. (A,B,E from Sasaki K. Penile reconstruction: combined use of an innervated forearm osteocutaneous flap and big toe pulp. *Plast Reconstr Surg.* 1998;104:1054–1058.)

interfere with function and physical mobility because of tightness or contractures. In addition, the patient may encounter difficulties with bowel movement because of gluteal contractures and cicatricial changes involving the anal opening.

The deformity developing in the perineal area is usually a tight band in the suprapubic area or between the ischial tuberosities. The scars result in inadequate spreading of the buttocks and discomfort while sitting, eventually producing significant functional impairment.

Although a contracted perineal band can be incised to achieve release, the task of reconstructing the resultant defect can be difficult. Recurrence of contractures is a common sequela following the use of a skin graft. Instead,

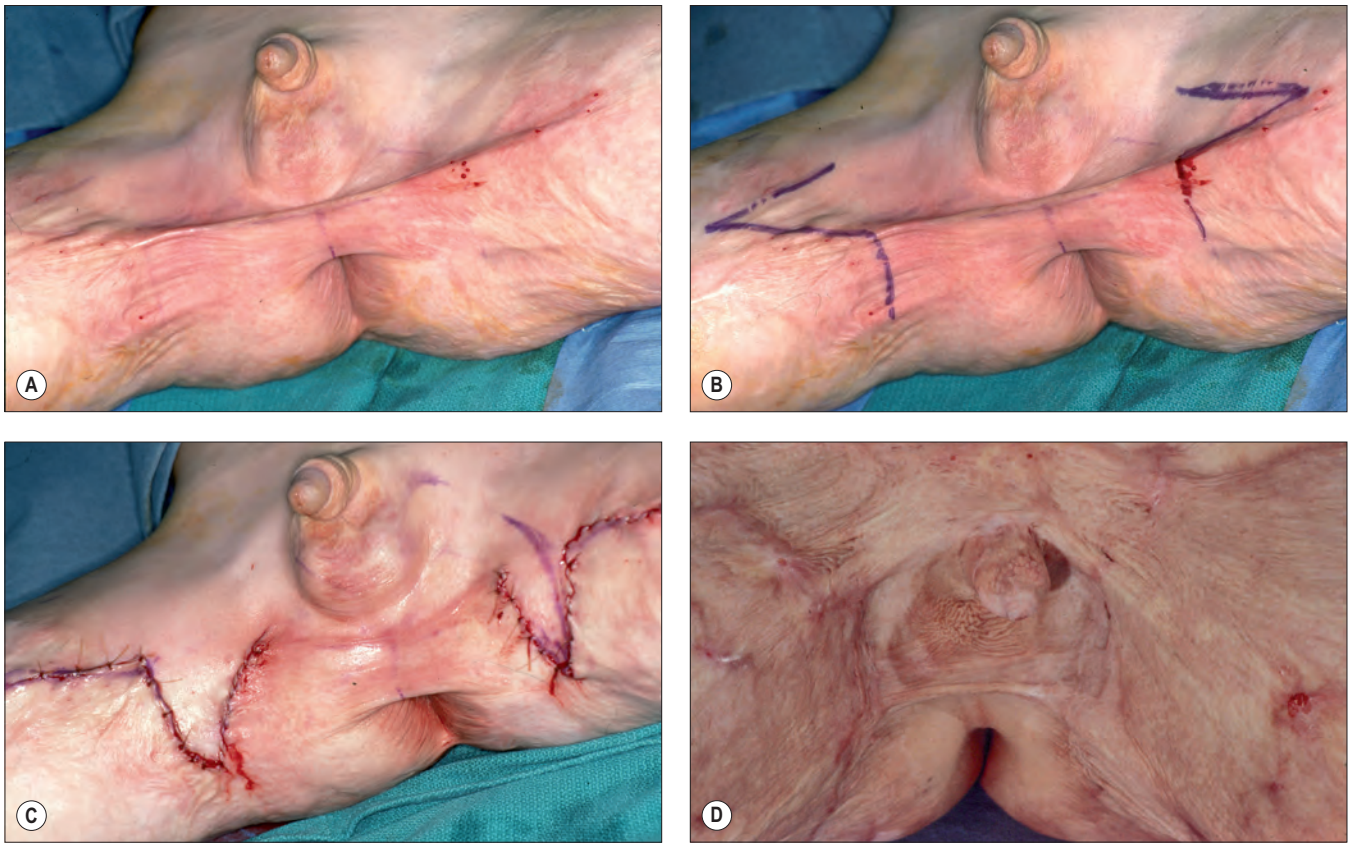

Fig. 55.8 **(A)** A tight scar band in the perineal area following burn injuries involving the perineum and the lower extremities. **(B)** Releasing incisions were placed in the areas distal to the anal opening to avoid injuring the anal sphincter. A triangular flap was designed within the uninjured area at each end of the scar band. A releasing incision was set perpendicularly to the direction of the scar band. **(C)** Each triangular flap was rotated 90 degrees to close the open wound resulting from incisional release. **(D)** Tight bands develop in the perineal area.

multiple z-plasties are the preferred reconstruction technique to release scar bands around the perineum.

The Technique of Multiple Z-Plasties

With the patient placed in lithotomy position, tightness and scar bands can be delineated with abduction of the hip joint (Fig. 55.8A). A line is drawn across the scar band along the horizontal direction of the band. The length of the horizontal line may extend from one side of the scarred area to the other. A triangular flap with its apex at the end of the horizontal line is marked. The angle may vary between 30 and 60 degrees depending on the uninjured tissues available at both ends of the horizontal line. The length of the limb of each triangle will be the same as the incision made perpendicular to the horizontal line to release the tight band (Fig. 55.8B).

Two z-plasties (i.e., two triangular flaps with a 30- to 60-degree angle and a 90-degree angle, respectively) are formed as the flaps are raised along the skin markings made. Release of a contracted scar band is achieved by rotating these two flaps at each end (Fig. 55.8C). The release of a tight band across the perineal area is maintained by interposing a segment of the soft tissues mobilized. Fig. 55.8D shows the appearance of the perineum 4 years following the releasing procedure.

Although the extent of perineal release may be limited because of the scarred tissues surrounding the triangular flaps, the z-plasty technique produces a change in the direction of scar tissue pull, thus diminishing the tightness around the perineal area.

RECONSTRUCTION OF ANAL STRICTURES

While burn injuries rarely involve the entire anorectal canal, it is not unusual for the perianal skin and the external sphincter ani muscle to be involved in extensive perineal burns. Anal strictures due to scar contraction and the cicatricial involvement of the external sphincter ani muscle are common sequelae. Cicatricial changes around the anal opening can and will usually interfere with bowel movement.

The treatment requires surgical release of constricted scar bands around the anal opening. An interpositional skin flap fashioned as an island flap or a modified z-plasty with skin flaps mobilized from the adjacent area is used to make up the tissue defect (Fig. 55.9).

The use of skin grafts to reconstruct the defect is not useful because, usually, graft application is difficult and stricture recurrence is common.

RECONSTRUCTION OF RECTAL PROLAPSE

Although the problem of rectal prolapse is, in most instances, self-limiting and the prolapse will recede spontaneously as

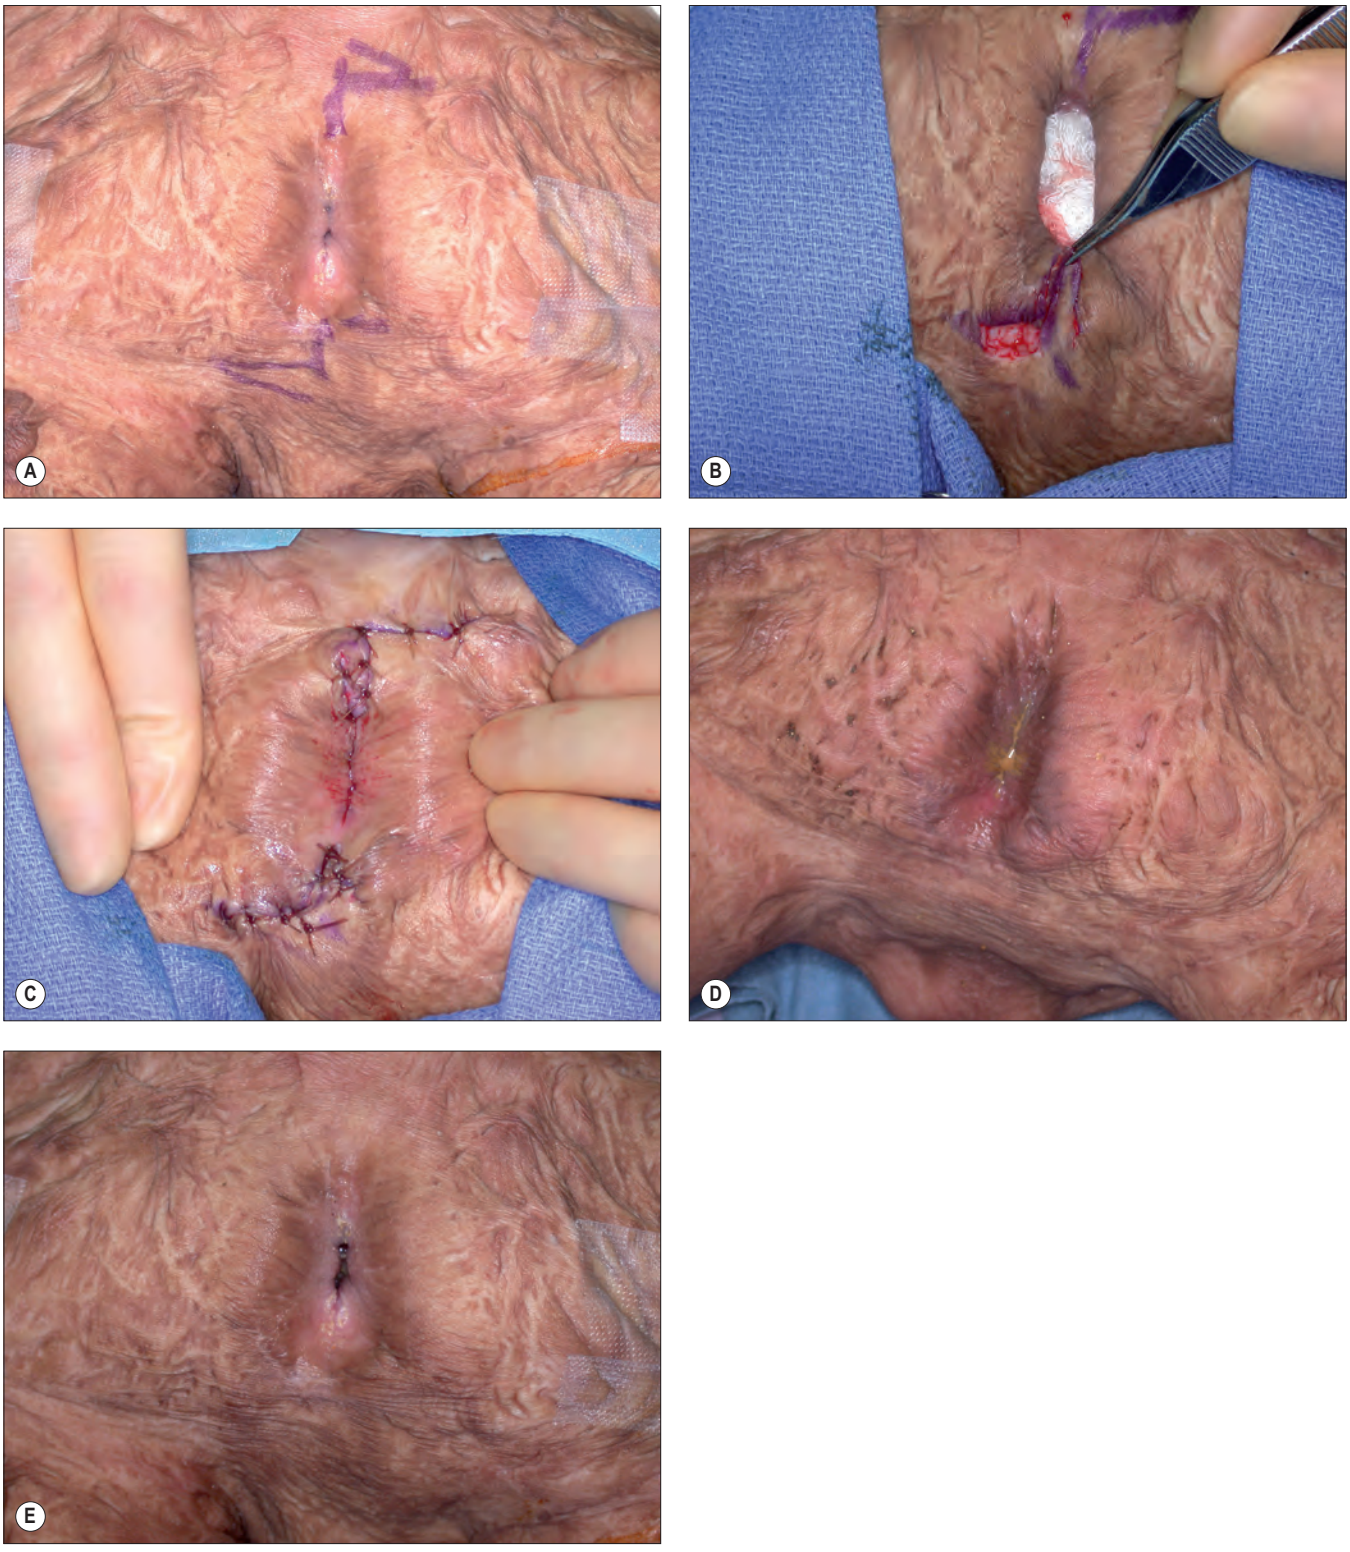

Fig. 55.9 **(A)** A 4-year-old boy developed, in addition to a tight scar band across the perineum, anal incontinence because of cicatricial contractures involving the entire perineal area. **(B)** A modified multiple z-plasties technique was utilized to reconstruct the perineal contracture and anal stenosis. **(C)** Skin flaps were rotated into the areas to reconstruct the deformity following the surgical release. **(D)** The appearance of the anal area before release. **(E)** The appearance of the anal area 9 months following release.

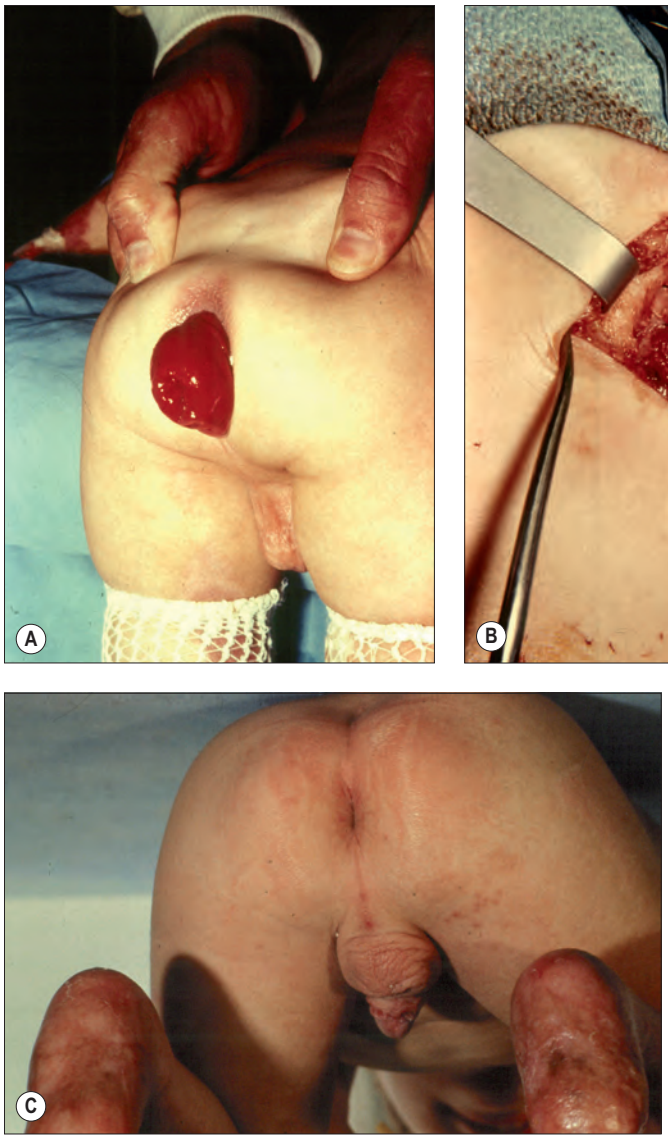

Fig. 55.10 **(A)** A 2-year-old boy who had sustained a third-degree scald burn that involved the lower extremities; he developed rectal prolapse 10 days following the injury. **(B)** He underwent a rectopexy procedure due to the persistent eversion of the rectal mucosa. **(C)** The patient regained anal continence 6 months after the surgery.

the nutritional status of the patient and wound healing improves, surgical intervention is required if the rectal prolapse becomes intractable (Fig. 55.10).[5]

Conclusion

Burn injuries of the perineum are relatively uncommon, and management during the acute phase of injury is conservative. The urethral tract is stented with an indwelling Foley catheter and the wound is cleansed daily. Neither a splint nor a brace is used to immobilize the perineal area, and the wound is usually left to heal by secondary intention. The resultant deformity, with the rare exception of total loss of the penis, is limited.

Instead disfigurement of the scrotal/labial contour and/or scar bands around the genital area are the common presentation in most patients. The reconstructive approach to these deformities centers around scar release of tight bands around the perineal structures. Incisional release and reconstruction utilizing z-plasty techniques or an interpositional skin flap is effective in correcting the deformities.

56 Reconstruction of Burn Deformities of the Lower Extremity

WILLIAM LINEAWEAVER and DEREK M. CULNAN

Assessment of Salvage Potential

Acute care of a burned lower extremity prioritizes circulation and coverage. These goals are achieved through escharotomies and fasciotomies as necessary and excision and coverage of the burn wounds. Reconstruction of lower-extremity burn sequelae, however, requires a more complex and detailed definition of defects, deformities, and functional goals. Assessment of a lower limb for secondary post-burn reconstruction is therefore directed toward a useful outcome.[1]

Sensation is an important element in lower-extremity salvage potential. A desensate foot can be a source of chronic wounds and may be a less functional outcome than a below-knee prosthesis. Treatable sites of sensory nerve compression are increasingly recognized in burned lower extremities, and nerve decompression at the tarsal tunnel (for plantar sensation) and the popliteal fossa (for dorsal sensation) can be initially considered to restore foot sensation.[2]

Muscle function must be sufficient to provide useful active motion at the ankle, knee, and hip. If direct muscle damage is incompatible with function, limb salvage may be abandoned. Some muscle deficits, such as peroneal nerve palsy with foot drop, may be associated with nerve compression, and decompression may be an effective reconstruction to restore muscle function.

Satisfactory lower-extremity salvage potential requires functional skeletal components. Associated fractures must be stably healed. Major joints must have sufficient cartilage surfaces and capsule integrity to contribute to limb function.

When evaluating a lower-extremity soft tissue burn complication, the surgeon should consider whether the problem is a deformity or a defect.[3]

A *deformity* implies a distortion of parts correctible by rearrangements of local tissue. For example, a single vertical scar band across a popliteal fossa, causing a flexion contracture of the knee, may be incised and lengthened by local Z-plasties that transpose adjacent supple tissue into the scar site and permit knee extension. A *defect* is an absence of parts and requires replacement by distant tissue. Dorsal toe contractures, when released, may be secondary to soft tissue deficiency which, when revealed by contracture release, will require skin grafts to cover the defect (Fig. 56.1). Full-thickness soft tissue loss around a knee joint may require a local muscle flap (e.g., a gastrocnemius belly) or a microsurgical flap for adequate treatment of the defect (Fig. 56.2). Clear definition of the problem should result in an appropriate selection of a reconstruction strategy.

Finally the status of the second lower-extremity provides a context for assessment of the burned lower extremity. A patient with one intact lower extremity may be less interested in complex reconstructive salvage of a functionally impaired extremity. Elective amputation with prosthetic may be a less complicated path to ambulation supported by the uninjured extremity. Two injured lower extremities, however, may make reconstruction a higher priority in either or both since loss of both lower extremities is a substantially greater disability than single lower-extremity loss.[4]

Amputations

Assessment of burn injuries to a lower extremity can lead to the conclusion that there is insufficient salvage potential to justify attempts at reconstruction. Lack of sensation, extensive muscle or joint damage, and a functioning second lower extremity may add up to a decision to amputate the impaired portion of a lower extremity.

Dislocated, dorsally contracted toes can be removed with simple amputations at the metatarsophalangeal joints. More extensive damage to the forefoot can be treated with amputations at the tarso-metatarsal level or through the ankle joint (Lisfranc and Symes procedures, respectively). Such amputations require sufficient sensation and circulation to obtain a stable result.[5]

Unreconstructable injury involving the foot and ankle can proceed to below-the-knee amputation. The priorities of that procedure include stable coverage of the tibia and fibula as well as preservation of sufficient skeletal length to support a prosthesis. The amputation closure is best achieved with tissue from the posterior calf. A refinement of amputation closure consists of using the proximal gastrocnemius muscle and its overlying skin to create a durable, myocutaneous pad.[6] This technique can be further modified to use gastrocnemius muscle covered with skin grafts from initial burn care (Fig. 56.3).

Severe damage extending proximal to the knee may lead to above-knee amputation. In this procedure, maximum secure length is useful. Anterior and posterior thigh muscles are mobilized and stabilized to each other to form the basis of closure of the overlying skin. Here also muscle covered with skin grafts can be satisfactory for stable stump closure.

Fig. 56.1 In children with recent onset of toe extension contracture, surgical manipulation of the volar plate of the MTP joint capsule is usually unnecessary. **(A)** Cicatrical dorsal toe contracture creating a hammer toe like deformity. **(B)** A Kirschner's wire of 0.020–0.035 inch size is inserted through the proximal phalanx to keep the digit in full extension while maintaining the MTPJ in 45–60° plantar flexion. **(C)** Split-thickness skin graft is placed to fill the skin defect. **(D)** The wires are removed 10–14 days later, once the take of skin graft or flap is established.

Hip disarticulation can be life-saving in burn wounds of the groin and perineum exposing major vessels. In late reconstruction of contractures of the hip, a hip disarticulation can replace a nonfunctional lower extremity with a stable wound that can support a prosthesis.

Early Reconstruction

Some specific maneuvers can contribute to the prevention of later complications.

For deep burns of the dorsum of the foot involving the toes, K-wire fixation of the toes across the metatarsophalangeal joints can effectively splint the toes to prevent hyperextension contractures while soft tissue coverage is established. Early splinting and physical therapy can be applied to ankle and knee burns to maximize range of motion and minimize contractions.

Flap reconstruction is a rare element in acute burn management, but such procedures can be considered to treat specific sites.[7]

Deep wounds around the ankle can be covered with local flaps to prevent unstable wounds, especially over the malleoli (Fig. 56.4). Full-thickness burns around the knee are within the range of local flaps that can provide stable coverage to protect the joint and avoid flexion contractures (Fig. 56.2).

Deep burns of the groin can lead to consideration of unilateral or contralateral inferiorly based rectus flaps that can securely cover the femoral canal structures and allow early motion at the hip (Fig. 56.5).

Late Reconstruction

By dorsal release of the metatarsophalangeal joints, hyperextension contractures of the toes are relieved. If scar incision reveals a defect, skin grafts can provide stable tissue replacement.[8] If the dorsal skin is sufficiently supple, the problem may be considered a deformity treatable by creating a V-shaped flap over the metatarsophalangeal joints, advancing the flap to allow reduction of the toes to at least

neutral, and closing the donor site with mobilized marginal skin (or well-healed skin-graft) to complete a V-Y advancement (Fig. 56.6).

Anterior contractures of the ankle result in dorsiflexion, whereas posterior contractures cause plantar flexion. Anterior contractures are treated by incision and/or excision of scarred soft tissue to restore ankle range of motion. Such a release creates a defect with exposure of the tibialis anterior tendon. Coverage here is best achieved by a flap, and consideration can be given to local perforator flaps or microsurgical flaps (Fig. 56.7). Perforator flaps should be carefully chosen to be certain that the critical vessels have not been obliterated by burn injury. Microsurgical flaps should also be considered within the possibilities of tissue not compromised by the burn injury.[9] Cutaneous flaps, including anterolateral thigh flaps, radial forearm flaps, and scapular flaps, may be critically damaged in a burn patient. In such cases, muscle flaps (including rectus, latissimus, and gracilis flaps) can be reliable reconstructive options. These muscles are covered with skin grafts after their vascular and marginal insets.[10] Muscles also can be harvested through overlying skin grafts, therefore increasing their potential availability in burn reconstruction.

Posterior ankle contracture frequently includes shortening of the Achilles tendon. This structure must be mobilized from adjacent and proximal scar. If this tenolysis does not provide enough ankle mobility, the tendon itself must be lengthened with a step cut procedure.[1] Soft tissue coverage of the resulting defect and tendon exposure requires a flap. Local flap options include perforator flaps, including, most simply, a lateral calcaneal flap if it is available[9,11,12] (Fig. 56.8). Microsurgical flaps are otherwise an option, and either cutaneous or muscle flaps can be used.[10]

A contracture of the knee can be as simple as a deformity caused by a vertical scar band that can be incised and restored to length with local Z-plasties. If resection of scar tissue results in a defect, a lateral or medial gastrocnemius muscle flap can resurface an entire popliteal fossa, with restoration of extension. If local muscle cannot be utilized, microsurgical flaps can be effective, and a large unit such

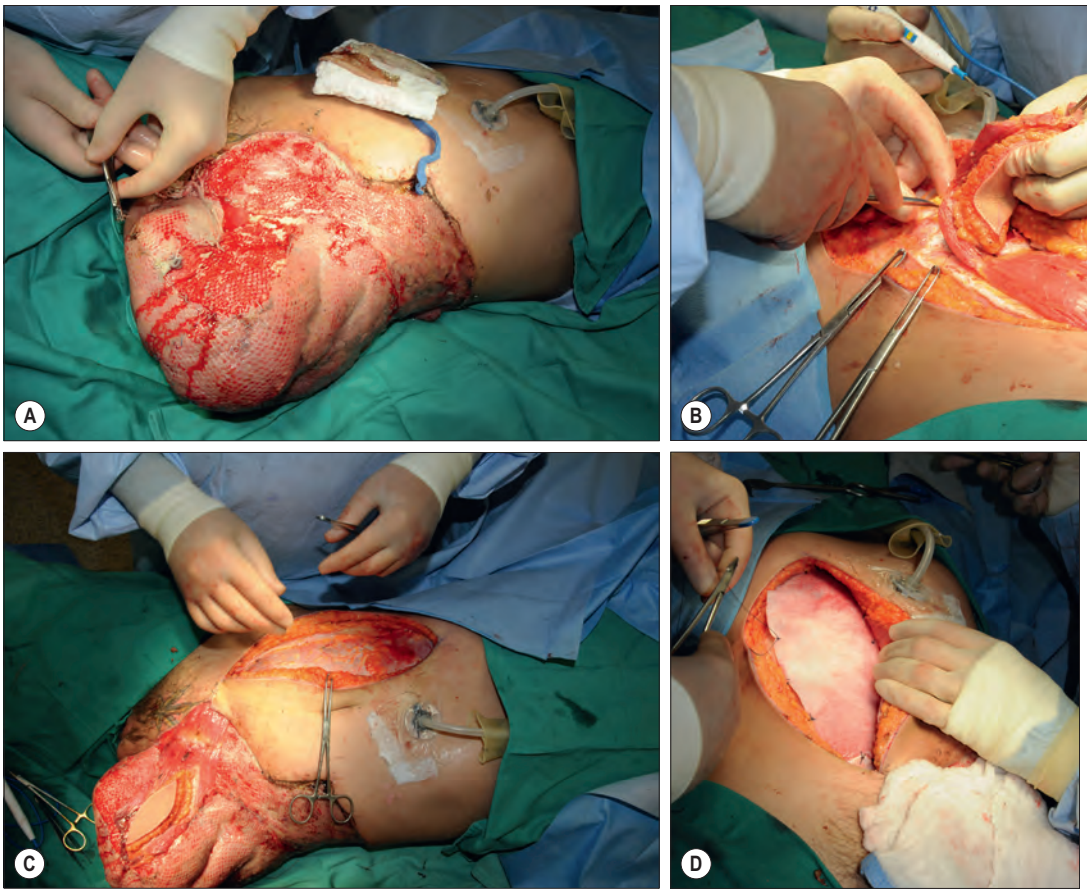

Fig. 56.5 **(A)** The stumps of the femoral vessels are exposed in scar tissue on the surface of the amputation stump. **(B)** The right rectus muscle with a superior skin paddle is elevated to the deep inferior epigastric vessels. **(C)** Transposition of the myocutaneous flap covers the vessels. **(D)** Primary closure is performed over the repaired rectus sheath while split-thickness skin grafts are applied to the rest of the stump.

Fig. 56.6 **(A)** Dorsal skin grafts have contributed to contractures that have fixed the toes in extension. **(B)** The "V" component has been elevated and advanced while the toes are pinned in metatarsophalangeal flexion. **(C)** Primary closure of the donor defect completes the "V-Y" flap advancement.

as a rectus or latissimus can be considered. The vessels in Hunter's canal are reliable, deep recipient sites for vascular insets using the long pedicle vessels harvested with latissimus or rectus flaps.[13]

Hip flexion contractures occur most commonly in children. Treatment consists of resection of superficial and deep scar to allow extension while protecting the femoral vessels and nerves. The resulting defect can usually be managed with a skin graft, while extensive wounds with wide neurovascular exposure may require an inferiorly based rectus flap or a sartorius turnover flap.[14]

Fig. 56.7 Late result of anterior ankle coverage with a microvascular rectus flap and a split-thickness skin graft.

Grafts and Flaps

Clear understanding of these reconstructive units allows coherent planning. Both grafts and flaps are applied to the treatment of defects. Both also must be selected from areas not compromised by burn injuries. The elemental difference between grafts and flaps consists of the difference between their blood supplies.

Grafts have no intrinsic circulation and must survive on the bed on which they are placed by the processes of serum imbibition, inosculation, and neovascularization. Grafts therefore require beds of vascular tissue and cannot be applied reliably to bone or tendon. Split-thickness skin grafts, usually harvested by a dermatome, revascularize more promptly, and their donor sites, which heal by epidermal regeneration from the dermis, allow large grafts to be utilized. Split-thickness grafts, however, tend to contract with their underlying beds and can be relatively fragile to external trauma. Full-thickness skin grafts include epidermis and dermis. Their donor sites must be closed as wounds, so the available area for these grafts is very limited. They also take longer to revascularize and require optimal beds and extended immobilization. These grafts have the

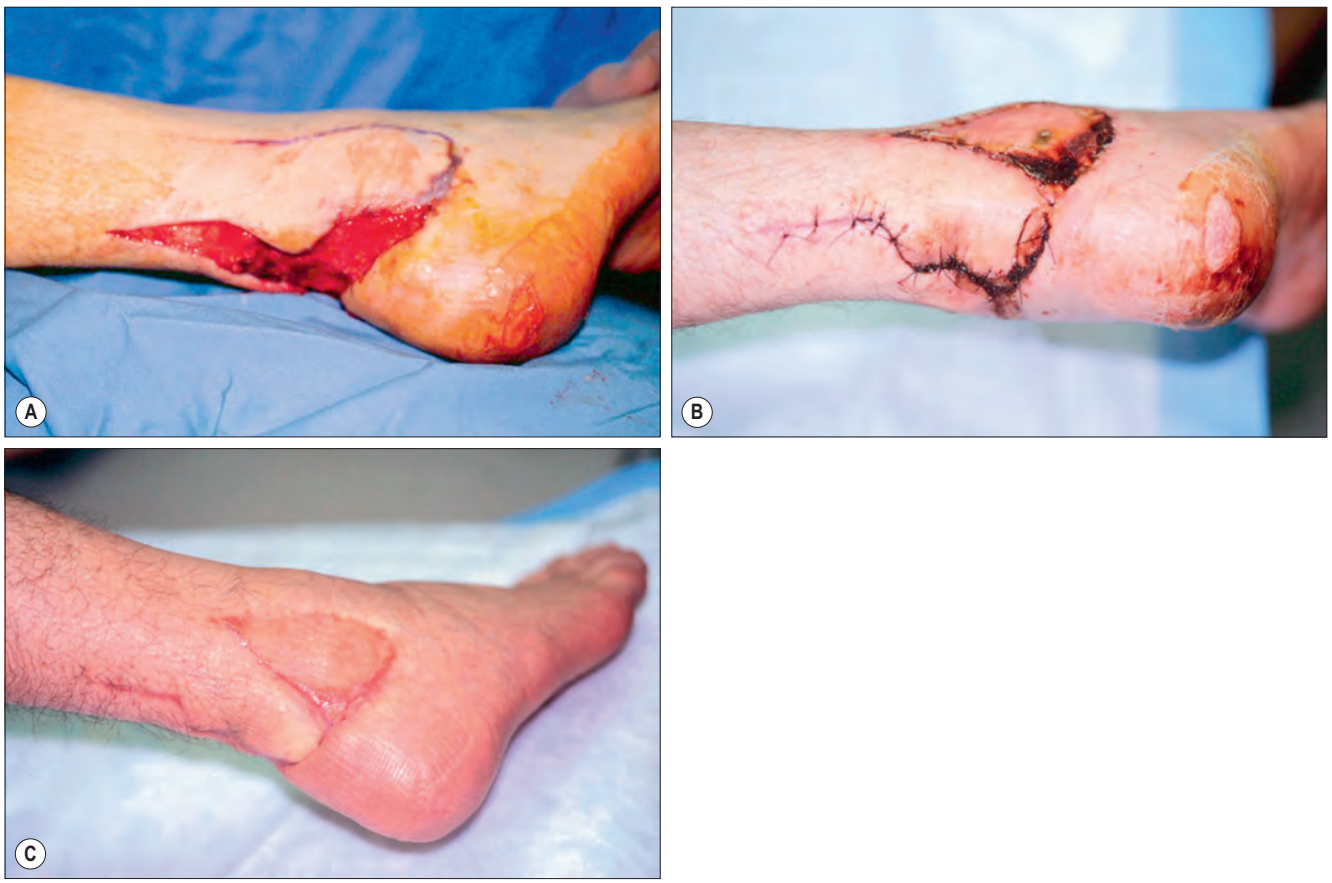

Fig. 56.8 **(A)** Contracted scar is excised and a lateral calcaneal flap is outlined. **(B)** The flap is rotated into the defect. **(C)** Late results include stable coverage and functional range of motion; the donor defect was covered with a full-thickness skin graft.

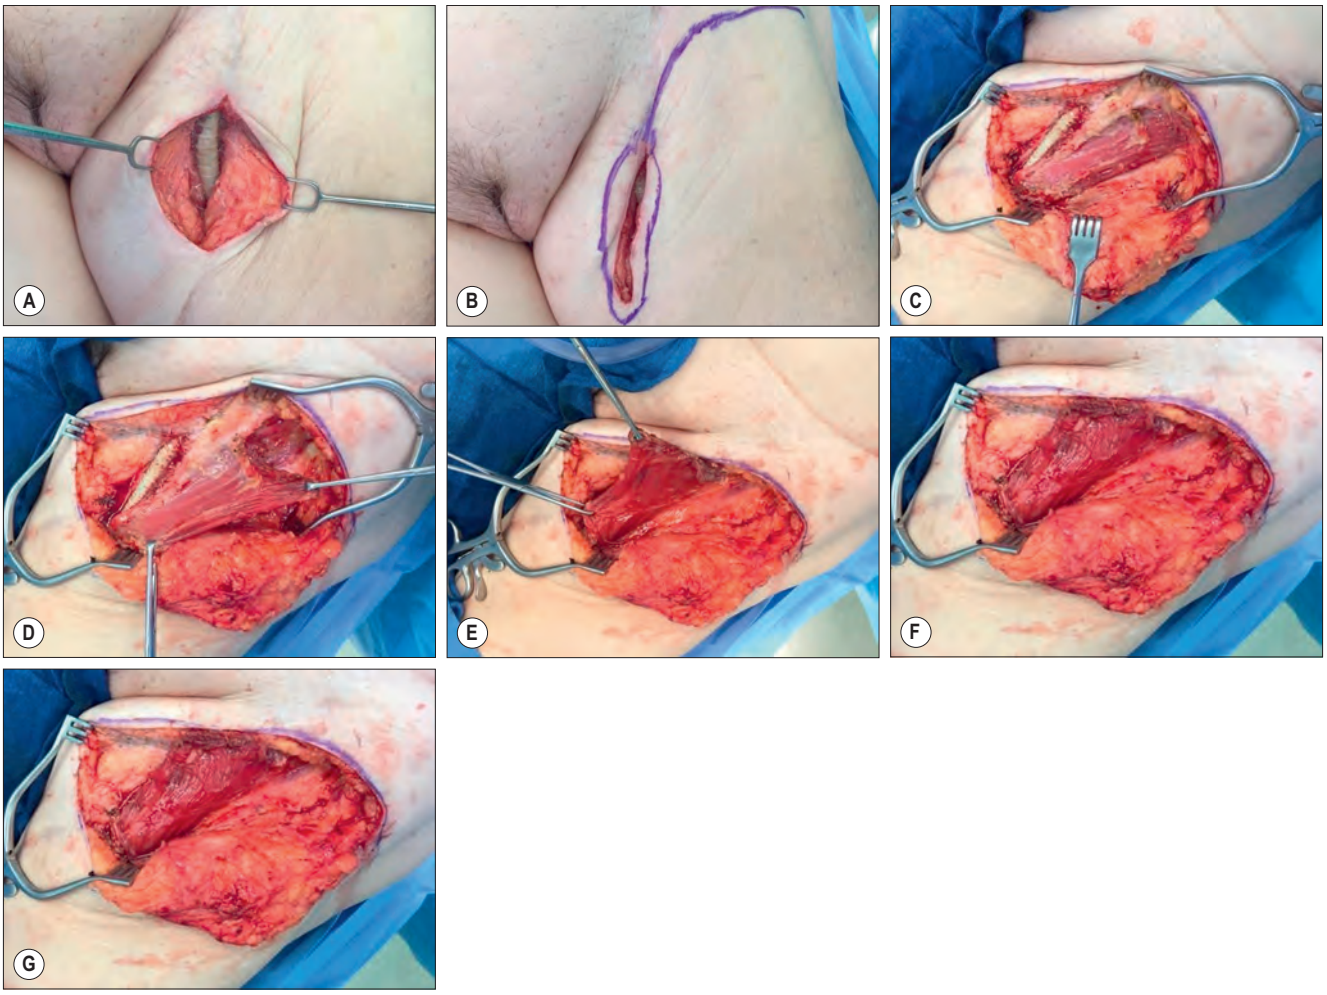

Fig. 56.9 **(A)** Resection of an unstable wound exposes an underlying vascular graft. **(B)** A rotation flap is outlined. **(C)** Elevation of the flap exposes the sartorius muscle. **(D)** The origin of the muscle is transected. **(E)** Using the muscle as a turnover rotation flap preserves the segmented medical vascular pedicles. **(F)** Flap inset covers the vascular graft. **(G)** Inset of the rotation flap completes the reconstruction. (From Dr. Lineaweaver)

advantages of decreased contracture, greater durability, and some potential for sensory reinnervation based on dermal end organs in the graft and nerve regeneration from the underlying defect.[14]

Flaps contain intrinsic blood supplies and therefore can be reliably used to cover bone, tendon, and poorly vascularized defect surfaces. Flaps also generally contain more tissue and can fill deep, irregular defects. Flaps have limited potential for contracture.

Cutaneous flaps include local pattern flaps that have no defined vascular pedicle. These flaps are based on empirical designs that include advancement flaps (e.g., V-Y patterns), rotation flaps, and transposition flaps (e.g., Z-plasties and rhomboid patterns). These flaps require supple tissue, although they interestingly can often succeed using well-healed skin grafts, especially if the grafts were placed over muscle. Pedicled flaps include defined arteries and veins critical to the flap's survival (Fig. 56.9). Perforator propeller flaps are increasingly utilized as versatile options in lower-extremity reconstructions.[15]

Microsurgical flaps can be harvested remote from the defect. Utilizing pedicle vessels, the flap insets will include microsurgical anastomoses to vessels at the site of the defect. Such procedures are reliable in acute and delayed burn surgery. There has long been a reluctance to employ microsurgical flaps in the acute settings due to prior reports demonstrating increased flap loss in the 5- to 21-day period following injury. Those data have been refuted in more recent series and microsurgical procedures can serve as reliable, versatile reconstructive units in critical defects.[16–18]

Conclusion

In approaching a burn complication in a lower extremity, the reconstructive surgeon proceeds from a careful analysis of salvage potential to specific definition of deformity and defect. This sequence leads to identification of an optimum reconstructive technique selected from the wide range of procedures available for modern reconstructive surgery.

57 Electrical Injury: Reconstructive Problems

PETER M. VOGT, ANDREAS D. NIEDERBICHLER, and ANDREAS JOKUSZIES

Introduction

Severe cases [of electrical injury] coming for reconstruction present a formidable problem of flexion contracture and loss of many tendons and nerves, new pedicled skin and grafted-in tendons and nerves usually being necessary. One encounters inside the limb the same type of destruction and cicatrix as is found after any severe infection.

STERLING BUNNELL, 1948

This chapter will focus on the multitude of surgical and reconstructive problems that result from electrical injury. The injury severity is complex due to various factors determining manifestation and the distribution of the resulting tissue damage. In common with other types of trauma, especially burn injuries, the consequences of electrical injury may affect a wide range of physiological functions. Its distinct features warrant a differentiated approach to this unique kind of trauma. The resulting tissue loss and the damage to essential structures of the involved body areas often require extensive plastic-reconstructive procedures.

Although the incidence of low-voltage burns has declined steadily over recent decades, most probably due to progress made in the field of home and occupational safety education and equipment, electrical injuries still account for 3–5% of all admissions to major burn centers.[1,2] Electrical fatalities are relatively uncommon, and most of them occur accidentally. Earlier reported limb amputation rates of up to 71% decreased over recent decades with the increasing ability to reconstruct anatomic parts and restore function, but limb salvage remains a surgical challenge.[3,4]

Physiological Basis of Tissue Destruction

The traditional pathophysiological understanding of electric injury was based on the assumption that the passage of electric current produces heat and triggers tissue damage.[5] Thus tissue-specific susceptibility (and vulnerability) is considered to increase progressively from nerve to blood vessels, muscle, skin, tendon, and fat to bone. As osseous tissue shows the highest electrical resistance, it will generate the most heat. Electric current will preferentially take the path of least resistance through the body so that the current will pass particularly along the neurovascular bundles. This theory further postulated that the lesions produced by the current would result in delayed vascular occlusion and progressive tissue necrosis.[6]

In high-voltage injuries, the internal milieu acts as a single uniform resistance.[7] Instead of conduction through specific preferential tissues, the body conducts the current with a composite resistance of all tissue components.[8] The crucial factor in determining the resistance and hence the magnitude of tissue damage is the cross-sectional diameter of the affected body part. Devastating injuries to the extremities occur with a significantly higher frequency than tissue damage to the thorax and abdomen[9] (Fig. 57.1). Because muscle tissue occupies the largest cross-sectional area in the limb it also carries the predominant electric current. Because joint areas are regions where the cross-sectional tissue composition changes from low-resistance muscle to high-resistance bone, tendon, and skin, a proportionally higher current and heat are produced in these areas according to Ohm's Law.[9]

Arcing describes the energy transmitted by a hot electrically conducting gas. However, this requires a voltage of more than 20,000 V to bridge even a short distance of 1 cm.[10] Effects on tissue vary from minimal skin wounds to charring and tissue vaporization.

The different trauma mechanisms of the burns induced by the arcing phenomenon are often referred to as "flush burns," heat burns that are induced by the massive heat generation. "Electrothermal burns" are caused by current passage through the body and the concomitant heat production.

Electrical damage to a large artery represents a grave prognostic sign for limb survival.[11] The reported risk of amputation is high, at between 37% and 65%.[12–14]

Further nonthermal mechanisms of cellular injury have been defined. This includes a voltage-induced loss of cell membrane semipermeability.[15–17] When the integrity of the cell membrane is lost, the impedance is markedly reduced, leading to a simultaneous increase in the area exposed to current flow.[18] In addition to breakdown in cellular integrity, electrical fields also induce denaturation of membrane proteins by altering their structural conformation and rendering them nonfunctional.[19] Both mechanisms are responsible for rhabdomyolysis and secondary myoglobin release, which depends directly on the imposed electric current and is not a thermal effect.[20]

The human body consists of about 60% water. The intra- and extracellular water content and their highly resistive plasma membrane separate these two compartments from each other.[21] Change in the current transporters from electrons to ions at the skin surface appears as metallic condensations of dark-grayish skin lesions that resemble eschar.[22]

Another central factor of the cellular effect of electrical current is its frequency, which can arbitrarily be divided

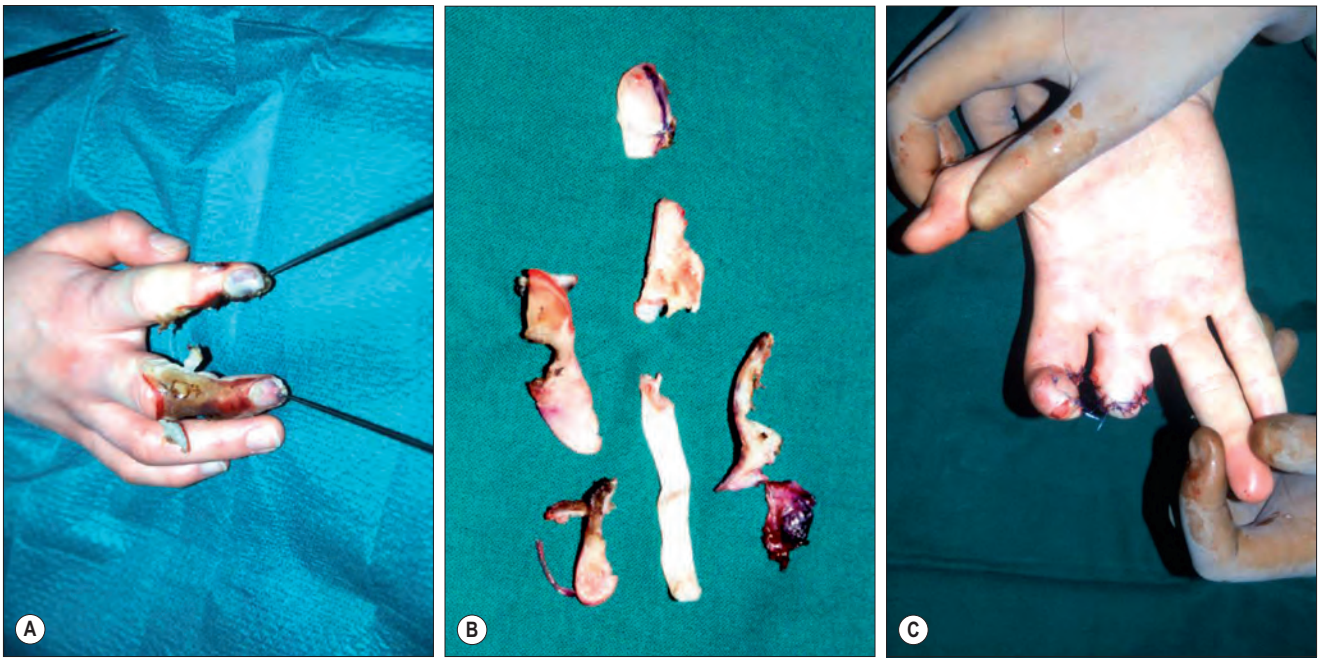

Fig. 57.1 Electrical burn from a domestic water heater (220 V). The 13-year-old girl manipulated the device while being immersed in the bathtub. She sustained third- and fourth-degree burns to the digits **(A)**. Debridement revealed full-thickness injuries involving tendons, nerves, and phalangeal bones **(B)**, which necessitated primary amputation **(C)**.

Table 57.1 Dependence of Cutaneous Resistance on Skin Moisture

	Resistance
Dry skin	100,000 Ω
Wet skin	2500 Ω
Skin immersion	1500 Ω
Rubber soles	70,000 Ω

Reproduced from Ohashi M, Koizumi J, Hosoda Y, et al. Correlation between magnetic resonance imaging and histopathology of an amputated forearm after an electrical injury. *Burns* 1998;24:362–368.

into low (<10 kHz) and high (>10 kHz, e.g., radio frequency, microwave, and ionizing frequencies).

Diagnosis and Acute Treatment

Diagnosis and acute treatment of electrical injury are described in Chapter 38.

Assessment of Tissue Damage

Accurate assessment of the extent of tissue damage is difficult. The percentage of burned body surface area grossly underestimates the injury to underlying tissue. Electrical burns may appear as mere pinpoint marks. In contrast, fatal electrocution may even take place without visible skin burns in the case of a large contact area (Table 57.1).

In contrast to thermal burns, deposition of metallic iron and copper is found on the epidermis after electrical injuries as electrolysis occurs in the extracellular fluid of the skin.[24–26]

Clinical determination of tissue viability is based on inspection and the demonstration of muscle contractility. As yet, there are no other diagnostic tools available to accurately assess the extent of tissue damage in the early phase following electrical injuries. The value of magnetic resonance imaging (MRI) for the detection of nonperfused nonedematous muscle is debated.[24–26] Angiography, although not providing information on tissue viability, demonstrates the absence of tissue perfusion and may lead to an early indication for limb amputation.[27]

Rhabdomyolysis and Myoglobinuria

Destroyed muscle cells release myoglobin, resulting in myoglobinemia. Hemolysis also often occurs with electrical injury. Serum levels of creatinine and creatinine phosphokinase (CPK) are used as indicators of rhabdomyolysis. After muscle injury CPK levels will peak by 24 h and return to baseline within 48–72 h.[28] This diminishes the diagnostic value of serum and urine chemistry testing.[29,30]

Renal Failure

Myoglobinuria has traditionally been considered a major risk factor for the development of acute renal failure. Recently patients with electrical injuries have been shown to have a surprisingly low risk for renal failure.[31] In 162

Table 57.2 Recommendation for Cardiac Monitoring in the Absence of Other Injuries

Admission and Cardiac Monitoring	Discharge
Loss of consciousness[59]	Asymptomatic patient[60]
Extensive burns[50]	Normal initial ECG[61]
Current passing through the thorax[52]	Uneventful 4-h observation[62]
Cardiac dysrhythmias[59]	Voltage less than 240/260 in adults[60,61]
	Voltage less than 120/240 in children[48,62]

patients, only 14% had myoglobinuria and none developed renal failure. Suggested criteria to evaluate the risk of acute renal failure after electrical injury include prehospital cardiac arrest, full-thickness burns, compartment syndrome, and high-voltage injury. The presence of at least two of these criteria should instigate immediate treatment because the timeframe to prevent progression to acute renal failure is limited to a few hours post injury.

Cardiac Monitoring

Among the estimated 1300 deaths that occur annually in the United States from electrical injury (including lightning strike), 30% of patients present with cardiac complications. The majority of electrocardiographic (ECG) abnormalities are sinus tachycardia and nonspecific changes in the ST-segment and T-wave.[32] Death from electric injury most commonly results from current-induced cardiac arrest.

However if an initial ECG shows no abnormalities, the delayed development of cardiac problems is very unlikely irrespective of whether the patient sustained high- or low-voltage injuries.[33–35]

Conversely, the presence of dysrhythmias or conduction abnormalities on initial presentation, electrical injury in children, or the projected path of the current flow crossing the thorax on initial presentation warrant prolonged cardiac monitoring.[36–39] Depending on the nature of the current-induced arrhythmia, pharmacotherapeutic and/or invasive interventions may be necessary. Table 57.2 outlines recommendations for cardiac monitoring of electrically injured patients based on central clinical findings and specific features of the trauma mechanism.[42]

Apart from specific therapeutic measures for cardiac complications, acute treatment of patients with electrical injuries adheres to guidelines of advanced burn life support (ABLS), advanced trauma life support (ATLS), and the current practice of intensive care medicine. The patient must be continuously monitored for signs of neurovascular compromise and deranged tissue perfusion and oxygenation.

Surgical Debridement

In recent decades the concept of progressive tissue necrosis has led to the treatment strategy of early debridement and fasciotomy, followed by serial debridement and delayed wound closure.[41] The observed changes may likely be explained by vascular changes similar to ischemia-reperfusion injury with immediate cessation of capillary blood flow in response to current passage. This event is followed by vascular spasms lasting for an extended period, with subsequent vasodilatation and restoration of flow.[43–45] Although still controversial, these findings may alter the acute treatment paradigm.

Although there is little discussion about the early time point of debridement, several recent studies question the need for extensive and total necrectomy and advocate the approach of delayed soft tissue coverage. *Conservative debridement* consisting of removal of charred and obviously necrotic tissue was promoted in a study on 40 patients.[46] In this study partially damaged tendons, muscles, and nerves were preserved, and wound closure was achieved by immediate flap coverage. Patients treated in this manner with immediate soft tissue coverage had a significantly better outcome than a control group who underwent serial debridement procedures. Similar results were found in a study using early free-flap coverage for electrical injuries, suggesting that careful limited initial debridement is an adequate measure.[47,48] According to this study overly extensive and repeated debridement to ensure viability of all remaining tissue appears not only unnecessary but quite likely harmful. It appears safe to abandon these strategies and to perform an early, extensive but selective debridement in order to preserve continuity of functionally important structures (Fig. 57.2). Limb salvage with functional preservation of vital structures should be attempted and may require revascularization using segmental vein grafts or segmental cable grafting of nerves. Pedicled flaps should be considered in cases of suspected arterial compromise.

Despite the encouraging results of the studies recommending early soft tissue reconstruction, by all means it should be noted that for the extent of electrical injury no scoring system has so far been established. Alternative approaches to salvage upper-extremity function, such as the temporary ectopic implantation of an undamaged hand, have been reported but cannot be considered standard of care.[49]

Compartment Syndrome

Muscle compartment pressure should be monitored clinically and by invasive pressure measurements. In contrast to blunt trauma, pain is not a reliable indicator of increased compartment pressure owing to the high incidence of electrical nerve injury. When compartment pressures exceed 30 mm Hg surgical decompression by open fasciotomy becomes necessary to prevent ischemic muscle injury. In the case of lower compartment pressure, progression may be prevented by administration of nonsteroidal antiinflammatory drugs (NSAIDs) and antioxidants, protective splinting, and rest without elevation of the affected extremities. However general operative decompression in high-voltage injuries to extremities appears not to be warranted. In a cohort study, Mann et al. found an increased amputation rate of 45% with immediate operative decompression compared to patients undergoing selective fasciotomy, and they recommend fasciotomy only in cases of progressive

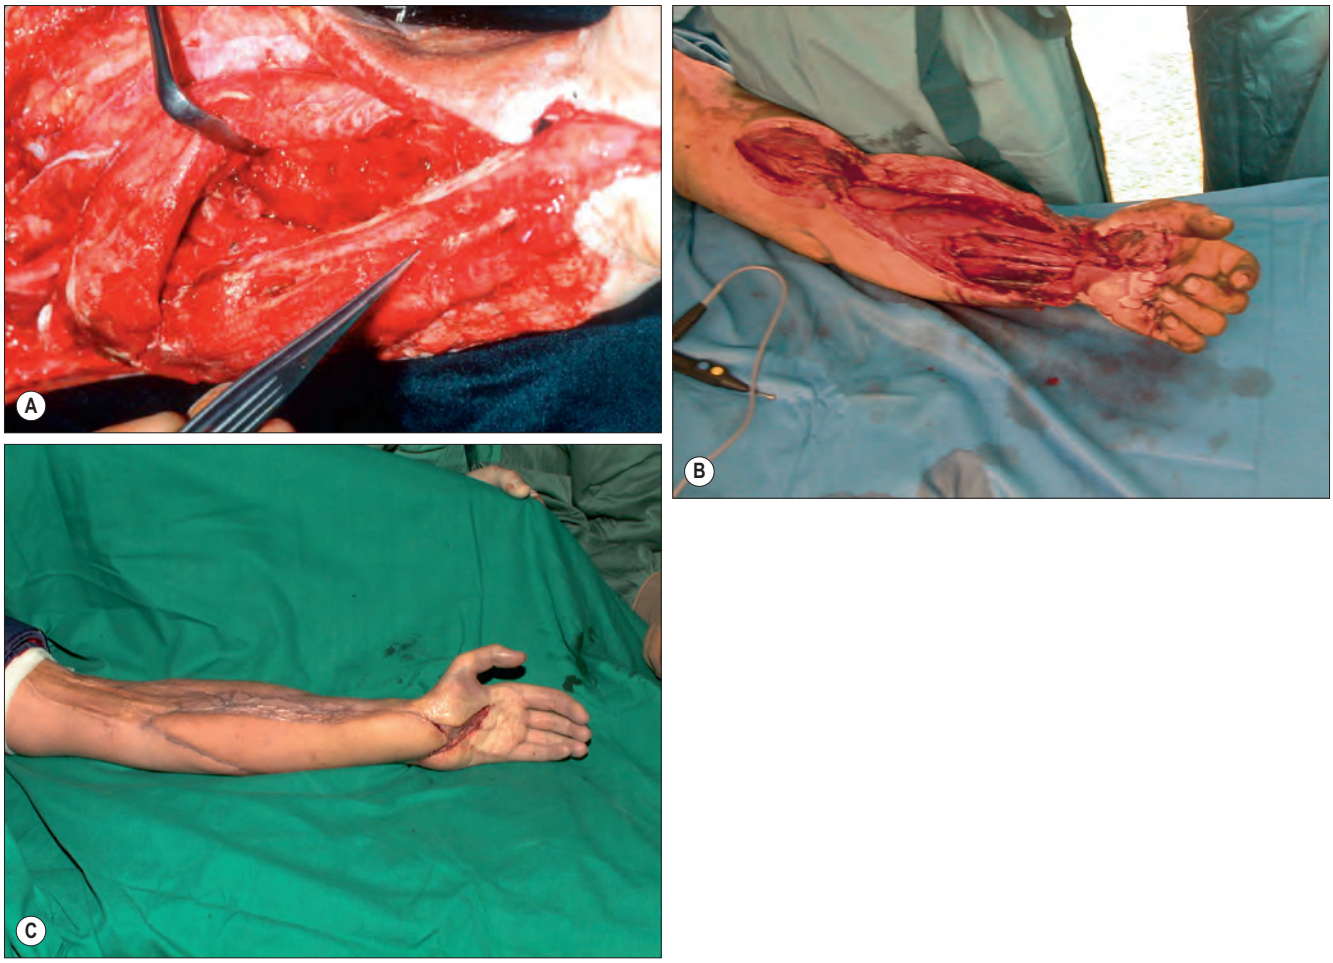

Fig. 57.2 High-voltage injury from an overhead power line (30,000 V). The teenager climbed a train and was struck by an arc without touching the power line. The spectrum of injury included third- and fourth-degree burns and deep tissue necrosis of the forearm **(A)**. After fasciotomy because of impending compartment syndrome **(B)**. Coverage with free latissimus dorsi flap after conservative debridement. Significant functional deficits after 4 years **(C)**.

peripheral nerve dysfunction, manifested compartment syndrome, or other major injuries[40] (Figs. 57.2 and. 57.3). With a fixed neurological deficit, however, surgical decompression shows no influence on outcome.[50] If the clinical situation remains doubtful, however, the performance of open fasciotomy with early debridement may be preferred.

Head: Scalp, Skull, and Mouth

Exposure and necrosis of osseous structures may lead to osteomyelitis and epidural abscess formation. Treatment strategies depend on the extent of the injury to the bone. In the case of only a partial necrosis of the bone, the outer table of the skull can be tangentially removed and the viable diploic cavity exposed. In cases of sufficient vascularization, the exposed bone can be grafted immediately or, when blood supply is questionable, grafted when suitable granulation tissue has developed.[51] Vacuum sealing of the wound can be of significant efficacy in growing adequate amounts of granulation tissue. When the initial wound debridement is delayed, necrotic and infected bone potentially becomes the source of a full-thickness skull defect. Full-thickness injury of the skull theoretically requires complete excision of the necrotic bone to prevent infectious complications.[69] Another approach suggested is partial debridement followed by definitive flap coverage of the exposed bone. This, however, requires early debridement and the prevention of localized bacterial colonization and infection.[52,53]

In a series of 10 male patients with nonviable cranial bone after class IV electrical burns, 3 weeks after initial soft-tissue debridement multiple burr holes in the nonviable and preserved bone were made and scalp flap coverage was performed.[54] Leaving the necrotic osseous structures in situ serves as a scaffold of substitution for bone regeneration.[55–57]

Skull contour was maintained in all 10 patients, making a secondary cranioplasty unnecessary. During a follow-up period of at least 1 year no postoperative infection, osteomyelitis, or cranial bone sequestration occurred.[54]

Another option is the use of glycerol-preserved allografts (GPAs).[58] The growth of spontaneous sufficient granulation tissue is promoted by its angiogenetic capacity, and split-skin autografts can be performed at a later stage. Further beneficial properties of GPA appear to be related to their permeable epidermal barrier, the subjacent network of dermal collagen, and protection of the bone by restoration

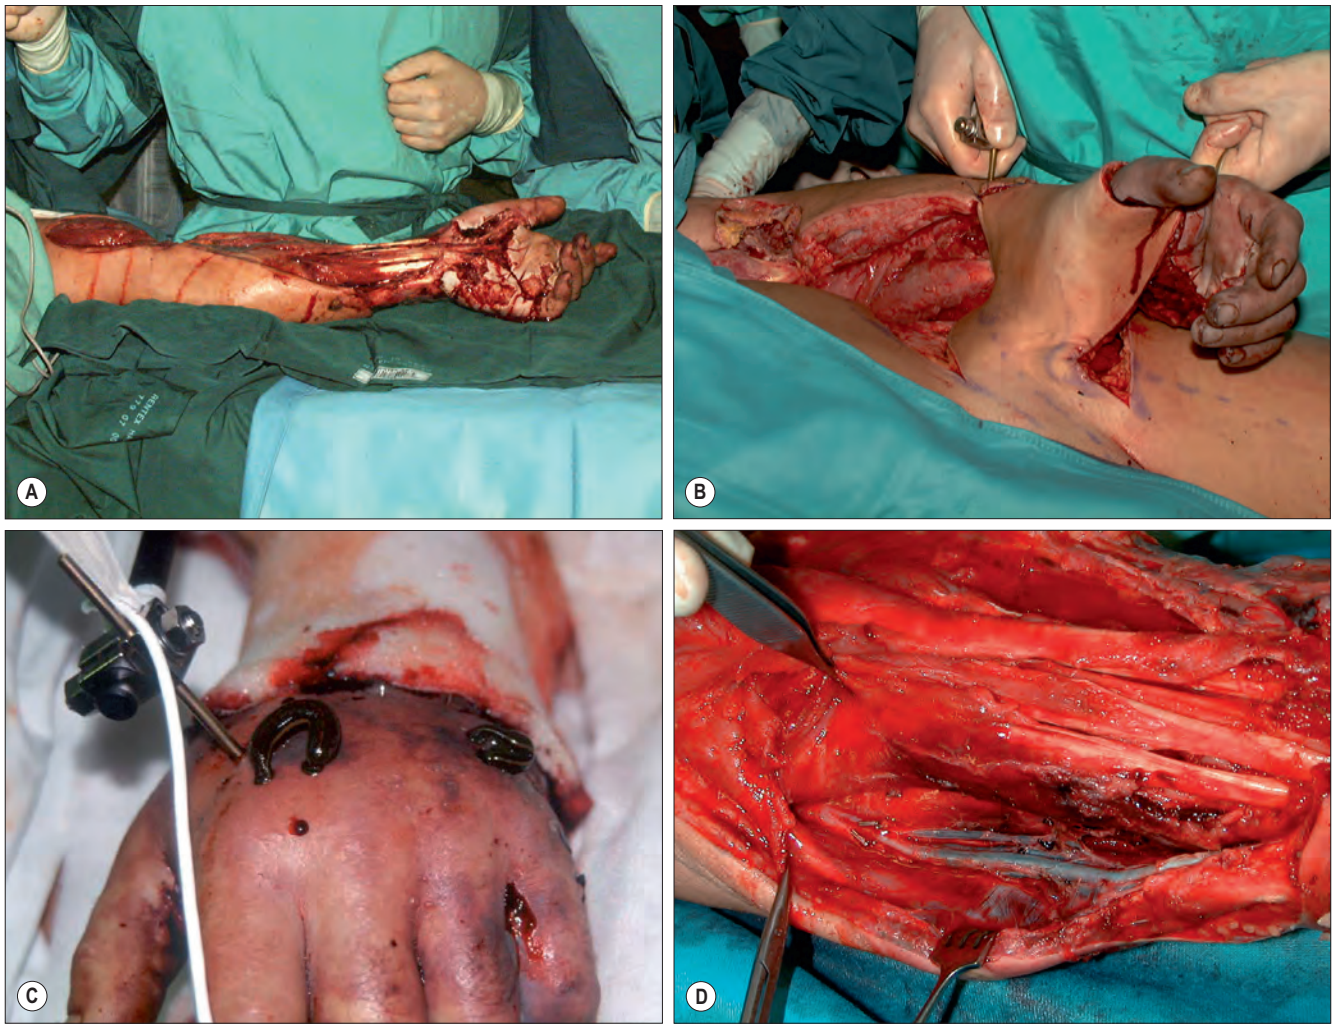

Fig. 57.3 High-voltage injury from a power line (50,000 V). Presentation with primary loss of perfusion, loss of function, and compartment syndrome. Initial operation with fasciotomy, revascularization of the radial artery, and necrectomies. On the following days, adequate perfusion with a patent radial artery without coexisting veins. Coverage with groin flap on day 6. Venous congestion and subsequent malperfusion was temporarily treated with leeches. Secondary amputation on day 10 due to late occlusion of the radial artery.

of a physical barrier that prevents drying out and reduces the risk of infection. With these allografts, the average healing time could be shortened to 6 weeks.

Fortunately, involvement of the dura occurs rarely. This usually requires an extensive free flap procedure.[59] We prefer to use the latissimus flap connected to cervical vessels, occasionally using interpositional vein grafts. This reduces the risk of perfusion problems considerably. When these options are not available, the use of acellular human dermis to reconstruct the dural defect followed by split-thickness skin grafting after vascularization may be an option.[60]

In children, especially toddlers, common sites of low-tension injury include the mouth, usually in the area of the oral commissure, affecting the commissure, the lips, and the tongue. The injury usually results in a localized partial necrosis of the lips and the commissure, and the subsequent contracture results in microstomia. The treatment strategies, conservative versus early surgical intervention, are debated. The more aggressive early approach of excision and reconstruction results in faster healing, a shorter hospital stay, and fewer surgical procedures.[61,62] However, in this sensitive age group early excision and reconstruction may also result in a tightened lower lip and consequent inhibition of normal mandible growth.[63,64]

The conservative management approach, which we prefer, performs the reconstructive procedure after maturation of the burn wound scar. Thus the extent of the damage is more apparent and the reconstruction can be performed electively.[65] Oral splinting has been advocated during the initial healing period to reduce the need for reconstructive surgery. However this more likely reduces scar contractures, so the planned reconstructive procedure can be performed after scar maturation.[66–68]

Thorax and Abdomen

Electrical injury to the trunk is generally a minor concern. However high-tension injuries can cause damage to underlying parenchymatous organs such as the lung. Clinically

this may lead to atelectasis and edema requiring aggressive ventilator support. Intra-abdominal injuries are uncommon but may require treatment as for penetrating injury. When exploration during escharectomy and debridement reveals necrotic underlying muscle and fascia, exploratory laparotomy may be indicated. Reconstructive options for the closure of chest or abdominal wall defects include direct closure or placement of a synthetic mesh covered by local fasciocutaneous or musculocutaneous flaps. However the potential negative effects of direct closure on intra-abdominal pressure and the subsequent development of an abdominal compartment syndrome or compromise of respiratory function must be considered.

Extremities

Electrical injuries to the extremities, especially to the arms and hand, are more common in adult members of the workforce. Electrical burns account for 3–5% of all admissions to burn units and approximately 1000 deaths per year in the United States.[70] There are three patterns of injury: direct, arc, and flash-type injuries. Direct injuries are associated with entry and exit wounds, and nearly 90% of these injuries involve the upper extremity.[71] Because the resistance and hence the local energy production are dependent on the tissue mass and the cross-sectional diameter of the injured body part, high-tension injuries often lead to extensive tissue damage and loss of the involved extremity. Despite aggressive treatment strategies with early debridement and decompression of neurovascular structures, the likelihood of amputation is high.[22–24,72] In the current literature the amputation rates for electrical injuries affecting the upper extremities range from 24% to 49%.[73,74] Even if amputation can be avoided the resulting outcome may be a nonfunctioning extremity. With the phenomenon of "kissing" lesions, extensive tissue damage may occur, with resulting thermal necrosis of muscle, tendon, nerves, and blood vessel. The superficial injury may appear innocuous, but debridement shows deep tissue destruction often mandating limb amputation. The importance of initial debridement cannot be overstated, as remaining nonviable tissue leads to infection and tissue loss. In our view the early debridement of nonviable tissue prevents this fatal development. When distal limb ischemia becomes obvious one can assume that the involved vessels have been severely injured. In these cases early vascular grafting of upper-extremity arteries may be indicated to salvage an ischemic upper limb.[75] Imminent or suspected compartment syndrome should always trigger open fasciotomy to prevent further compromise to the involved extremity. Sometimes it appears wise to perform a simple skin grafting procedure followed by elective secondary flap coverage and nerve cable grafting.

In high-voltage injuries (>1000 V) the point of entrance of the electrical current is usually located on the distal extremity. Tissue destruction decreases from distal to proximal. Zelt et al. described specific regions or so-called choke points, such as the wrist and elbow. These are characterized by smaller cross-sectional areas and highly resistant tissue components (tendinous and bony configuration) that result in increased heat production and more severe damage.[76]

The main area of reconstruction is the forearm, and limb salvage is the sole cause of free flap coverage.[77]

Fascial flaps provide thin, pliable coverage for reconstruction of the dorsum of the hand.

The serratus fascia flap is the flap of choice for larger defects; for smaller defects the temporoparietal fascial flap is preferred.[78]

Other regions of selective destruction in the upper extremity are the elbow and axilla. Debridement often leaves a vast tissue defect, which may be covered by rotation flaps from the anterior or posterior chest wall in the axilla. Microvascular free flaps at the level of the elbow are rarely used. For extensive defects on the hand and forearm pedicled groin flaps provide good coverage and an independent blood supply. The groin flap also avoids a vascular "steal phenomenon" as can be seen after microvascular free flaps in such severely injured extremities.

Newer approaches comprising early wound excision, coverage, and revascularization of damaged vasculature with flow-through free flaps and aggressive endovascular interventions will offer an opportunity to improve outcomes for these devastating injuries.[79–82]

Saint-Cyr and Daigle compared the use of free flaps with conventional multistage procedures and found a statistically significantly reduction in the number of operations, the time required to achieve wound closure, and the duration of hospitalization in the microsurgical group.[83]

The flap survival rate as described in the current literature is lower in the high-voltage injury group than in the burn injury group. It ranges from 62% to 100% and is lowest when performed early, within 5–21 days of trauma.[83–85]

In conclusion, free flaps play a key role in treating high-voltage electrical injuries to the extremities by reducing morbidity and functional impairment, which are characteristically high after these injuries.[83]

Amputations

Although distressing to the patient, amputation often remains the only option. As already mentioned, the amputation rates for electrical injuries affecting the upper extremities range from 24% to 49% in the current literature.[73,74] Despite an increased awareness of the potential danger of electrical burns, devastating outcomes with four-limb and penis amputations are still presented in the literature.[86–88] Although very rare, Haik and colleagues presented a case of a 5-week-old girl undergoing MRI for evaluation of spina bifida. She sustained a full-thickness burn encompassing her right forearm and wrist in the area where a non-MR-compatible pulse oximeter was attached. A possible cause for this incident could have been an electrical injury due to an exposed wire segment in direct skin contact. Despite immediate escharotomy, this injury led to amputation of the forearm and hand.[89]

The optimal level of amputation is determined by the extent of remaining viable tissue and the intention to create sufficient stump length for function and cosmetic appearance of a prosthesis. In electrical injury involving the lower extremity, this often requires higher amputation than initially anticipated in order to achieve sufficient stability of

the stump and thus allow early prosthetic fitting and ambulation. However, open (guillotine) amputation should be avoided whenever possible. Split-thickness skin grafting onto open stumps is an additional but less preferable approach because skin breakdown occurs more often in grafted areas, especially at graft borders or at points where grafts adhere to underlying bone, and further surgical interventions will be required. However, if valuable stump length can be maintained by skin grafting it should be attempted because secondary plastic surgical correction and specific prosthetic fitting are available.

In the upper extremity, more length should be preserved because the resulting weightbearing load on the stump is less than in the lower extremity. This allows for better control of the prosthesis by the patient and thus enhanced functionality. In the forearm, the muscle length of the flexor–extensor system should be preserved to improve function. In long forearm stumps, atraumatic handling of tendons and muscles is necessary to preserve pronation and supination. Upper-arm amputations should preserve as much length as possible as this eases subsequent kineplastic procedures for a functional prosthesis. As in the forearm, muscular length of the flexor–extensor system is maintained by joining them over the bone end. Although it is technically feasible to maintain extremity length by coverage with a free flap, this appears only useful in upper-extremity amputation where the functional implications warrant such large-scale surgery and the load on the stump is reduced.

Despite the availability of sophisticated modern myoelectric prostheses, the old techniques of surgical rehabilitation should be kept in mind. This includes the Sauerbruch kinemato-myoplasty of the biceps humeri muscle and the Krukenberg plasty of the forearm, which provides sensible chopstick-like stumps. Especially for upper-arm amputations, distraction osteogenesis procedures (Ilizarov technique) provide a valuable option to lengthen a short amputation stump.

Peripheral Nerve Injury

Peripheral nerves are very sensitive to electric alterations, and even minor injury may cause transient dysfunction. Clinical findings may be anesthesia, paresthesia, or dysesthesia of usually short-term duration. In rare cases minor electrical injury may cause temporary autonomic dysfunction and trigger a complex regional pain syndrome (sympathetic reflex dystrophy). Treatment for reflex sympathetic dystrophy should be initiated early and include elevation of the extremity to reduce edema formation, active exercise, NSAIDs, and adequate pain relief. The autonomic dysfunction may be influenced by α-adrenergic antagonists, calcium-channel blockers, and low-dose diazepam or may require intravenous regional blocks and sympathetic ganglion blockade.[90]

Electrical injury to the upper extremity commonly results in peripheral nerve injury to the median and ulnar nerves. The clinical findings may resemble upper-extremity compression syndromes or peripheral neuropathy.[91,92] Nerve lesions may be caused by secondary factors such as incorrect positioning and splinting, constricting dressings, or delayed inadequate escharotomy or fasciotomy. Owing to the accompanying severe muscle loss and scarring, the extent of pure nerve damage is sometimes difficult to determine.

Direct damage to peripheral nerves occurs following the above-mentioned mechanisms of local heat production, depending on cross-sectional resistance and the proximity of peripheral nerves to underlying bone. The local thermal effect affects vascularity and perfusion of perineural tissue by producing thrombosis, necrosis, or hemorrhage of epineural vessels. Delayed development of fibrosis and therefore a delayed onset of symptoms are not uncommon. Especially in areas of minimal cross-sectional area, the peripheral nerve is in close proximity to bone and fibrous tissue, which results in perineural fibrosis and symptoms of a compressive peripheral neuropathy. The treatment of choice to gain nerve recovery is decompressive corrective surgery.[93] Other mechanisms of nerve injury are the development of focal axonal degeneration following axonal excitation,[94] or electroporation, which more likely affects myelinated axons, and collagen type I deposition.[95–98]

Complications

CENTRAL NERVOUS SYSTEM

Approximately 60% of all patients with high-voltage injury present with immediate neurological complications, predominantly loss of consciousness.[99] Involvement of the spinal cord has been described in 2–27% of patients with an entry point of the current located in the head region.[100–102] The incidence of a delayed paralysis progressing to tetraplegia followed by partial remission has been described.[103] Although mortality in patients with neurological complications from electrical burns is not high, these patients are at great risk of permanent disability. The neurological sequelae were classified in 1964 by Silverside into immediate, secondary, and late effects.[104]

Immediate spinal cord injury is transient, and symptoms usually clear within 24 h after the accident. The late effects are characterized by progressive traits where complete recovery is not the rule. The ischemic injury in the distal area of the sulcal branch, the longest branch originating from the anterior spinal artery, is due to the susceptibility of the anterior horn cell and the spinal cord at T4–T8 to ischemic injury. Early administration of prostaglandin E_1 or steroid treatment is recommended to reduce ischemic spinal cord injury in cases of electrical burns.[105] The neuropsychological effects of electric injury have been described, mainly in case reports and retrospective studies. Typical consequences and complaints are related to physical, cognitive, and emotional changes.[106,107] In a study of 481 professional electricians, 97% reported having experienced an electrical shock at some point in their career.[108] The low incidence of neuropsychological dysfunction in this study differed from other findings about the nature and progression of a characteristic neuropsychological syndrome of electrical injury.[107,109] Although the development of transient and progressive neuropsychiatric complications is possible and undisputed, the actual specific effects of electrical injury are difficult to determine.

OCULAR MANIFESTATIONS OF ELECTRICAL INJURY

An increased incidence of cataract formation has been described after electrical injury, varying from 1% to 8% in different reports.[110,111] Patients with head and neck wounds appear to be most at risk. However the path of the current and the location of the entry point were not related to the development of ocular sequelae. Cataracts may also occur without injury to the head and appear even years after injury. Common initial complaints are blurred vision or diminished visual acuity.[112]

Cataracts usually develop from 1 month to 2 years after injury but may occur as soon as within several hours.[113] The mechanisms for formation are debated and several theories have been proposed, such as decreased permeability of the lens capsule, direct coagulative effect on the lens proteins, a disturbance in nutritional mechanisms of the lens cells due to iritis or impaired circulation, and exposure to ultraviolet and infrared radiation.[114]

Lightning strikes are a common cause of ophthalmic injuries, and the most common permanent sequela by far is lightning-induced cataract.[115] The lens of the eye is seemingly very sensitive to electrical current or the resultant heat, and prompt evaluation by an ophthalmologist is imperative.[116] Iritis and uveitis have also been described as possible sequelae after electrical injury.[117] Visual prognosis in patients with lightning-induced ocular injury will depend on the extent of irreversible retinal damage and optic nerve damage. Long-term follow-up of these patients is recommended according to the late onset of pigmentary changes at the fovea and papillomacular bundle, which may further prevent visual improvement.[118]

Patients should undergo serial ophthalmologic examinations, and treatment should be started immediately when abnormalities are recognized.

Skeletal Injury

In addition to direct tissue destruction through electrical energy, additional trauma can be indirectly inflicted by electric current. Fractures occur due to secondary falls or with forceful tetanic muscle contractions. These are mostly seen in the shoulder,[119] wrists,[120,124,125] femurs,[121,123] and spine[122] and may require open reduction and internal fixation. Late sequelae of electrical injury similar to severe thermal burns include major joint contractures and limited function of the extremities.

Another common late complication of electrical burns is heterotopic calcifications in periarticular tissue of large joints, especially the elbows. Causative factors include forced passive mobilization, secondary articular bleeding, and calcium precipitation and deposition in damaged or degenerating muscle and connective tissue. Particularly for electrical injury, heterotopic bone formation also occurs in amputation stumps of long bones. This, as well as the common formation of bone cysts in the amputation stump, may lead to secondary skin erosion, inflammation, and difficult adjustment to a prosthesis. In both situations surgical excision and wound closure may be adequate therapy.[126]

Conclusion

Electrical injuries result in deceptively large tissue loss often leading to amputation of involved extremities. After initial resuscitation, early debridement, necessary decompression of neurovascular structures, and early wound closure are essential to successful restoration of function. Extensive surgical procedures including free soft-tissue transfer may be necessary to achieve wound closure and to save and restore limb function. Sometimes, however, early amputation may provide easier and earlier recovery and reintegration into daily life. Long-term complications such as central nervous sequelae, cataracts, and heterotopic ossification must be considered and addressed early in the rehabilitation process.

58 The Role of Alternative Wound Substitutes in Major Burn Wounds and Burn Scar Resurfacing

NAIEM S. MOIEMEN and KWANG CHEAR LEE

Introduction

Early excision of major burns has been shown to improve patient outcomes. The lack of available donor sites from which to harvest conventional autologous skin grafts to achieve wound closure is challenging. Burke and Yannas in the early 1960s pioneered the introduction of alternative wound cover after burn excision. They invented a dermal scaffold composed of bovine collagen and shark glycosaminoglycan matrix with an epithelial equivalent, the silicon layer. This became known as Integra. During that same period, Rheinwald and Green, in 1975, described the technique of cultured epidermal autografts (CEA), which provided another alternative to help achieve wound cover. The first multicenter clinical trial using Integra was published in 1988.[1] Integra was eventually granted approval by the U.S. Food and Drug Administration (FDA) in 1996 for use in acute burns.

Alternative wound substitutes provide biological wound cover either on a temporary or permanent basis. Permanent substitutes are mostly in the form of scaffolds that become integrated into the wound and eventually are replaced by host cells, with the scaffold itself finally undergoing reabsorption. Temporary substitutes, on the other hand, do not integrate into the wound; they temporarily adhere to the wound bed and may induce growth and promote healing of the underlying wound.

Classification of Alternative Wound Substitutes

The wide variety of alternative wound cover products may be classified into temporary or permanent (Tables 58.1 and 58.2). Other classifications include autologous, allogenic, or xenograft; biological or synthetic; cellular or acellular, and single layer or composite.

Clinical Applications of Alternative Wound Substitutes in Major Burn Wounds

Temporary alternative wound substitutes are used to cover partial-thickness burns, full-thickness excised burn wounds, widely meshed skin grafts, and, occasionally, skin graft donor sites.

For partial-thickness burns, temporary substitutes, in contrast to traditional wound dressings, provide a biological wound cover that promotes healing by reducing moisture loss and accelerating epithelialization. However they are not incorporated into the architecture of the healed wound, as in the case of permanent substitutes. In addition, most of these products (such as Biobrane, Suprathel, and amniotic membrane) are applied only once. This is a significant advantage, especially for children, because it avoids the pain and associated psychological trauma of repeated wound dressing changes.

For full-thickness excised burn wounds, temporary alternative substitutes can provide cover if skin grafting or application of a permanent substitute is planned as a staged procedure. In certain circumstances, to allow for a reduction in wound exudate and to ensure complete hemostasis, this may be delayed for 24–48 hours after wound excision in a major burn. Due to lack of available donor sites for skin graft harvest, it may be decided to apply a permanent substitute, and "take" can be optimized by staging the procedure; during this time a temporary substitute can be very helpful.

Temporary substitutes are very valuable for covering widely meshed skin grafts (the Alexander technique). Alexander described applying allograft on top of widely meshed autograft to provide biological wound closure that protects the open wound within the interstices (gaps) of the meshed graft. While allograft tends to adhere to the wound bed and may in fact interfere with epithelization of the interstices, E-Z Derm dries out after a week of its application with almost complete epithelization underneath. This may also represent a cost saving.

Rapid healing of skin graft donor sites is critical to patients with major burns. Expanded pre-confluent autologous epidermal cells (ReCell) or sprayed CEA may accelerate epithelization and allow more frequent harvesting from the limited donor sites in these situations. However wider use is prohibited by cost and efficacy. ReCell has also been shown to accelerate healing of partial-thickness burn wounds when covered with widely meshed skin grafts.

Permanent alternative wound substitutes are used to cover full-thickness wounds after burn excision. One example of a bilayer acellular substitute is Integra, which has been used for decades in patients with major burns and has

Table 58.1 List of Temporary Skin Substitutes and Their Biological Value

Example	Structure	Biological Value/Mechanism of Action
Amniotic membrane	The innermost layer of the placenta; it consists of a single epithelial layer, a basement layer, and an avascular stroma. Available in frozen or glycerol-preserved forms	Promotes migration and adhesion of epithelial cells. It has high concentration of hyaluronan and Decorin and has anti-inflammatory, antiangiogenic, antimicrobial, and antiscarring actions
Allograft	Human cadaveric split-thickness skin grafts. Can be either cryo- or glycerol-preserved	Allogenic skin graft vascularizes initially as per autograft; however, it is eventually rejected by the host within 3–4 weeks
Xenograft	Animal-derived skin graft (usually porcine, although frog skin has been used). Examples include EZ Derm (acellular dermis)	Used as an alternative to allografts. It does not vascularize. It adheres to wounds and provides temporary coverage
Biobrane (Smith & Nephew, London and Hull, United Kingdom)	Consists of a silicone membrane bonded to a nylon mesh that is impregnated with porcine dermal collagen peptides	The collagen peptide coating enhances adherence to the wound. Biobrane has no inherent antimicrobial properties
Suprathel (PolyMedics Innovations GmbH, Denkendorf, Germany)	Entirely synthetic and composed of synthetic copolymers, mostly polylactic acid	This has similar indications to Biobrane and is used for temporary cover of partial-thickness burns and donor sites
Oasis (Smith & Nephew, London and Hull, United Kingdom)	Acellular porcine intestinal submucosa	Indicated as a single-application dressings for deep dermal burns
Omiderm (Omikron Scientific Ltd., Rehovot, Israel)	Synthetic polymer made from hydrophilized polyurethane	Indications are similar to Biobrane and Suprathel

Table 58.2 List of Permanent Skin Substitutes and Their Biological Value

Example	Structure	Biological Value/Mechanism of Action
Epicel (Vericel Corporation, Ann Arbor, Michigan, United States)	Consists of a petroleum gauze and autologous keratinocyte sheets that have been co-cultured with murine cells	Indicated for deep dermal and full-thickness burns; sheets are 2–8 cell layers thick
ReCell (Avita Medical, Cambridge, United Kingdom)	Pre-confluent autologous keratinocytes obtained by trypsinizing a small biopsy and directly sprayed onto the wound	Other cells such as fibroblasts and melanocytes are also delivered
Alloderm (Lifecell Corporation, Branchburg Township, New Jersey, United States)	Donated human skin that is processed to remove the epidermis and cells leaving an acellular matrix	Acellular dermis acts as a scaffold for fibroblast and vascular ingrowth, split-thickness skin grafts are applied over it during the same procedure
PriMatrix (TEI Biosciences Inc., South Boston, United States)	Acellular fetal bovine dermal scaffold	A scaffold to support new dermis formation
Matriderm (Medskin solutions, Billerbeck, Germany)	A single layer of matrix of non-crosslinked bovine collagen and tendon-derived elastin hydrolysate. Available in 1- and 2-mm thicknesses	A scaffold that promotes the regeneration of a new dermis. Split-thickness skin graft is applied on top as a single-stage procedure
Orcel (Forticell Bioscience Inc., New York, United States)	Bilayered collagen constructs seeded with allogenic keratinocytes and fibroblasts derived from neonatal foreskin	The matrix acts as a scaffold, and the allogenic cells produce growth factors and are eventually replaced by the host own cells within a few weeks
Apligraf (Organogenesis Inc., Massachusetts, United States)	Similar to Orcel, it is formed from collagen type I constructs seeded with allogenic keratinocytes and fibroblasts derived from neonatal foreskin	As with Orcel, the matrix acts as a scaffold and the cells induce a suitable environment for host cells to migrate into and populate. However, unlike Orcel, the top layer of keratinocytes is exposed to the atmosphere during manufacture, forming a stratified layer with better barrier function
Stratagraft (Stratatech Corporation, Madison, Wisconsin, United States)	Bilayered construct with a dermal layer with human dermal fibroblasts and an epidermal layer that is produced by near-diploid immortalized keratinocyte S (NIKS) cells	A fully stratified multilayered epidermal equivalent is generated by the NIKS cells, which are a pathogen-free keratinocyte cell line. The substitute releases bioactive molecules that condition the wound for healing
Permaderm (Regenicin Inc., New Jersey, United States)	Bilayered collagen matrix with basement membrane seeded with autologous keratinocytes and fibroblasts	A permanent alternate substitute that can provide complete wound cover and closure. Only a small autologous skin biopsy can potentially be used to cover the entire body after 3–4 weeks. It has been used in major burns
Integra (Integra LifeSciences, New Jersey, United States)	These consist of an outer silicone epidermal equivalent and a lower cross-linked bovine collagen and shark glycosaminoglycan. Single layer of collagen only is also available	The bilayered dermal template is widely used in burns. This requires a two-stage procedure while the single layer is used as a single-stage procedure. The single layer is used both in acute burns and in reconstruction. Cross-linked collagen provides the stability of the dermal construct
Pelnac (Gunze Limited, Kyoto, Japan)	Consists of cross-linked calf collagen with a thin silicon outer layer	Very similar to Integra but the silicon layer is thinner for better pliability and conformity to the wound bed

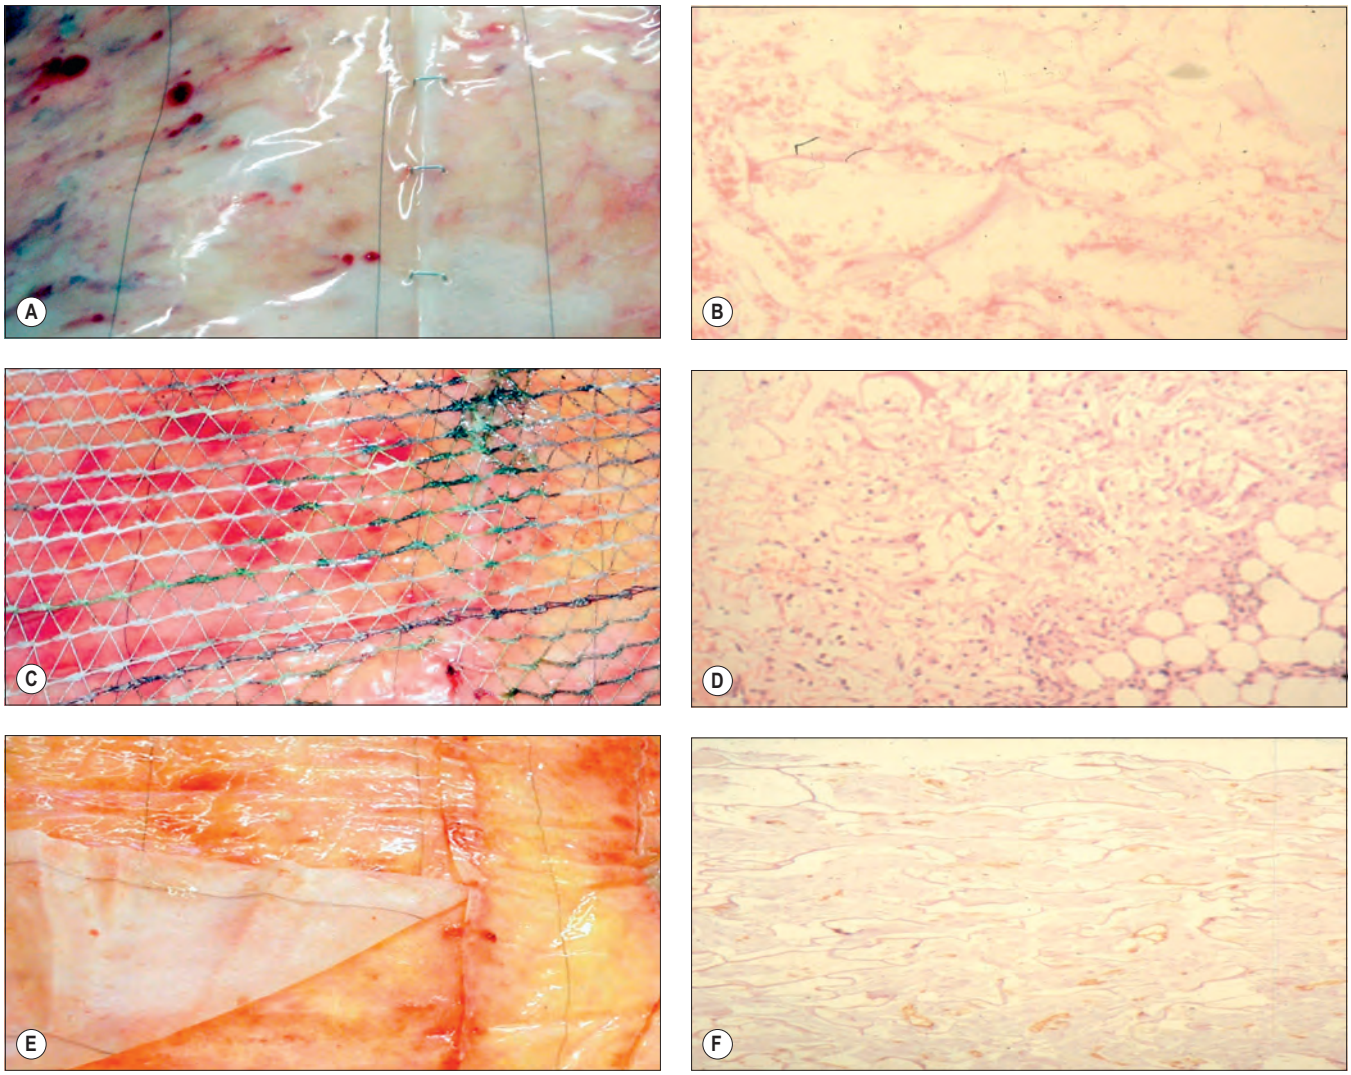

Fig. 58.1 Stages of Integra vascularization. Matrix color is correlated with the stage of vascularization. Clinical (*left*) and histological appearances (*right*). Appearance at first stage, day 0 with pale colored matrix **(A,B)**; matrix developing a pinkish color at day 21 **(C,D)**; and a peachy color at 4 weeks **(E,F)**. CD31-stained endothelial cells in the superficial layer of the neodermis **(F)**. (From Moiemen NS, Vlachou E, Staiano JJ, Thawy Y, Frame JD. Reconstructive surgery with Integra dermal regeneration template: histologic study. Clinical evaluation and current practice. *Plast Reconstruct Surg*. 2006;117(7 Suppl.):160S–174S.)

yielded favorable short- and long-term outcomes.[2] The matrix vascularization and formation of the "neodermis" occurs over a period of 3–4 weeks (Fig. 58.1)[3] under the protective cover of the silicon epithelial-equivalent layer. This allows wound closure during the critical time of waiting for limited donor sites to heal and be ready for reharvesting. In fact, the fully matured vascularized matrix can be left in place, even for several further weeks, as long as the silicon layer remains adherent to it.

When Integra is used in acute major burns, immediate or early burn excision is important. This allows adherence of the matrix to the wound bed before wound colonization occurs, thus decreasing the risk of infection. If immediate excision has been performed, it is prudent to delay application of Integra for 24–48 hours, as mentioned earlier. Fibrin sealant may be useful to promote adherence and prevent hematoma formation. Integra may also be meshed at a 1:1 ratio with a noncrushing mesher (Brennen, Molnlycke Health Care, Gothenburg, Sweden.) to reduce the risk of hematoma and to allow antimicrobials to access the wound bed. Surgifix (BSN medical GmbH, Hamburg, Germany) applied directly onto the silicon layer can be very useful to prevent early silicon separation, especially if the second stage is to be delayed for several weeks until donor sites are available (Fig. 58.2). Antimicrobial dressings followed by an absorbent gauze layer are applied over the Surgifix, and a firm bandage completes the dressing. When compared to Integra application for scar resurfacing, wound care in acute burns is of paramount importance because early identification of complications can avoid disastrous consequences with loss of the entire Integra layer and the potential for sepsis. Frequent inspection of the matrix, especially during the first week, by a member of the team with experience in the use of Integra is crucial. To ensure successful Integra engraftment, the whole multidisciplinary team should be aware of how to mobilize

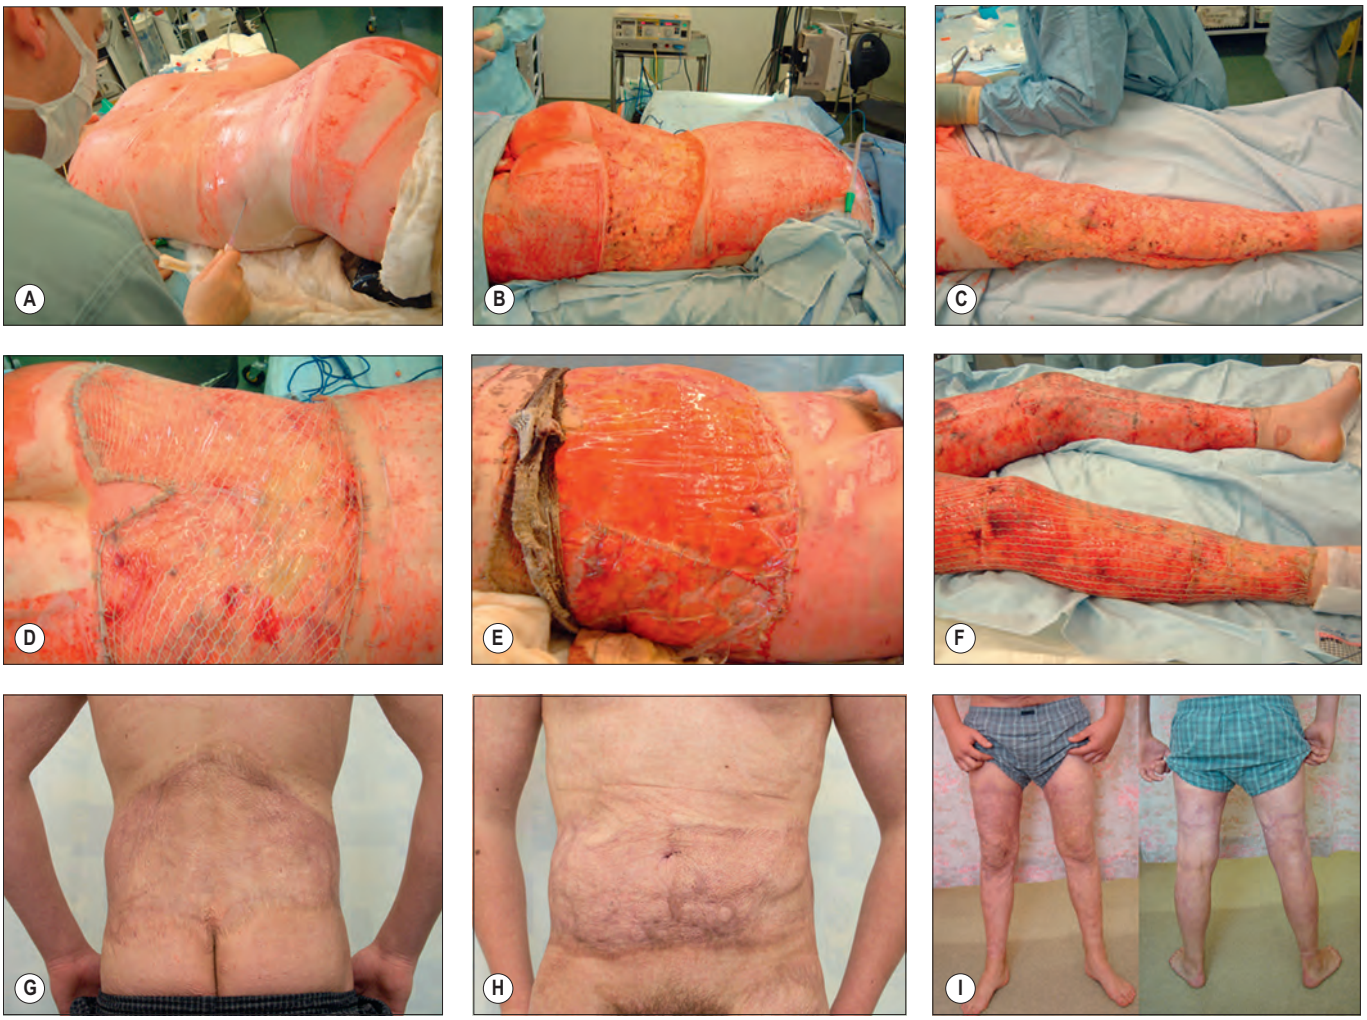

Fig. 58.2 Acute early burn excision and Integra application with 7-year follow-up. *Top row*: 14-year-old female with 60% total body surface area (TBSA) flame burn **(A)**, post-excision of burn on back **(B)** and legs **(C)**. *Middle row*: Day 9 post-excision appearance of burn wound and application of Integra on back **(D)**. Day 18 appearance of abdominal **(E)** and leg **(F)** burn wounds postexcision and application of Integra. *Bottom row*: Appearance of the healed burn wounds 7 years post burn of back **(G)**, abdominal area **(H)**, and lower limbs **(I)**.

and turn the patient and perform therapy, including chest therapy, without disturbing the matrix. Wound care after the second stage (removal of the silicon layer and application of partial-thickness grafts) is the same as in other major burns.

Matriderm is mainly used as a single-stage procedure, with the skin graft applied onto the matrix in the same operation. It has applications in burns where function and aesthetics are important (e.g., in the hand over joints or on the face). However the requirement for immediate grafting is a limitation in major burns when donor sites are sparse. Matriderm, being formed of noncross-linked collagen, is vascularized more quickly than Integra and also resorbs more quickly; however additional analysis of long-term results is still needed.

Other bilayer cellular substitutes include Apligraft, Orcel, and the Engineered Skin Substitute (ESS or Permaderm). Only ESS, which was first introduced by Steven Boyce of the Shriners Hospitals for Children, Cincinnati, contains autologous epithelial cells and fibroblasts that, once produced, allow complete wound cover of major burns and require only a very limited skin biopsy from the patient.[4] ESS has been granted orphan status by the FDA for use in acute burns and a phase II multicenter trial will soon be under way.

Clinical Applications of Alternative Wound Substitutes in Burn Scar Resurfacing

Resurfacing of extensive postburn hypertrophic scars has become possible with the availability of permanent alternative wound substitutes such as Integra. The outcome is superior to that of partial-thickness skin grafts, but it falls short of full-thickness skin grafts that are still the gold standard option for scar resurfacing. However, following major burns there can be limited availability of donor sites for full-thickness grafts.

The timing of scar resurfacing is important. The wisdom of experience has shown that extensive resurfacing

Fig. 58.3 Long-term outcome of Integra scar resurfacing. Post-excision of a scar on the back of a child and application of Integra **(A)**, which is further secured with negative-pressure dressing **(B)**, and final appearance of dressing **(C)**. Appearance of resurfaced burn wound scar 4 years postop **(D)**.

procedures are more successful when the scars have matured and become pale in color. At early stages of post-burn scarring, other surgical approaches including flaps or modalities such as laser may be more appropriate. Radical excision of all scar tissue, especially at the depth of the excised wound bed, is important to achieve good results with skin substitutes and to avoid recurrence of any contracture. Certain anatomical areas are challenging to reconstruct, such as the neck, axillae, and groin. Transposition flaps, if possible, may be used to avoid applying Integra directly over joints. Negative-pressure therapy (NPT) can assist with adherence and minimize shear; whether or not it accelerates vascularization and cell migration is debatable (Fig. 58.3). The skin substitute is covered with an antimicrobial dressing (e.g., Acticoat, Smith & Nephew, London and Hull, United Kingdom), then a layer of gauze (Kerlix, Medtronic, Dublin, Republic of Ireland) and a bandage. For resurfacing on the limbs, a foam circumferential cylinder firmly applied provides gentle pressure and may prevent complications including shear and hematoma formation.

Aftercare following surgery is very important to detect any early signs of infection. In the author's practice, patients are usually discharged home the day following surgery in extensive resurfacing or on the day of surgery in smaller cases. Patients are reviewed by a member of the team with experience in dealing with Integra. Readmission for the second stage to apply the partial-thickness skin graft (0.008–0.010 inch) occurs 3–4 weeks after the first stage. The same dressings are applied as at the first stage for 1 week, and the patient is followed-up weekly. Patients are seen regularly by the therapy team during the postoperative period, and the same splinting and scar management as for conventional skin grafts is applied.

Fig. 58.4 Long-term outcome of Matriderm resurfacing. Excision of hypertrophic burn scar **(A)**, post application of Matriderm and split-thickness skin graft **(B)**, appearance at 2 weeks **(C)**, appearance at 3 weeks **(D)**, and appearance of healed scar at 3 months **(E)** and 9 months with good range of motion at the elbow joint **(F)**.

Matriderm operative and postoperative care is similar to that of Integra; however occlusive dressings that are not disturbed for 1 week usually give good results because the skin graft overlying the Matriderm requires a moist environment until vascularization occurs (Fig. 58.4). Since Matriderm does not have a silicon layer, NPT should be used with caution because it may shrink the matrix.

Future Directions

Permanent alternative wound substitutes can improve survival and outcome in burn patients but remain prohibitively expensive. Ninety-five percent of patients with major burns live in low- and middle-income countries where these products are not easily affordable. New products that could be produced less expensively on a large scale may reduce the cost and help these patients.

Unlocking the regenerative potential of skin, together with new innovations such as scaffolds that deliver molecules to the wound bed to promote healing and reduce scarring, are exciting directions for the future.

59 Aesthetic Reconstruction in Burn Patients

JUAN P. BARRET

Introduction

The severity of injury and deformity from burn trauma range from relatively minor to severe.[1] The psychological and social impact of sequelae do not parallel the severity of the deformity; even minor disfigurements can have severe psychologic and social impacts on the patient. Basic concerns common to all burned patients include function, comfort, and appearance.[2] The approach is that of total patient care; it must include all healthcare team members and it is predicated on aesthetic and functional reconstruction. Burn reconstruction is a complex and long process that starts when the patient is admitted in the acute phase and lasts until the patient's expectations have been reached and/or there is nothing more to offer. It is normally a lifelong commitment, and, even if there may be no other possibilities to offer at that point, the patient–surgeon relationship still continues. It is preferable, although not imperative, that burn reconstruction be performed in close vicinity to the burn center and that it has the constant support of and coordinated treatment with the multidisciplinary burn team. If this is not the case, good communication with the team referring the patient is desirable.[3]

Preventing and minimizing scarring and deformity in burn patients starts during the acute phase. Reducing the inflammatory and catabolic responses after burn injury using a team approach and early closure of the burn wound is paramount to control wound healing in these patients.[4]

It is preferable that the surgeon managing the acute injury be responsible for later reconstruction. If this is not the case, the reconstructive surgeon should be consulted early on so that the needs for reconstruction enter into the plan of the acute care.[5]

Different procedures are important during the acute phase to minimize later reconstruction. Splints, face masks, silicone gel sheets, early pressure therapy and ambulation, and skeletal traction and fixation are of great importance to produce the best result and avoid future operations (Fig. 59.1).

Burn trauma requires aggressive intervention by rehabilitation services to prevent debilitating deformities. Burn distribution as well as burn depth is a good predictor of rehabilitation outcomes. Prevention of burn deformities includes proper positioning with or without splints, exercise to maintain joint range of motion, maintenance of muscle strength and muscle tone, and early mobilization. All this is true not only for the acute period, but also for the reconstructive period.[6,7]

Burn patients tend to assume the position of comfort, which is often responsible for deformities that require reconstructive surgery later during the recovery phase (Box 59.1). Thus, positioning in bed is one of the most important ways to prevent deformities (Box 59.2). It is not the responsibility only of rehabilitation services, but of the whole burn team as well. Exercise reduces edema, maintains joint motion and strength, reduces scars, and, in the pediatric patient, maintains development level. Ambulation can begin as soon as the patient is deemed medically stable, with wounds properly dressed and doubly wrapped lower limbs.

Prevention by positioning and splinting affects many problems in the care of burned patients. Static and dynamic splints are used for either immobilization or mobilization, respectively. Initially splints are used at all times except for exercise and immediately postop during the immobilization period. As active range of motion increases and is maintained, the protocol changes to night-only splinting. Skeletal traction and fixation also are used on a limited basis to prevent and correct burn scar contracture formation and are always tailored to the patient's needs.[8]

Timing of Reconstruction

It has been advocated that definitive correction of burn scarring should be delayed for 1 year or longer after healing in the acute period. It is certainly true that unaesthetic and ugly scars mature over time, and, with the effect of pressure and splints, many of them do not require surgery once the acute phase of scar maturation has taken place. Patience is often the best tool of the reconstructive surgeon. However some problems encountered early during the recovery phase must be dealt with and operated on before the golden period of scar maturation is over. In these circumstances it must be absolutely certain that an operation is needed to correct the deformity. Urgent procedures must be planned to correct functions that are not amenable to other treatments, often because time is of the essence. An eyelid release to protect an exposed cornea, correction of distracted or entrapped neurovascular bundles, severe fourth-degree contractures, and severe microstomia fall into this group. Intense rehabilitation, splinting, and pressure therapy are mandatory after correction of these deformities. In some patients deformity may be addressed nonoperatively, but if this approach does not lead to appropriate results, an operation may be considered. In this section fall all burn scar contractures that do not respond to rehabilitation and hypertrophic scarring and contractures that prevent the patient from eating, bathing, moving, and performing activities of daily living.

Most of the problems that patients may present are aesthetic ones and scar contractures that, although not

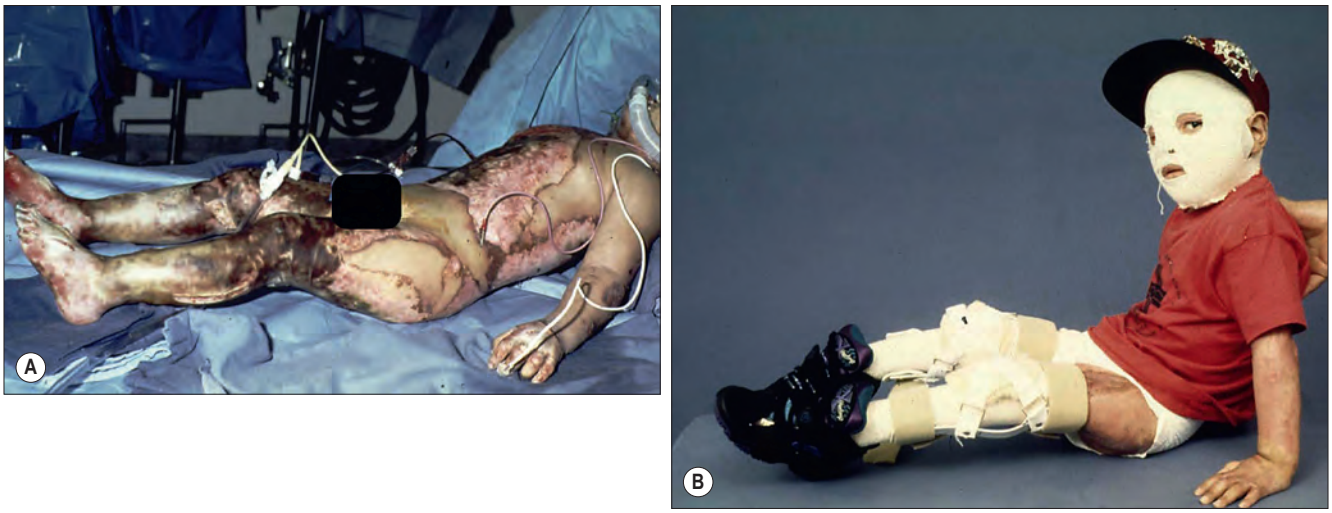

Fig. 59.1 **(A)** Sixty percent full-thickness total body surface area (TBSA) burn. **(B)** A comprehensive rehabilitation team approach is necessary to achieve good functional and aesthetic outcomes.

Box 59.1 Position of Comfort After Burn Trauma (to be Avoided)

1. Neck flexion
2. Shoulder protraction
3. Elbow flexion
4. Metacarpal extension
5. Interphalangeal flexion
6. Wrist flexion
7. Hip flexion
8. Knee flexion
9. Ankle plantar flexion

Box 59.2 Prevention of Deformity: Positioning in Bed

1. Maintain straight alignment of the trunk and neck
2. Neck should be in slight extension
3. Arms should be elevated in the neutral plane or in line with the glenoid at approximately 15–20 degrees of horizontal flexion and 80 degrees of abduction
4. Elbow should be in full extension
5. Hand should be in the intrinsic plus position with the thumb in flexion and abduction
6. Hips should be in extension and abduction
7. Knees should be in full extension
8. Foot should be in neutral position and with 90 degrees or greater dorsiflexion

prominent, produce great discomfort. Many of these problems disappear in the first 2 years postburn with appropriate care, and these problems benefit most from patience and time. Many important deformities seen a few months post burn improve with time and can be treated with simple or less extensive procedures later (Fig. 59.2).

Many factors other than scar maturation, however, affect the decision of whether to operate on burn scars. Psychologic and socioeconomic factors are very important when making this decision. The patient's mood plays an important role because an unmotivated or depressed patient will not appreciate the procedure as much as a healthy patient. Moreover, operating on such a patient may produce discomfort and discouragement that, eventually, can jeopardize the patient's compliance and prevent further reconstruction. The social status of the patient is also of great relevance. Emotional support received from friends, family, and co-workers is important, as is the patient's economic status. When making a treatment plan, all these particular circumstances need to be taken into account when considering the number of procedures to be done at a time, recovery time, family support in the recovery phase, and what is to be done first.[5]

Patient–Surgeon Relationship

Burn patients require an intense and good relationship with their surgeon. The relationship is normally a long-lasting one, many times extending to a lifetime. Patients require a surgeon's professional expertise, but also the surgeon's time, a good dose of optimism, and compassion. The initial meeting is one of the most important events in burn reconstruction. A patient presents with a set of complaints that have to be evaluated together with the patient's motivation for surgery and his or her psychologic status. Chief complaints, patient motivation, and expectations are evaluated. Limitations of surgery and any relevant technique are explained, together with the master plan for reconstruction and the order of reconstructive priorities. Photographic workup is extremely important to document the case, assist in definitive preoperative planning, and for documentation. When dealing with long-term scars and burn deformities, different problems may be encountered intraoperatively that might require a complementary technique. These specific issues of burn reconstructive surgery have to be explained in detail to the patient, and the surgeon needs to foresee and include them in the preoperative planning and

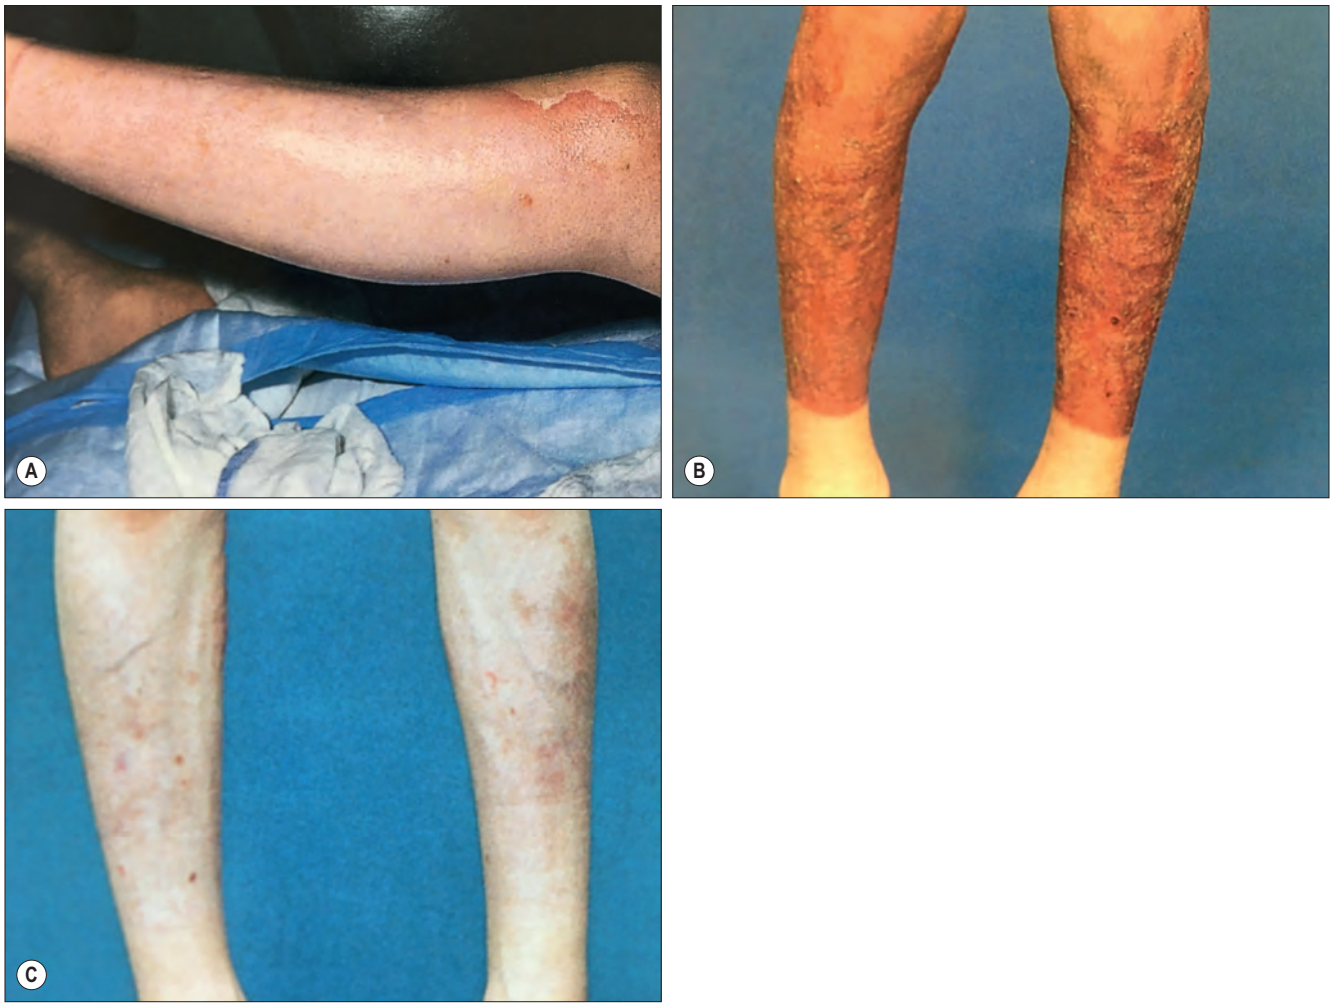

Fig. 59.2 (A) Second-degree burn to the lower extremities. **(B)** Same patient at 2 months. Erythema, hyperpigmentation, and scarring are present. **(C)** Result at 18 months with conservative treatment. Scarring is minimal with good overall result. In many cases scar maturation renders optimal outcomes and allows good planning for reconstructive planning if necessary. (From *Color atlas of burn care*, London 2001, First Edition, Elsevier.)

the informed consent meetings so that unpleasant surprises are not encountered later.[9]

Patients need to be reassured frequently. A burn reconstruction project involves several operations, many clinic visits, and often a long time to make a final assessment. The patient's feelings and impressions must be addressed continuously and any trouble, minor disappointment, or depression detected early on and treated as needed (Box 59.3).

Box 59.3 Characteristics of Burn Reconstructive Plastic Surgery

1. Starts during acute period
2. Strong patient–surgeon relationship
3. Development of a "master plan"
4. Involvement of the burn team using a multidisciplinary approach
5. Long and staged procedures
6. Complex and technological implications
7. Involvement of plastic surgery and aesthetic surgery/medicine techniques

Pre- and Postoperative Care in Burn Reconstruction

A complete record of all encountered problems has to be performed during the initial and any follow-up visits before surgery. Quality and color of the skin in the affected areas must be noted, including abnormal scars, hyper- or hypopigmentation, contractures, atrophy, and open wounds. Function has to be addressed next: all involved joints are explored, range of motion noted, and skeletal deformities addressed. Often scar contractures distract joints and the body maintains an abnormal position to overcome the deformity. A complete X-ray workup must be obtained to explore the status of bones and joints. In severe restriction of function, good radiological imaging must be obtained to rule out heterotopic calcification.

The needs for physiotherapy, occupational therapy, and pressure garments have to be considered at this time. The

Box 59.4 Essentials of Burn Reconstruction

1. Strong patient–surgeon relationship
2. Psychological support
3. Clarify expectations
4. Explain priorities
5. Note all available donor sites
6. Start with a "winner" (easy and quick operation)
7. As many surgeries as possible in the preschool years
8. Offer multiple, simultaneous procedures
9. Reassure and support the patients

patient is referred to the rehabilitation department for consideration. Finally, an inventory of all possible sites for donor tissue is made.

All reconstructive possibilities are discussed with the patient, and the timing and order of such procedures are outlined. All important points and pitfalls are explained to the patient. The importance of addressing all urgent, essential, and functional problems first has to be understood by the patient. This is essential because the patient can become extremely upset when important cosmetic problems are disregarded at the beginning while other not so obvious problems (to them) are addressed first.

Finally, in children, it is also important to perform as many procedures as possible during the preschool years and to offer the patient multiple, simultaneous procedures. Time, effort, and money are then best invested. Essentials of burn reconstruction are summarized in Box 59.4.

Pre-, intra-, and postoperative care of burn reconstructive patients include all techniques and special treatments of general plastic surgery and any state-of-the-art special plastic surgery techniques. The scope of procedures performed in burn reconstructive surgery ranges from split-thickness grafts to tissue expansion and microsurgery. More recently composite vascularized allotransplantation has emerged as a new technique for catastrophic burn deformities.

The plastic surgeon operating on burn patients works most of the time with scarred and injured skin. In this particular setting, it is very important to handle all tissues with extreme care because vascularization in the area is normally altered. Patients are instructed to stop smoking for at least 3 weeks before surgery. All meals and drinks containing active vascular substances need to be tapered and any medications noted so that all unnecessary drugs can be stopped. The patient is instructed also to avoid medications such as aspirin that may increase intraoperative and postoperative bleeding. Uncontrolled hypertension, cough, nausea, and disorders of coagulation need to be known by the surgeon and treated as needed since they are known to increase the risk for hematoma. It is always advisable that the patient presents for surgery with a responsible adult to take care of them after surgery.

The evening before surgery the patient is instructed to have the skin cleansed with bacteria-reducing soap, and a light dinner is advised. Burn patients normally have hypertrophic scarring, seams, and intradermal cysts that are prone to a high bacterial load. It is also advisable to include in the operative planning the perioperative use of antistaphylococcal agents. If a skin flap or introduction of alloplastic material is to be performed, antibiotics should be continued in the postoperative period for at least two more doses.

Probiotics are also advised to avoid any antibiotic side effect. Intraoperatively large doses of local anesthetics are to be avoided, and the extensive use of electric coagulation is minimized because it increases the risk of necrosis of scarred skin. Similarly the use of subcutaneous epinephrine is limited because of the same risks.

A smooth emergence from general anesthesia, one free of coughing and vomiting, is essential in burn reconstructive surgery, as are controlling high or low blood pressure episodes, nausea, and vomiting. Hyperactive and anxious patients may benefit from anxiolytic medication to avoid sudden and uncontrolled movements in the immediate postoperative period. Light dressings are applied after surgery and any high pressure avoided since it can injure burned tissue. When aesthetic procedures are planned (such as fat grafting, CO_2 laser therapy, chemical peels, aesthetic surgery), patients are left without dressings to allow accurate and correct wound healing. Immobilization is kept to a minimum, and passive and active range of motion is started as soon as possible in the postoperative period. Movement helps to avoid edema formation, congestion, and recurrence of contractures. Splints, prostheses, and pressure garments must be used either immediately or very soon after the operation. Rehabilitation is normally part of the reconstructive master plan, so it must be included and started after surgery. Silicone inserts in grafted areas have been found helpful in controlling the early phase of scar maturation because they apply gentle and uniform pressure to the wounds and position joints properly.

It is also very important to administer good pain control because having a comfortable and cooperative patient helps positioning, rehabilitation, and the success of any operation. Patient-assisted analgesia is the best option if the patient is able to use it. Other than that, scheduled hydrocodone and morphine are good alternatives. Anxiolytics must always be considered as part of the pain control program, and the addition of antiitch medications and antiemetics such as diphenhydramine and droperidol is very helpful.

Finally, providing the patient and family an environment that is cozy and relaxing helps them and the burn reconstructive team to cope better with periodic admissions and decreases fear and anxiety before every step in the progress of the reconstructive plan.[10,11]

Surgical Approach to the Burn Reconstructive Patient: The Role of the Reconstructive Ladder

Some progress has been made in burn reconstructive surgery in the past decades, although its impact is not as dramatic as in other areas of plastic surgery. Burn reconstructive surgery involved for many decades incisional or excisional releases of the affected scars and skin autografting. Today, however, the first approaches that the reconstructive surgeon should bear in mind are local or regional

Box 59.5 Techniques Available for Aesthetic Burn Reconstruction

1. Classic workhorse techniques: skin grafts, cartilage grafts, z-plasty, local and regional flaps, keystone flaps
2. Dermal regeneration templates
3. Tissue expansion with or without flap prelamination/prefabrication
4. Free flaps, with or without prelamination
5. Fractional CO_2 laser and others
6. Fat grafting and stem cell therapy/keratinocytes
7. Aesthetic plastic surgery techniques: liposuction, rhinoplasty, facelifts, breast surgery, etc.
8. Chemical peels
9. Hair transplantation
10. Osseointegration and dental surgery
11. Micropigmentation
12. Composite vascularized allotransplantation

flaps.[5] They provide new and vascularized tissue to the area, they grow in children, and they render the best functional and cosmetic results. These flaps can be raised either with normal skin or burn scar. Even though it is generally true that burned tissues present a high tendency to congestion, ischemia, and necrosis, such tissue can be used as a reliable flap if extreme care is used while raising the flap and the injured skin is left attached to the underlying tissues.[12] This expands burn reconstruction into new territories and techniques.

Moreover, tissue expansion offers reconstructive surgeons the possibility to produce new pre-expanded flaps that may be transferred as free flaps or tailored or prefabricated flaps.[13–15]

For years surgeons used to evaluate the chief complaint or complaints and wait for immature scars or increasing deformities to mature with time and the use of pressure garments. Only then, after the deformity was stable, would they begin with simple techniques. At that point, depending on the type of deformity, skin grafts or simple techniques such as z-plasties or the like were used. Today, the burn reconstruction plan needs to be tailored to the individual patient, and complex and advanced techniques are utilized since they offer better function and cosmesis.[5]

Aesthetic Reconstruction of Burned Patients

The evaluation of reconstructive needs in burn victims should follow a holistic approach. In the best hands, the approach is developed under the umbrella of a group of experienced plastic, reconstructive, and aesthetic physicians in which all techniques are mastered. Not only have simple, traditional plastic surgery operations to be contemplated, but also new additions in aesthetic surgery and aesthetic medicine (Box 59.5). These include skin grafts to free flaps, composite vascularized allotransplantation, fat grafting, hair transplantation, and laser treatments or chemical peels.[16] Fig. 59.3 summarizes a master aesthetic burn reconstructive plan.

Fig. 59.3 Burn wound sequelae to the face. Aesthetic master plan includes pre-expanded flaps, full-thickness skin grafts, scar revision, commissuroplasties and lip correction, fat grafting, vertical subperiosteal mid face lift, monofollicular hair transplantation, ear reconstruction, osseointegrated implants, CO_2 fractional laser treatment, and micropigmentation. Mastering all techniques of reconstructive surgery, aesthetic surgery, and aesthetic medicine is a must to provide excellent outcomes.

HEAD AND NECK

Burns to the head and neck are still a challenge to the burn team. Residual deformities produce severe distortion, with disfigurement and functional limitations. Bridging scars from chin to neck to anterior shoulder result in exaggerated kyphosis with neck flexion and protraction of the shoulders. The most frequent deformity in the periorbital area is ectropion, although more severe cases present distraction of the canthal folds, fusion of part of the eyelids, and distortion of the lacrimal punctate. Release of upper and lower eyelid contractures has to be performed separately, with undermining of the surrounding tissues. Full-thickness grafts are most suitable for lower eyelids where stability is the goal, while split-thickness skin autografts are used on upper eyelids to improve mobility.[17] Fat grafting has been successfully used to restore the aesthetic appearance of the upper eyelid. Lower eyelid ectropion may also benefit from fat grafting. Good repositioning of deep structures can be achieved by this technique, often solving difficult ectropion problems.[18] Eyelashes and eyebrows can be restored by monofollicular or multiple-follicular hair transplantation, rendering in many situations better outcomes than traditional techniques. Micropigmentation is another good solution in selected patients, restoring normal appearance and even providing the disguising look of three-dimensional facial architecture.[19,20]

The nose anatomy deserves careful attention. Small deformities may be corrected by secondary rhinoplasty and dermabrasion with or without sprayed keratinocyte cells. More extreme deformities (destruction of the columella or alar rims) are good indications for helical rim free flaps, whereas subtotal or total destruction of the nose calls for a

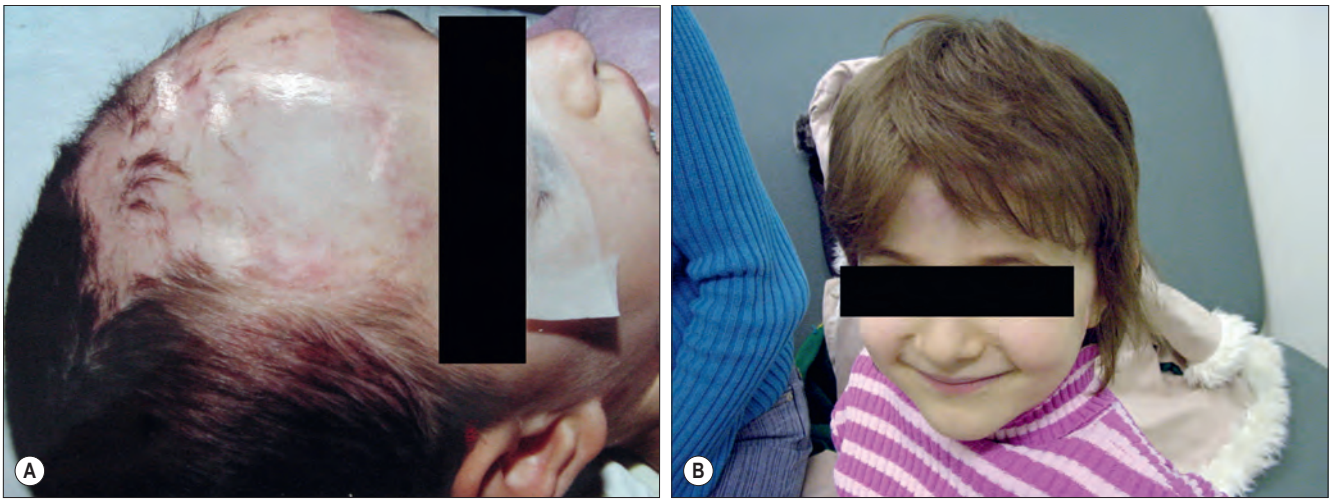

Fig. 59.4 (A) Burn scar alopecia, including the anterior hairline. **(B)** Result after reconstruction with scalp tissue expansion with rectangular tissue expanders.

traditional nose reconstruction with paramedian forehead flap (if this donor site is absent, a prelaminated free flap is a good option).[21]

Lip deformities and microstomia are normally addressed with local flaps, commissuroplasties, and skin grafts. Micropigmentation is a good aid to finish the reconstruction and to restore the vermilion border. Fat grafting can be utilized for lip volume, whereas laser treatment and dermabrasion clear superficial irregularities. Loss of hair follicles in male patients has been traditionally reconstructed by means of scalp grafts or flaps, but monofollicular hair restoration is the ultimate solution for this problem.[22]

Another area that deserves aesthetic (and indeed functional) attention is dental malocclusion. It is not uncommon for burn patients to lose teeth and present with an altered smile and poor projection. The growing child deserves extra attention too. Tight scars, inelastic skin, and scar contractures may alter the correct growth of facial bones and produce malocclusion. If these anomalies are detected, orthodontics, tooth replacement, osseointegrated implants, and even orthognathic surgery may be required.[23]

Other passive deformities include ear deformities. Ear reconstruction in burned patients can be done with rib cartilage grafts. If there is no suitable subcutaneous pocket, a superficial temporalis fascial flap can be used to wrap the framework, with a split-thickness skin graft on top. Other times, tissue expansion to the retroauricular area can be performed prior to the creation of a rib cartilage framework.[24]

BURN ALOPECIA

One of the areas where the effects of burn injury are most noticeable is the scalp. Healing of deep partial- and full-thickness burns very often leads to areas of scalp alopecia. This produces an important psychologic impact for the patient because it affects self-esteem and image. Small areas of patchy alopecia can be effectively treated with excision and direct closure; however, tissue expansion is still the gold standard of treatment for burn alopecia (Fig. 59.4).

Box 59.6 Classification of Burn Alopecia (after McCauley et al.)

Type 1: Single alopecia segment
- A, <25%
- B, 25–50%
- C, 50–75%
- D, 75%

Type 2: Multiple alopecia segments amenable for tissue expansion
Type 3: Patchy burn alopecia
Type 4: Total alopecia

McCauley et al. classified burned scalp alopecia in terms of the pattern and extension (Box 59.6). This classification has proved very useful in our approach. Patchy burn alopecia extending across the entire scalp or total alopecia are not suitable for classical reconstruction.[25] However micropigmentation or even monofollicular hair transplantation has produced great results and provided new tools for burn reconstruction of these difficult problems.[19] On the other hand, alopecia extending to up to 50% of the scalp can be corrected with single expansion and closure, whereas larger areas of alopecia or different concomitant segments of alopecia can be managed with sequential expansion. Many times overinflation of the expander is necessary, and it is important to bear in mind that expanded tissue normally contracts by 20% of the initial surface. Care of these patients is similar to that of any patient undergoing tissue expansion. In our hands rectangular tissue expanders with overexpansion are the best possible solution for these types of problems.

Selected patients with good-quality scars and limited areas of burn alopecia may be offered hair transplantation. If this technique is selected, the same tenets and aftercare utilized in male pattern alopecia restoration apply. It is important to recognize the male pattern alopecia areas in the subject of relatives to select the appropriate donor site.[26]

Fig. 59.5 Typical hand deformity. A comprehensive approach with a program of functional reconstruction and aesthetic consideration of skin coverage is advocated.

UPPER EXTREMITY

Hypertrophic scars and contractures to the upper extremity promote the position of comfort: protraction and adduction of the shoulder, elbow in flexion, and the "burned hand position" with wrist in flexion, metacarpophalangeal extension, interphalangeal flexion, and first metacarpal extension and adduction. The overall appearance of the hand is that of a "claw deformity" (Fig. 59.5). Many of these problems can be prevented with correct acute care and splinting, which include the arm elevated in the neutral plane or in line with the glenoid at approximately 15–20 degrees of horizontal flexion and 80 degrees of abduction, elbow in full extension, and hand in intrinsic plus position with thumb in flexion and abduction.

Linear contractures to the shoulder can be addressed with local flaps, keystone flaps, or two-staged dermal regeneration burn reconstruction techniques. The addition of fat grafting and stem cell therapy are promising grounds for best outcomes and clinical research. Often four- and five-flap z-plasties are very useful. When the contracture extends to all or nearly all of the axilla, incisional release and autografting is preferable, although regional rotational flaps or free flaps can be used if available. It has to be noted, however, that a contracture to the axilla cannot be released at the same time a neck release is performed since it is not possible to maintain correct neck hyperextension while abducting the shoulders in the postoperative period. The neck needs to be addressed first, followed by the shoulder release, thus allowing a perfect result in each operation.

Contractures to the elbow normally include flexion deformity, which is best addressed with local z-plasties or, when not possible, incisional release and autografting. It must be noted, however, that heterotopic calcification has to be ruled out when dealing with limitations of extension. In some cases, peripheral nerves, in particular the ulnar nerve, need to be transposed for complete functional correction of the deformity.

The most common deformities of the hand are wrist and dorsal contractures with extension, web space contractures, and boutonniere deformities. Extension deformity to the wrist and dorsum of the hand normally requires an incisional release and autografting, whereas web space contractures are best reconstructed with local flaps. Fascial free flaps are also often utilized, covered with dermal regeneration templates in a two-stage operation. Occasionally a skin autograft is necessary to add length to the reconstruction of the linear contractures. Boutonniere deformities need reconstruction of the extensor mechanism. If contracture to the palmar surface co-exists, a full-thickness graft or a cross-finger flap is necessary. However, in our experience, full release of the contracture followed by a fascial free flap and skin graft, versus a single- or two-stage dermal regeneration template procedure, together with the injection of platelet-rich plasma is a great solution. Extensor tendon destruction or adhesion is normally treated with tenolysis, and, if tendon repair is necessary, a flap must be considered. Stem cell therapy often helps in controlling excessive scarring, although future clinical research will show its real indications in burn care reconstruction. Finger transfers, thumb lengthening, and internal and external fixation are to be considered in severe and selected problems.[5]

Other available techniques that provide better cosmetic outcomes include fat grafting, chemical peels, and fractional ablative CO_2 laser therapy.[27]

One of the most important parts of the reconstruction of the burned hand is the rehabilitation plan. It must be started as soon as the skin coverage is stable. Pressure therapy, web spacers, and night splints are necessary to achieve the expected results.[28]

BREASTS

Breast deformity, asymmetry, and displacement of the nipple areola complex (NAC) is a commonly encountered deformity. Even though they may affect both genders, the presence of a breast deformity and NAC alteration has a deeper emotional and psychosocial impact in the female population.

Traditional techniques for treatment include release and autografting. Novel additions to the reconstructive armamentarium are integral and other dermal templates, which provide pliability and elasticity with good recreation of the breast mound and submammary fold. They also aid in the growing breast, allowing for better symmetry and good aesthetic outcome.

Other patients require augmentation mammoplasty with breast implants or fat grafting. In this situation it is not uncommon for patients to require the temporary placement of a breast tissue expander to augment the tissue envelope and better accommodate a definitive implant with enhanced symmetry and breast aesthetics.[24]

LOWER EXTREMITY

Severe burns to the lower extremity can be a source of important morbidity. Deformity to the feet can affect gait and normal living. Severe destruction may even prevent the patient from standing. Patients are often concerned about the appearance and correct positioning of the feet, plus the correction of nail deformities; fractional ablative laser therapy and fat grafting are parts of an integral functional and cosmetic reconstruction. A good and durable skin covering must be supplied to these areas to improve weight-bearing and ambulation. Good acute care can prevent some

of the deformities to this area, and excision and grafting to all full-thickness burns with early ambulation and physical therapy are also important. When in bed, the feet should be in neutral position and at 90 degrees or greater dorsiflexion. Orthopedic shoes and metatarsal bars are helpful in positioning foot burns in infants and small children.

Common deformities in the lower extremity include hip and knee flexion, whether anterior or posterior, and most often impose the position of knee flexion, equinovarus deformity of the foot, and extreme extension of the toes from dorsal foot burns. In all deformities, the overall functional goal is restoring anatomy, which in turn provides good cosmetic appearance.

Other relevant techniques that improve functional outcomes and overall cosmesis in lower extremities are free flaps and keystone flaps. The former are often utilized as fascial free flaps with dermal regeneration templates or full-thickness skin grafts. Fat grafting and stem cell therapy help in improving function and aesthetic appearance through a modulation of the inflammatory response and reduced scar deposition.[5,24]

60 Laser for Burn Scar Treatment

JILLIAN McLAUGHLIN, LUDWIK K. BRANSKI, WILLIAM B. NORBURY, SARAH E. BACHE, LIN CHILTON, NAGUIB EL-MUTTARDI, and BRUCE PHILP

History of Laser and Intense Pulse Light

Albert Einstein was the first to describe the theoretical physics of the laser in 1917. He described the interaction of atoms and molecules with electromagnetic energy in terms of the spontaneous absorption and emission of energy and concluded that stimulated emission of energy was also possible. In 1959, the first instrument was developed by Drs. Townes and Schawlow based on those concepts. It was known as the microwave amplification through the stimulated emission of radiation (MASER). Shortly thereafter, in 1960, Theodore Maimon developed the first laser light with use of a ruby crystal. Early clinical studies with the ruby laser began in 1964, with Dr. Leon Goldman, a dermatologist considered by many to be the father of laser medicine. The rapid development of additional lasers occurred with the helium-neon laser appearing in 1961, the argon laser in 1962, the carbon dioxide (CO_2) laser in 1964, the Nd:YAG laser in 1964, and the erbium-YAG laser in the mid-1990s.[1]

However, early lasers had limited control of energy parameters, leading to frequent thermal injury and scarring. The concept of selective photothermolysis (SPTL) introduced by Anderson[2] led to the development of the first laser that was specifically designed to treat a medical condition; it was named the *pulsed dye laser* (PDL) and was almost instantly accepted in treating port wine stains in very young patients, a condition that had hitherto been very problematic.[3]

Further developments over the ensuing decades included the introduction of pulsed energy resulting in decreased laser exposure time.[1] Reliant technologies unveiled the ability to split the treated zone into specific area, resulting in multiple microtreatment zones within the target area; this was termed *fractionated laser treatment.*[4] The advent of short-duration Er:YAG lasers in the mid-1990s offered an additional option for resurfacing, either alone or in combination with the CO_2 laser. Around the same time, high-intensity flashlamp exposure was presented as a suitable tool for treating vascular lesions;[5] this resulted in the release of intense pulsed light (IPL) as a medical device. In the following years, multiple technical modifications allowed easier handling, increased safety, and widened the spectrum of potential indications.[5]

Physics of Laser

Lasers are devices that rely on the stimulated emission of radiation to produce a beam of light. The word LASER is an acronym for the term *light amplification by stimulated emission of radiation*. The device itself consists of an active medium, an energy source, and a resonating chamber.

In most lasers, there is a population of atoms known as an *active medium*. The active medium of a laser is a material of controlled purity, size, concentration, and shape. This material can be of any state: gas, liquid, solid, or plasma. The gas lasers consist of the argon, copper vapor, helium-neon, krypton, and CO_2 devices. One of the most common liquid lasers, the PDL, contains a fluid with rhodamine dye. The solid lasers are represented by the ruby, neodymium:yttrium-aluminum-garnet (Nd:YAG), alexandrite, erbium, and diode lasers.[1]

In the atom's resting state, electrons orbit around the nucleus at their ground state or lowest energy levels, in orbitals. When an electron absorbs energy from an energy source, electrons become excited and orbit into higher orbitals. The energy source used to excite the electrons can be a light source, an electrical field, or a chemical. When these excited electrons fall back into their resting orbitals, energy is released, generating photons (electromagnetic radiation). Photons have wavelengths specific to the atom excited. Since lasers have a consistent population of atoms, the photons emitted are all identical. These identical photons are considered monochromatic, meaning that all photons in a laser beam are of the same wavelength. By contrast, IPL consists of many different wavelengths.

The resonant chamber consists of two reflective mirrors between which photons reflect back and forth. If a photon collides with an excited electron, that electron falls back to its resting orbital, releasing another photon of the same wavelength. The two photons are "in phase" or "coherent," meaning their wave patterns are synchronized and reinforce each other. By comparison, the photons in conventional light travel randomly. As these photons hit other excited electrons, more photons are released and the light energy increases. The resonant chamber allows for more and more atoms to become excited and then return to ground state, thereby amplifying the energy produced (amplification of stimulated emission) and allowing for photon coherence.

One of the mirrors is only partially reflective and partially transparent. Those photons traveling in a perfectly parallel direction will exit the transparent portion of the mirror, also known as the optical resonator, taking the form of the "laser beam."

Light energy can be visible or invisible depending on its wavelength. The spectrum of electromagnetic radiation ranges from long radio waves (wavelength >10 cm) to extremely short γ rays ($<10^{-11}$ m). The entire spectrum includes radio, microwave, infrared, visible (400–700 nm), ultraviolet, X-ray, and γ rays.

The specific wavelength emitted by a laser will determine how the laser beam interacts with tissue. When the laser strikes tissue, a variety of desirable and undesirable effects result as the laser is reflected, scattered, transmitted, or absorbed.

Reflection is the proportion of laser that bounces off the surface and is redirected in a different direction. When laser is directed perpendicular to the skin, approximately 5% of the laser is reflected. Reflection of laser is one of the reasons why it is imperative to wear appropriate safety goggles at all times when performing laser treatments.

Scatter is the increase in spatial distribution of a laser beam as it passes farther through tissue, leading to irradiation over a larger area of tissue. The main scattering wavelengths are between 400 and 1200 nm (those where tissue water absorption is poor).

Absorption can be described as the conversion of the energy of the laser to heat when its photons strike a specific molecular target, known as a *chromophore*. The mechanism by which lasers are used to target specific tissue is called *selective photothermolysis* (photo = light and thermolysis = decomposition by heat).

Transmission occurs when a laser that has not been absorbed is transmitted into deeper tissue beyond the chromophore.

Multiple variables must be considered when selecting a type of therapeutic laser, in addition to the appropriate wavelength. The additional laser parameters that optimize the result are *fluence*, or power density (joules/cm^2); pulse width or duration; mode of delivery; and spot size (increasing spot size increases penetration).

The theory of selective photothermolysis first described by Anderson and Parrish explains the principles behind the clinical application of photothermal lasers.[2] The wavelength of laser light chosen must be selective and appropriate for the target tissue, which must be destroyed without damaging the surrounding tissues. The pulse width or duration of the laser pulse must be within the thermal relaxation time of the treated tissues. Thermal relaxation time is the amount of time it takes to transfer two-thirds of the resultant heat to the surrounding tissues.

The laser's effect on the epidermis can further be classified as ablative or nonablative depending on whether or not the epidermis is left intact. Fractional lasers treat only a portion (or fraction) of the tissue. Nonablative lasers will thermally injure the tissue, whereas ablative lasers will destroy entire columns of tissue, including epidermis.

Overview of Lasers in Hypertrophic Burn Scar

The ultimate goal in the treatment of hypertrophic scars is to make improvements both aesthetically and functionally, as well as reduce itching and pain related to the scars. Traditional and emerging laser- and light-based technologies offer new hope for patients with burn scars.

GENERAL CONSIDERATIONS

An important tool in the evaluation of the patient for a resurfacing procedure is Fitzpatrick's scale of sun-reactive skin types, and this should be assessed prior to laser treatment.

The type of anesthesia employed prior to laser therapy depends on several factors, including the mode of laser treatment (e.g., ablative lasers are more painful than nonablative lasers), size of the scar, and the age of the patient. Children may require general anesthesia, whereas adults can be treated with topical anesthesia. This is more often required when treating areas of hyperpigmentation. Pain response can be assessed during a test patch procedure. If necessary, Eutectic mixture of local anesthetic (EMLA; lidocaine 2.5%/prilocaine 2.5%; AstraZeneca AB, Södertälje, Sweden) cream can be applied to reduce the stimulation of the procedure and reduce postoperative pain. The use of topical anesthetic as part of multimodal analgesia for fractionated laser treatment of burn scars significantly decreases the requirement for opioid analgesia and reduces procedure to discharge times.[6] Similarly an opioid sparing regime in children has been shown to have the potential to provide adequate post-operative pain following laser treatment under general anaesthesia.[7]

Patients undergoing ablative fractional laser treatment routinely receive perioperative antibiotic prophylaxis, which is typically not indicated for patients undergoing nonablative laser treatments. Patients undergoing fractional ablative laser are routinely washed with chlorhexidine and thoroughly dried prior to initiation of laser treatment. All patients receiving fractional ablative laser to the face are given acyclovir for herpes simplex prophylaxis.

Ice packs are used on the skin immediately following treatment. Wound care after laser treatment is initiated on the first postoperative day and includes a topical antiseptic wash and application of a generous amount of emollient for several days. Wound care for IPL consists of aloe vera cream applied every 15 min for a couple of days or until the stimulating effect has receded. Hydrocortisone 1% cream is also provided to those patients undergoing fractional laser treatment to help with itching. Analgesia is usually achieved with over-the-counter pain medications; however, some patients may require a short course of narcotic medication. Patients may resume normal activity almost immediately, including physical or occupational therapy. Depending on the discomfort level and the desired type of activity, patients may return to school or work after 1–3 days. Compression garments may be worn once wounds reepithelialize. Sun avoidance and use of broad-spectrum sunscreens with a sun protection factor (SPF) of at least 30 are mandatory for 12 months postoperatively to reduce the likelihood of postinflammatory hyperpigmentation.

PULSED DYE LASER THERAPY

The PDL is the most studied laser for hypertrophic scarring.[8] Over the past decade, the PDL has been shown in multiple studies to provide significant and long-term improvement in hypertrophic scars.[9] However, further studies have yielded conflicting data, with some more recent investigations finding no difference in PDL-irradiated hypertrophic scars over untreated controls.[10,11] Developed several decades ago, the vascular-specific, flashlamp-pumped 585- and 595-nm PDLs became the standard of care in the treatment of port wine stains, capillary malformations, and some hemangiomas.[9] This laser selectively targets hemoglobin and coagulates microvasculature in the papillary and reticular dermis up to a depth of 1.2 mm. Although the mechanism of action for scar improvements is unknown, most theories are based on the principle that vascular proliferation plays a key role in hypertrophic scars. The PDL

causes photothermolysis, in which light energy is absorbed by hemoglobin leading to coagulation necrosis.[9] Beneficial effects of PDL on burn scar pruritus have also been observed. This may be secondary to either decreased mast cell count following PDL treatment or decreased amounts of substance P and calcitonin gene-related peptide (CGRP), which mediate the vascular response of the skin.[11] The settings for PDL in the treatment of hypertrophic burn scar are found in Table 60.1.

ABLATIVE/NONABLATIVE FRACTIONAL LASERS

Fractional resurfacing leads to controlled destruction of tissue columns, also known as microscopic treatment zones (MTZs), without significant collateral damage. Similar to a z-plasty, the laser breaks up the thick, disorganized collagen fibrils that created the scar, allowing these regions to repair in a more organized fashion. However, a significant amount of epidermis and dermis remains intact, which assists in wound healing.

Fractional laser injury has also been shown to induce a molecular cascade including heat shock proteins and matrix metalloproteinases as well as inflammatory processes that lead to a rapid healing response and prolonged neocollagenesis.

ERBIUM-YAG LASER

In a prospective, single-arm, pilot study, treatment with a nonablative fractional erbium laser resulted in at least mild improvement in scar appearance in 90% of subjects and moderate to excellent improvement in 60% of subjects.[13] However, this study did not separate out patients who had hypertrophic burn scars versus scars from other etiologies. Two additional studies also investigated 1540-nm nonablative fractional erbium laser in mature burn scars and found a similar lack of improvement in thick scars.[14,15] Based on findings in these studies, it is likely that hypertrophic burn scars benefit from even deeper penetrating laser energy. There is a significantly greater potential depth of thermal injury with ablative fractional laser when compared with nonablative fractional laser devices (approximately 4.0 and 1.8 mm, respectively).[16] Ablative erbium:YAG laser emits infrared light with a wavelength of 2940 nm. The major innovation of the erbium:YAG laser over the CO_2 laser is its shorter wavelength, which increases its absorption coefficient through water 10- to 16-fold. Also, there is less thermal necrosis at the treatment site. One study cited improvement in hypertrophic burn scars in 24 patients on face, neck, or low neckline, and eight on the hands.[14] The settings for ablative erbium:YAG lasers in the treatment of hypertrophic burn scar are found in Table 60.1.

CO_2 LASER

The CO_2 laser has a wavelength of 10,600 nm and is used to target water in abnormal collagen several millimeters below the surface of the skin. The absorption of CO_2 laser by tissue water is significantly less than that of erbium:YAG leading to a relatively greater potential for surrounding tissue ablation. However, the increased ablation appears to induce a modest immediate photomechanical release of tension in some restrictive scars and appears to facilitate the subsequent remodeling response more effectively. In fractional ablative CO_2 laser-treated skin specimens, a collagen subtype (types I and III collagen) profile resembling that of nonwounded skin was found.[18] Also, pinpoint bleeding after ablative fractional laser is much less problematic with the fractional ablative CO_2 laser because of the increased zone of coagulation when compared to the erbium:YAG laser. The fractional ablative CO_2 laser has been shown to be highly effective in the treatment of hypertrophic scars,[12,18-28] including cosmetic and functional enhancement of traumatic scars and contractures, with treatment ranging between one and six sessions. Improvement of tactile sensation after treatment of burn scars of the palm has also been reported. Patients who underwent fractional ablative CO_2 laser procedures for treatment of symptomatic burn scars also had a 49% decrease in pruritus after laser treatment.[19] Our institution (UTMB, Galveston) recently performed a review[29] of the patient cohort who underwent treatment with fractional ablative CO_2 laser therapy for postburn hypertrophic scarring. A total of 452 fractional ablative CO_2 laser treatments were performed in 245 pediatric patients (126 females and 119 males) in 3 years. Fractional ablative CO_2 laser was used 256 times on the face, 103 on the neck, 164 on the torso, 164 on the upper limbs, and 74 on the lower limbs. Treatment providers have seen a reduction in scar thickness and improvement in scar pigmentation, as well as improvement in burn scar itch in patients treated with fractional CO_2 laser.

In 2012, Lumenis introduced a modification to the high-energy CO_2 laser (UltraPulse Encore; Lumenis, Santa Clara, CA) by adding a module for the treatment of scars—Synergistic Coagulation and Ablation for Advanced Resurfacing (SCAAR FX). The device generates hundreds of very deep microchannels that penetrate up to 4 mm. Usually after the first procedure patients feel a reduction of tension and softening of the scar. This is now the mainstay of the CO_2 laser treatment at our institution for thick hypertrophic scars (for more details on laser settings refer to Table 60.1).

LASERS TO TARGET PIGMENT

There are several lasers available that target pigment including the Ruby laser which is near infra-red (wavelength 694 nm) and targets pigment. A long pulse is used for hair removal (by destroying hair follicle stem cells) and ultra short (nano-second) pulse for interfollicular and follicular melanocyte destruction. Combination lasers include the TriVantage and GentleMAX (Candela Laser Corporation, USA), which both combine an alexandrite laser (755 nm) and Ng:YAG capabilities (1064 nm. This creates a broad spectrum of different wavelengths to enable targeting of different pigments and depths of melanocytes. They are thus useful for the removal of pigmentation and pigmented hairs to treat burn scar folliculitis.

INTENSE PULSED LIGHT

Although not technically a laser, IPL delivers focused, controlled light energy through a coupling gel across the 515–1200 nm (visible to near infrared) spectrum and at a fluence of up to 40 J/cm^2. IPL sources are filtered xenon

Table 60.1 Common Laser/IPL Settings

PULSE DYE LASER		
Wavelength		585–595 nm
Handpiece (spot size)		7-mm or 10-mm spot
Pulse duration		1.5 ms
Cryogenic cooling settings		30-ms spray and 20-ms delay
Fluence (7 mm)		6.0–11.0 J/cm^2
Fluence (10 mm)		4.0–5.0 J/cm^2
Overlap		Yes
Endpoint		Purpuric skin change
ERBIUM:YAG LASER		
Wavelength		2940 nm
Spot size		3–6 mm
Frequency		4–8 Hz
Fluence		11–12 J/cm^2
Overlap		No
Endpoint		Pinpoint bleeding
CO_2 LASER		
Wavelength		10,600 nm
DeepFX Handpiece	**SCAARFX**	**DeepFX**
Indication	Severely thickened hypertrophic scar	Intermediate-thickness hypertrophic scar or atrophic scar
Energy	70–100 mJ	15–20 mJ
Frequency	250 Hz	600 Hz
Pattern	2	2
Size	10	10
Density	1%–3%	10%
Overlap	No	No
Endpoint	Pinpoint bleeding	Pinpoint bleeding
Ultrascan CPG	**ActiveFX Central**	**ActiveFX Peripheral**
Indication	All central scar	All peripheral scar (feathering)
Energy	60–100 mJ	50 mJ
Frequency	125 Hz	125 Hz
Pattern	3	3
Size	7	5
Density	3%	3%
Overlap	Yes	Yes
Endpoint	Full coverage of scar	Full coverage of peripheral scar
INTENSE PULSED LIGHT		
Wavelength Filter		590 nm
Pulse Duration		5 ms
Delay		20 ms
Fluence		15–17 J/cm^2
Guide		Large rectangular light guide

flashlamps that release pulses of noncoherent polychromatic light. The mechanism of IPL is not fully understood, but it probably targets the vascular proliferation essential to collagen overgrowth and its effect on pigmentation (both melanin and artificial pigments) that results in scar development (hyperpigmented, erythematous, and proliferative scars).[10] Specific filters in the handpiece allow the user to select a window of wavelengths, such as 755 nm for collagen stimulation, 695 nm to remove superficial leg veins, and 515 nm to treat rosacea.[12] Multiple studies have shown IPL to be helpful in the management of burn scar dyschromia, long-standing hypervascularity, and chronic folliculitis without the risks or downtime of PDL photothermolysis or laser resurfacing.[10,12] The settings that we use for IPL in the treatment of hypertrophic burn scars are found in Table 60.1.

Treatment of Specific Post Burn Scar Conditions

FOUR-YEAR REVIEW

A recent review (2011–2014) in our unit (St Anderws, Chelmsford) demonstrated a wide use of different lasers for the treatment of various post burn scar conditions.[30] We carried out 194 procedures on 40 patients with an age range of 3–73 years. The fractionated CO_2 laser was used for 66 (34%) procedures alone and 112 in total, combined with other lasers in the same sitting. Indications included hypertrophic scar, contracture bands, unstable or thick, cracked scars. The PDL was used for 19 (10%) procedures, 137 in total. The main indications were red, itchy symptomatic scars. It was also used to soften scars prior to injection with dermal steroids. The Ruby laser was used for 30 (15%) of procedures alone and 51 procedures in total, with indications being hyperpigmentation and folliculitis. In 2014 this was replaced by the TriVantage and Gentlemax. These were used for 4 procedures alone and 27 in total. Indications were hyperpigmentation (TriVantage short pulse) and folliculitis (GentleMAX long pulse).

VASCULAR AND HYPERTROPHIC SCARS

Red scars with visible telangiectasia which blanch on touch are common in the months and years following healing of a burn. These are often lumpy and thick, or cracked and shiny, unstable or non-healing. The patient often complains of pruritus and pain. We have found that these scars respond well to PDL to reduce the erythema, followed by CO_2 to flatten the scar and enable stable healing Intradermal steroids may also be applied.

Folliculitis

Commonly, hair becomes trapped under scars or grafts causing irritation and repeated localized infections, This can be particularly problematic in the beard area of men. Fig. 60.1 illustrates this 25 months following a burn. We use the PDL to soften the scar in order to access the hair and decrease erythema. Following this a laser targeted at pigment (in this case Alexandrite laser) is used to remove the hair. As tight, thickened scar is usually also present, we would use the CO_2 laser in addition to address areas of tightness.

Fig. 60.1 Before (above) and after (below) photographs of a man with hypertrophic scars and follocilitis to the beard area, 25 months following burn injury, who was treated with PDL, Alexandrite and CO_2 lasers.

SCAR CONTRACTURE

Wide contracture bands and thick sheets of scar contracture can be well addressed with fractionated CO_2 laser, with the addition of steroid injections. This allows the relaxation of tissues, enabling release of skin around the neck and in the webspaces of the hand.

HYPERPIGMENTATION

Patients with darker skin types may develop areas of hyperpigmentation following burns or on donor sites. This is very unpredictable. Lasers to target pigmentation such as the Alexandrite or ND:YAG laser can be used to address these areas. Patients must be comprehensively consented, as the laser will cause hypopigmentation which may be equally distressing.

Laser Complications and Laser Safety

LASER COMPLICATIONS

Although infrequent, complications do occur. Common complications of PDL therapy include transient purpura and mild to moderate erythema or edema that usually resolves in 7–10 days. However, in some cases, a mild erythema can persist up to 3 months posttreatment. Occasionally skin blistering or crusting may occur in the early posttreatment phase. Hypo- or hyperpigmentation may also occur, especially in patients with darker skin types. Overtreatment of burn scars may induce scarring exacerbation, especially in skin with darker pigmentation, in which melanin acts as a competing chromophore. Intraprocedural cryogenic cooling of the skin may limit these adverse reactions.[31]

Fractional ablative lasers have an improved adverse effect profile compared with nonfractional ablative devices. However, delayed wound healing, ulceration, postinflammatory hyperpigmentation (PIH), and scarring, particularly in areas of thinner skin and in decreased adnexal structures such as the neck, have also been reported with fractional lasers. Postoperative topical application of ascorbic acid has been shown to decrease the duration as well as the severity of erythema. Because PIH can be a major problem for those undergoing fractional laser therapy, some units attempt to reduce pigmentation within the target zone prior to application of laser therapy using hydroquinone. If a patient is likely to elicit PIH, then a treatment we have found to be successful is Azelaic acid gel (15%); this has a tyrosine kinase inhibitory action that reduces the recurrence of PIH. (I emphasize that it is not a treatment for PIH but a preventative measure.) Those wishing to treat PIH with topical therapy often use a combination of steroid, hydroquinone, and tretinoin. Patients with a history of herpes who undergo laser treatment around the face may experience an outbreak if not pretreated as discussed earlier in the chapter.

LASER SAFETY

When performed by properly trained medical personnel, laser therapy has low risks for harmful outcomes and can be executed safely. National safety requirements are based on the American National Standards Institute (ANSI) Z136.3, Guide to the Safe Use of Lasers in Healthcare. This document is a benchmark standard for safe practice in the United States. Although not regulatory and without legal enforcement, this document is evidence-based and is considered best practice; as such, it is the foundation for state laws, Occupational Safety and Health Administration (OSHA) guidance, the Joint Commission (TJC) surveys, and professional recommended practices.[32] Proper handling and installation of lasers in hospitals and private practices is overseen by OSHA, which uses a set of standard guidelines issued by the American National Standard Institute. However, institutional guidelines and state regulations differ. These regulations determine the licensing requirements for who can operate a laser under the supervision of a physician.

The greatest risk when operating a laser is that of eye injury to either the medical personnel or the patient. Medical personnel operating lasers should be fully trained and should cover their skin and wear correct protective eyewear (different forms of eyewear filter different wavelengths; therefore it is important that appropriate eyewear is worn for each specific laser). The protective specifications (wavelengths and optical densities) are usually printed on the goggles, generally near the top of the unit. Protective eyewear should also be placed on the door(s) outside the laser operating room in case emergency entrance is required.

To help prevent eye injury, laser procedures should be restricted to dedicated rooms that are clearly labeled and only allow the necessary personnel. Those rooms should limit the amount of reflecting surfaces (e.g., mirrors, computer screens, windows) to avoid scattering laser beams inside and outside of the room.[33]

If the procedure is being performed on the head and neck, metal scleral eye shields that fit the patient's cornea are filled with an ocular lubricant and placed directly on the corneal surface. However, if the procedure is being done below the neck, burnished stainless steel eye cups are fitted over the eyelids and secured so that the entire periorbital area is covered.

Appropriate signage on the laser operating room door(s) is a requirement. The sign should describe the nature of the laser being used, its wavelength, and energy. Signs should only be posted when the laser is in actual use and removed or covered when the laser is turned off and the key removed.[32] All operating room windows should be closed and covered. Lasers that have foot pedals are helpful in allowing expeditious use of the laser. However, accidental activation of the foot pedal is one of the most commonly reported accidents.[32] Any repositioning of the foot pedal should take place when the laser is deactivated, and only the operator of the laser should use the foot pedal. The control panel of the laser should never be left activated and unattended. When not in use, the laser should be turned off and the key removed. The footswitch for activating the laser must be given only to the credentialed laser user.

Operating room fires and airway fires are both possible when using a laser. Production of a flame requires that the triad of heat source (laser), fuel source (patient's tissue), and an oxidizer (supplemental oxygen) be present. The risk of operating room or airway fire is rare, but most commonly occurs in patients undergoing laser treatment near the face. The risk is significant when patients who are under conscious sedation require supplemental oxygen via standard nasal cannula. Eliminating supplemental oxygen altogether is the safest way to prevent operating room or airway fire. However, the risk of fire is significantly reduced when supplemental oxygen is delivered directly to the posterior pharynx using the nasopharyngeal tube or when the patient is intubated.[32,34,35] Moist towels should cover areas around the treatment zone to avoid thermal radiation and damage to adjacent tissue. A moist towel can be safely wrapped around the endotracheal tube if present. Additionally moist gauzes should also be placed into the patient's nares and mouth when operating lasers in close proximity.

It is best to keep a fire extinguisher either inside or positioned just outside the room, so it is quickly available for

someone either inside or outside the room. All staff should be notified of its location and operation.

Along with ocular hazards and fire hazards, the laser smoke plume is a significant occupational hazard. Research has proved that thermal disruption of viable human cells, regardless of the instrument used, results in the release of mutagenic and carcinogenic materials, including carbon particles, viruses, bacteria, DNA, aerosolized blood, bloodborne pathogens, and more than 41 known hazardous gases such as benzene, formaldehyde, toluene, and acrolein.[32] Masks are not meant to be the first line of protective devices against plume exposure in the breathing zone. There are no masks on the market today, including N95 masks, that are capable of filtering out all airborne contaminants.[32] Laser masks can be used instead of standard surgical masks, but one should note that the filtration medium stops working when the mask becomes damp from breathing, thus defeating its purpose.[28] Instead the most effective way to prevent this occupational hazard is to utilize a high-efficiency ultra-low-particulate air filter. It should be rated to 99.999% efficiency and placed within 1–2 cm of the laser smoke plume source to be effective.

Logistical and Financial Considerations

Starting a laser practice dedicated to the treatment of burn patients with hypertrophic scar formation can be quite daunting.[12] The ability to collect revenue from these procedures is absolutely essential for the sustainability of the practice.[36] Third-party insurance carriers specify that hypertrophic burn scars that cause significant pain or result in a significant physical functional impairment are candidates for laser.[36] Critical to the success in obtaining preauthorization from insurance companies is a thorough history and physical, clinical photography, and the use of accurate, specific, and complete CPT and ICD-10 codes. Because specific CPT codes for the laser treatment of burn scars do not exist, Hultman et al. recommend using 17106, 17107, and 17108 (laser destruction of cutaneous vascular proliferative lesion, $<10\ cm^2$, 10–50 cm^2, and $>50\ cm^2$, respectively). The rationale for using these codes is that burn scars are hypervascular, hypertrophic, and hyperpigmented, all of which are due to a proliferative, neovascular, and hyperplastic response of the injured tissues. While not hemangiomas or vascular malformations, burn scars act like these lesions due to similar pathophysiologic mechanisms, resulting in similar endpoints.[12] Also important for documentation is using the correct ICD-10 diagnosis terminology to signify that these scars are from burns and corrosions of external body surfaces. Use T20 for head, face, and neck; T21 for trunk; T22 for shoulder and upper limb, except wrist and hand; T23 for wrist and hand; T24 for lower limb, except ankle and foot; and T25 for ankle and foot. Also utilize ICD-10 codes L91.0 to describe keloid or hypertrophic scars and L90.5 to describe scar conditions and fibrosis of skin.

Acquiring the laser platforms may be done through rental, lease, or purchase, but the capital requirement can be considerable.[12] Because laser technologies can become obsolete quickly, and because warranties can be quite expensive, at least in the beginning of the venture, leasing is one way to start a practice offering laser treatments.[36]

The clinician must also have access to an accredited surgical facility that includes all of the safety features of an operating room or surgical suite. Most patients require a large area of treatment that generally exceeds the area that could be covered by local anesthesia. These patients require treatment in an operating room with either monitored anesthesia or general anesthesia with supervision by an anesthesiologist.

One element that is particularly attractive to all stakeholders, patients, providers, and third-party payers is that laser therapy for hypertrophic burn scars has the potential to dramatically reduce the cost of care.[12] It is possible that laser treatments might preclude the need for invasive surgery in some patients with mild to moderate contractures and permit less aggressive and less costly procedures in patients with moderate to severe contractures.[36] From experience at our institution, patients expressed preference for the less-invasive laser treatment compared to a more invasive surgical scar release.[29] Laser treatments can decrease pharmacologic requirements for such medications as narcotics, antihistamines, anxiolytics, and antidepressants leading to decreased healthcare costs.[12] Also, patients who have had successful treatment of their hypertrophic burn scar may return to work or school sooner and require less clinic follow-up.

Future Investigations

Although the effect of lasers on hypertrophic burn scars has only been studied in the past few years, this work is very promising and therefore just beginning. High-quality, prospective, blinded, randomized, controlled trials are necessary to assess which lasers or light-based therapies are best for hypertrophic burn scar modulation, pruritus, and dysesthesias. Within each type of therapy, standardization of several different laser parameters, such as fluence, pulse time, density, and timing of surgery, will be developed. Any additional benefit from adding topical medications to the treatment area also needs to be standardized. Studies assessing economic benefits will allow for other institutions to adopt lasers for the treatment of hypertrophic scarring.

Conclusion

Lasers and light-based therapies are safe and effective treatment options for hypertrophic burn scars, and they are now becoming the standard of care for all burn patients. Although not a panacea for all scars, they are a worthy addition to the armamentarium of all burn reconstruction surgeons.

Although laser treatments are clearly effective, they have not yet been optimized. Prospective, randomized clinical studies are necessary to provide evidence-based and quality care for patients with hypertrophic burn scars.

61 The Ethical Dimension of Burn Care

ARTHUR P. SANFORD and MICHELE A. CARTER

Introduction

Burns are a leading cause of accidental injury and death in the United States and worldwide, and they can often raise profound concerns about autonomy, mortality, quality of life, and suffering. In seeking optimum health for each patient, contemporary burn care aspires to integrate the highest standards of evidence-based medicine with excellence in patient care delivery and clinical research. Optimal care of patients with burns is a virtuous practice involving highly integrated, team-oriented, interdisciplinary,[1] and humanistic encounters. It includes adherence to certain norms of professional conduct as well as a process of reflection on how to incorporate those norms in individual patient care or research settings. It involves increasingly complex layers of technological and professional sophistication, clinical judgment, and expertise and sensitive attention to the ethical values at the core of medicine. Clinical situations can be complex, not simply because of the wide range of medical facts and situational factors that constitute burn care, but because of the diversity of human needs that lay coiled beneath the surface of illness or trauma. Given that patients with burns are among the most vulnerable of patients and have needs that expand the full range of the human condition, all members of the healthcare team are called upon to offer care that is tender, skillful, comprehensive, and ethically conscientious. The core ethical ingredient of these encounters is the doctor–patient relationship and the underlying expectations of trust that patients and their families bring to the clinical setting.[2]

Caring for the burned patient encompasses a long-standing commitment to the safety, healing, rehabilitation, and growth of patients. As such it is thoroughly infused with ethical values and goals. As conceived in ancient Athens and during most of its history, Western ethics involves the quest for achieving the good life, living it excellently, and setting forth ideals of human flourishing. In contemporary times, these ideals continue to inform the practice of medicine and contribute to the evolving field of clinical ethics. Clinical ethics is "the systematic identification, analysis, and resolution of ethical problems associated with the care of particular patients. Its goals include protecting the rights and interests of patients, assisting clinicians in ethical decision making, and encouraging cooperative relationships among patients and those close to patients, clinicians, and healthcare institutions."[3] Over the past several decades, the field of clinical ethics has become an essential part of hospital life and culture, reflecting the complexity and poignancy of the real-life ethical puzzles clinicians frequently encounter. It involves critical thinking about right and wrong and of what should or should not be done[4] in terms of our responsibilities to others. It also legitimates the importance of ethics teaching and ethics dialogue in all phases of professional practice, whether that is in the classroom, the board room, or on "ethics rounds at the bedside."[5] Clearly caring for burned patients invites moral reflection and imagination, and clinical ethicists increasingly are part of the integrated approach.

In general, most healthcare providers hold certain values in common and are thus not in doubt about what morality requires. That is, we hold firmly to the conviction that it is a good thing to preserve life, to cure disease, or to lessen someone's pain or suffering. For the most part, we are clear about what our ethical responsibilities are: to respect the values and dignity of human life, to tell the truth, to avoid harming patients, and to treat them and their families fairly and with compassion. Indeed ethical decision-making for some is therefore like breathing,[6] something we do without even thinking. At times however disagreements about what we ought to do or what we ought to value occur. That is, while we may be clear on the general principles of ethics, it is not always so clear how to apply them in a particular case. This uncertainty can give rise to ethical problems and dilemmas, some of which occur at the bedside of the patient and others that may involve questions of institutional policy, resource allocation, or even larger societal issues about how we ought to distribute goods and services.

What Is an Ethical Problem?

An ethical problem is present when it involves a conflict of two or more of the following: rights or rights-claims, obligations, goods, and/or values.[7] For example, disputes about writing a "comfort-measures-only" order for a patient without decision-making capacity and with a very low probability of survival commonly involve a conflict between an obligation and a good: the obligation not to abandon aggressive therapy prematurely and the good of a maximally pain-free and unprotracted death. In this case, the burn team and the patient/surrogate are ordinarily the major stakeholders and appropriate decision-makers, and they are addressing *a problem in clinical ethics*. On the other hand, consider the burn center's or healthcare organization's (HCO's) responsibility to ICU patients when a safe nurse-to-patient ratio cannot be consistently met despite the burn center's best efforts. If discerning what should be done in such circumstances requires decision-making at the managerial level of the burn center or HCO, *a problem in organizational ethics*[8] is the correct term to use.

As indicated, conflicts among rights, obligations, and the like are very common and vary greatly in difficulty. When should they be taken seriously? An ethical problem is serious when there are stakeholders involved who stand to be seriously affected by the problem or its outcome. Stakeholders working collaboratively without outside help can successfully manage the vast majority of such problems. When are such problems so serious that assistance should be sought from an ethics consultant or a healthcare ethics committee (HEC) or its equivalent? An ethical problem is serious enough to refer to an HEC:

a. When you suspect the Smell Test would be positive; that is, "What would the action or situation we are considering smell like if we read about it in a front page news article or in a popular blog? Would I be comfortable explaining it to my spouse, or my grandmother?" The problem with this, as the olfactory image reminds us, is that living with bad smells or unethical conduct for a long time may dull a person's ability to notice them.
b. When there is persistent disagreement among the major stakeholders and codes, rules, laws, and more discussions fail to lead to a resolution within generally acceptable ethical boundaries in a reasonable amount of time.

How Should Clinical Ethics Problems Be Managed?

In the United States, the informed consent process was developed by the American judiciary to safeguard the legal rights and welfare of all the stakeholders participating in bedside decision-making. Throughout the United States, this legal process has become the foundation of the healthcare provider's approach to avoiding and managing serious ethical problems at the bedside. Its application in the burn center was explained and diagrammed in detail in the first edition of this book,[9] and what follows should be considered an update and development of what is stated there.

On the vast majority of occasions, there is little or no difficulty achieving agreement and patient consent about a proposed course of burn management. There are many predictors of clinical outcomes that are without controversy.[10] Occasionally, however, the process of obtaining informed consent leads to problems involving disagreements, anxieties, and/or controversies about what should or should not be done. At this point, the participants must give careful attention to the quality of the discussion in attempting to resolve the problem, part of which requires respect for the patient's underlying values.

Increasingly, ethics consultants are seen as important stakeholders in optimizing the care of patients suffering from burns, especially when treatment decisions are ethically complex or psychologically difficult. Through facilitated dialogue, the rights, interests, and needs of the patient are brought to the center and deliberated upon, but the values and concerns of the team are honored as well. Additionally, ethics consultants facilitate the process of making and justifying moral judgments on the basis of certain ethical principles that transcend individual personal opinion or perspective. That is, a judgment that a certain act—say, withdrawing life-saving treatment for a dying patient—is to be performed or not is justified on the basis of some rule or standard applicable in all relevantly similar cases. In this way, ethical dialogue becomes more than simply ensuring that a patient has provided an informed consent for treatment. Instead ethical dialogue becomes the means by which we examine the full range of our ethical responsibilities to others, drawing on principles of trust, autonomy, dignity, beneficence, justice, and care (Fig. 61.1).

THE ROLE OF THE CARE-PROVIDER IN ETHICAL DIALOGUE

Approaching the resolution of ethical conflict through dialogue fosters in the burn team a sense of moral inquiry and agency and makes explicit the process of respecting the patient and family. At its best, ethical discourse begins by establishing an interpersonal "relationship" made safe for transparent and self-critical honesty and furthered by active listening and openness to learning about the relevant norms that constitute good care.[11]

To do this the care-provider should explore the bio-psycho-social-economic and cultural/religious information required to approach the patient and his family and/or surrogate with empathy for their lives and values. One of the strongest ways we show respect for the patient and family is to honor religious values, even when such values may differ from those of the healthcare team. For instance, Western religions often proclaim that there are certain limitations to earthly life and advocate adherents to look to a future beyond the present for ultimate value and meaning. By contrast, Eastern religions hold that our present lives are reflective of past deeds and future conditions, that life is oriented to the present. Many confer extreme respect on the spirit of departed ancestors and live their lives in service to their honor. Finally, some individuals do not have religious affiliations at all and may live for different goals or ideals. These belief perspectives illuminate diverse ways of deriving meaning in life and understanding those ends that make life worth living. At times, this diversity can render decision-making about treatment decisions more challenging and can give rise to ethical uncertainty or moral distress in members of the healthcare team. Many patients, based on personal values and beliefs, may decide against life-prolonging treatments in hopes of not burdening their family with large hospital bills. Other patients may demand care that is arguably futile, care that has no possibility of conferring any physiological benefit to the patient. For some practitioners, such reasoning patterns may appear to be fundamentally flawed and can spawn difficult emotional contests. In these situations, the ethical dialogue may expand beyond the doctor–patient relationship and involve policy-makers, legislators, practice plans, and regulators, all of whom are stakeholders in the system of trust that society relies upon. Given that patients with burns reflect the diversity of the American population and a plurality of values regarding life and death, care of the burned patient is complex and challenging. Consideration of patient values and preferences should occur early on in the plan of care so that proper respect for patient autonomy, culture, and religious perspectives can occur.

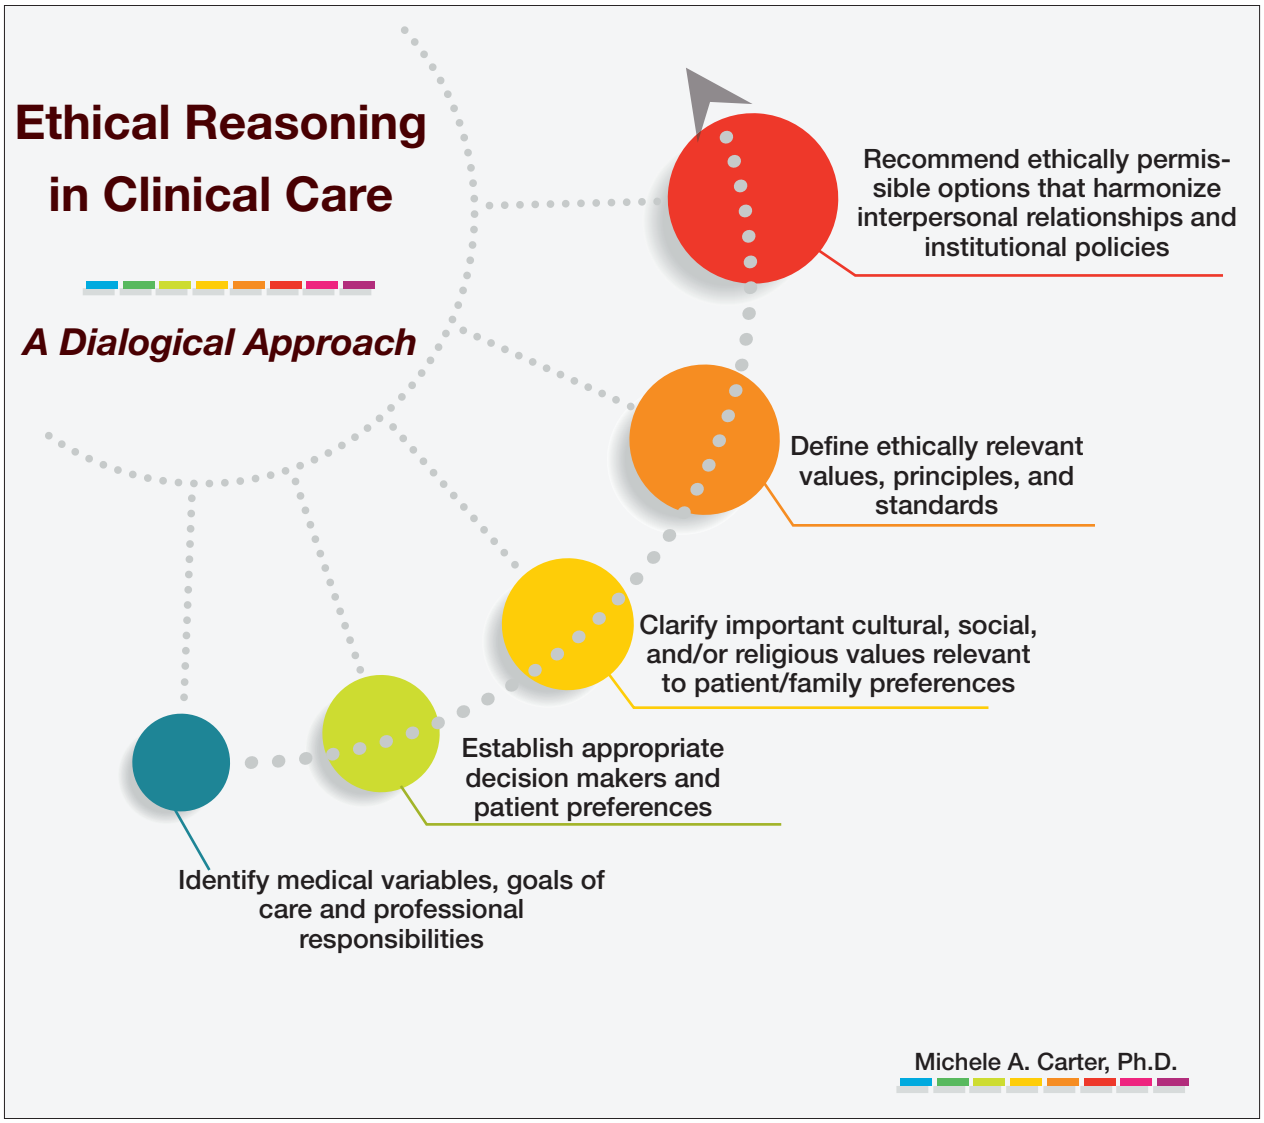

Fig. 61.1 Ethical Reasoning in Clinical Care—A dialogical approach.

The care-provider must assess the patient's capacity for decision-making. To have decision-making capacity, the patient should be able to understand proposed treatments and their relevant risks and benefits, comprehend the consequences of various actions and/or alternatives, and evaluate whether they accord with his or her personal values. Also patients should be able to meaningfully deliberate and express their preferences regarding recommended treatments; this standard is often difficult to meet in the emergency or intensive care setting and appropriate surrogate decision-makers should be identified early in the hospital course.[12] Decision-making capacity is enhanced by optimizing the patient's physiological stability, consciousness, and pain control as much as possible. It is typically verified by ascertaining orientation and by asking the patient to rephrase the information provided in his or her own words and to offer a reason or rationale for the decision. In general, the physician is authorized to determine whether or not a patient is capacitated sufficiently to make a health-related decision. Determination of decision-making capacity by judicial process (i.e., determination of legal competency) is rarely necessary. If despite all efforts the patient is found to lack decision-making capacity, an appropriate surrogate should be sought among the patient's family or friends, depending on local laws to determine priority.

The care-provider has a duty to provide accurate information pertaining to the patient's diagnosis, prognosis, and treatment plan so that the capacitated patient or appropriate surrogate can properly deliberate. This includes relevant information about plausible alternatives, including the option of forgoing proposed therapies. This duty is part of the ethical standard of care and is an ongoing responsibility throughout the hospital course. In providing optimal care for burned patients, allegiance to this ethical norm is an essential ingredient of the doctor–patient relationship and the foundation of trust.

THE ROLE OF THE PATIENT OR SURROGATE IN ETHICAL DIALOGUE

Patients and families bring to the clinical encounter previous experiences with loss and suffering, and these experiences influence decisions about their goals for care and recovery. The role of the patient is to assimilate information provided by caregivers into their own value system and to participate honestly and sincerely in conversations about their preferences and concerns. One cannot expect an acutely injured patient to fully understand medical information, and most often they will require assistance from the team before they are able to render a values-based decision. Behavioral therapists, nurses, social workers, and clergy are often needed to provide support and counsel, and they often help patients discover internal resources needed to meet or revise their life goals. In addition, critically burned patients are often unable to participate meaningfully in treatment decisions and must have their right of self-determination carried out by a surrogate decision-maker. By entering the patient's personal world and participating in the unfolding narrative of his or her experience, care-providers are better able to arrive at ethically sound decisions.[13] Patients and their surrogates thus are essential participants in the integrated approach to optimal burn care, and, without their involvement and solicited participation, the ethics dialogue is incomplete.

HOW SHOULD PERSISTENT ETHICAL CONFLICT BE MANAGED?

Even when participants make a sincere effort to establish consensus about treatment decisions, disagreements occasionally persist. To resolve them, a patient care conference is needed and ideally should include all major stakeholders. The goal of these conferences is to collaboratively arrive at ethically appropriate solutions that respect the values of the patient and accord with appropriate standards of care. Patient and family conferences are important components to managing conflict in patient care decision-making. These conferences usually involve representatives from multiple disciplines who are involved in the care of the patient and often are organized to help resolve ethical disagreements or dilemmas. In any serious ethical inquiry, three questions must be answered: What seems to be the problem? What can be done? What should be done? A seven-step decision-making model has been found helpful in answering these questions and is illustrated in Table 61.1.[14]

In Step 1 of this decision-making model patients and/or their surrogate are asked to speak first, and care-providers listen carefully and respectfully. This approach helps equalize power and create a safe place for shared understanding. Participants are asked to introduce themselves, explain the conflict as they see it, and indicate what they hope to achieve by the discussion. Thereafter, the care-providers do the same. This step typically takes the most time but is the most important of all the seven steps. It lets off steam, makes the patient/surrogate and allies feel listened to, and optimally leads them to ask for the corrective and supplementary information they need from the care-providers, which (in Step 2) they usually can provide or obtain. (Note the similarity of these early steps to those of the SPIKES protocol for delivering bad news, described by Buckman; see Foley[15].) If successfully carried out, Steps 1 and 2 transform a potential or actual power struggle into a collaborative search for the answers to the next and then the final question listed in Table 61.1.

Table 61.1 Three Questions to Be Addressed When a Clinical Ethics Problem Is Serious and Persistent and the Steps Appropriate for Answering Each Question

1.	What seems to be the problem?	Step 1.	Discover conflicting values of stakeholders
		Step 2.	Discover the relevant information
2.	What can be done?	Step 3.	Identify principles, laws, other values relevant to the decision
		Step 4.	Identify alternative courses of action
3.	What should be done?	Step 5.	Compare alternatives and values: is decision clear?
		Step 6.	If not, assess consequences
		Step 7.	Make decision, collaboratively, if possible

Modified from May WW. *Ethics in the accounting curriculum: cases and readings.* Sarasota, FL: American Accounting Association; 1990:1. With permission of the American Accounting Association and the author.

The conversation of Step 3 may address principles (like respect for persons, beneficence, etc.) but more typically cites relevant laws and rules of the community and/or institution, and/or other values (no unnecessary pain, what the patient would want if able to speak, etc.). Step 4 is usually best carried out using a white board or equivalent to brainstorm and record all the plausible alternative courses of action. In Step 5, the group collaboratively may find a principle, rule, value, or some combination thereof so compelling that the proper alternative is clear. For example, because it is considered unlawful homicide in most locations, large doses of a narcotic primarily intended to stop breathing rather than control pain may be found unacceptable. If the decision is still not clear, Steps 6 and 7 will usually lead to a mutually acceptable decision within boundaries that are acceptable institutionally, legally, and ethically. Rarely, consensus will elude the most sincere adherence to the seven-step process. If further discussion, efforts to transfer care of the patient, and the like fail, an appeal to the courts, or (in at least one state[16]) an appeal to relevant legislation for relief from responsibility for care of the patient, may be necessary.

The Patient Without Decision-Making Capacity, Surrogate, or Advance Directive

In such cases, care-providers typically have no way of knowing or deducing with confidence what the patient's wishes might be in a given set of circumstances. In general, the decision made must seek the best interest of the patient, but the process required may vary. In some jurisdictions, consultation with another physician, the healthcare institution's legal counsel, and/or HEC is mandatory. In others,

a court-appointed conservator might be required. In all such cases (1) the search for a surrogate should be diligent, (2) all relevant medical information must be obtained and reviewed, (3) real or apparent conflicts of interest must be disclosed, (4) the opinions of the healthcare team and of one or more physicians in addition to the responsible attending should be reviewed, (5) the burden versus benefit ratio must be weighed from the patient's point of view, and (6) steps should be taken to ensure the benefit of continued life to a disabled patient is not devalued or underestimated.[17] Some institutions also require that consideration of economic impact on healthcare providers and the healthcare institution be excluded from consideration in such cases. Eventually a surrogate decision-maker is identified, and, hopefully, this is a person who has previously known the patient and his or her values prior to the accident, who has possibly had discussions about extreme end-of-life issues and can speak on the patient's behalf. The surrogate decision-maker must not make the decision based on what he or she would want for the patient. However the surrogate decision-maker must know what that patient would prefer and act as an advocate in this situation since the patient is not able to participate in the decision. They should be expressing the patient's views, not projecting their own views onto the patient.

How Should Organizational Ethics Problems Be Managed?

Currently healthcare decision making affecting burn care occurs at three levels: in the clinic, in the organization, and in society.[8] The disciplines designed to improve ethical decision making at the first and third levels are called *clinical* and *societal ethics*, respectively. They discern facts and values for guiding clinical or societal decisions that affect patient care and have received wide attention in both the media and scholarly journals for years. Recently attention has been called to the need for discernment of facts and values for guiding managerial decisions that affect patient care.[8,18] For example, at times, problems present as difficulties in clinical decision making but have their root causes in areas that require decision making at the managerial level. With dwindling numbers of nurses entering training, increasingly fewer nurses will be available to provide intensive care, and managerial decisions will be required to produce or recruit more nurses and to judge just when it is no longer safe to admit new patients to beds without adequate staffing. Also, when rehabilitation services in a given geographical area have not kept up with the increasing numbers of patients with large burns who survive but require longer and more expert rehabilitation, managerial decisions about the distribution of scarce resources will have to be made if adequate rehabilitation care is to be available. Such decisions are ethical: they involve conflicts of rights, obligations, goods, and/or other values. They tend to be less dramatically immediate and more deferrable, but they usually affect more persons and require more resources and follow-up than clinical ethics decisions.[18] They sometimes appear to be made in the front office, apparently without satisfactory input from care-providers, patients, or other stakeholders and without the availability of extensive literature or assistance from a committee or consultant skilled in ethical analysis and critique applied at the organizational level.

The development of the discipline of "organizational ethics" is just beginning and is overdue in the judgment of JACHO[19] and other authorities.[20] The obligation to be ethical at every level of healthcare decision making will become increasingly obvious and pressing, with continuing changes in the ways health care is delivered. Increasingly institutional leaders are expected to be accountable for their policies, practices, and decisions and to convey their expectations, actions, and results in transparent ways.

Conclusion

Illness, trauma from being burned, and hospitalization can impact a person's sense of wholeness, integrity, autonomy, and sense of identity. In cases involving severe burns, patients are often dependent on others for the most intimate functions of daily life and must rely on the good will, skills, and ethical conduct of others. While it is clear that optimal burn care is infused with technological innovation, clinical sophistication, and the application of evidence-based knowledge, it is also a profoundly moral activity. It requires deliberate sensitivity to the values and needs of others, profound regard for the dignity of each individual, and courage to enter into the world of a vulnerable human being who is in need of help. Providing total care to the burned patient requires an educated heart, an empathic mind, and a humanistic team.

62 Intentional Burn Injuries

LISA L. TROPEZ-ARCENEAUX and KWABENA O. SARPONG

PowerPoint Presentation Online

Introduction

Forensic medicine has made tremendous advancements in developing scientific measures to identify child maltreatment and intentional injuries. Despite these advancements, deliberate injury by burning is often unrecognized. According to the U.S. Department of Health and Human Services Administration for Children and Families,[1a] child abuse and neglect are defined as "any recent act or failure to act on the part of a parent or caretaker, which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm." In January 2016, The Children's Bureau published the National Child Maltreatment Data from 2014, which reported that 1580 children died as a result of abuse or neglect.[1b] Within the United States alone, 1.5 million children are abused or neglected each year, with 4–39% of these occurrences being reported as intentional burn injuries and less than half ever being substantiated.[2a] In 2015, children aged 0–4 who sustained small burn injuries (total body surface area [TBSA] 0–29%) had a mortality rate of 0.25%, medium burn injuries (30–59.9% TBSA) had a mortality rate of 9.6%, and large burn injuries (≥60% TBSA) had a mortality rate of 29.06%.[2b] These mortality rates are significantly higher than in children over the age of 4, indicating that children younger than 4 years of age are at greatest risk.

It is imperative that all clinicians be aware of the importance of recognizing signs and symptoms of intentional injury presentations because the opportunity for intervention is critical when taking into account that 50%[3] of children experience recurrent abuse and 30% are ultimately fatally injured.[4] Reporting suspicious injuries to child protective services (CPS) is mandated by law for all clinicians working with children.[5] Some treating facilities identify specific treatment team members (i.e., psychologist or social workers) to be responsible for all reporting. In these situations, it may be necessary to follow the protocol of the hospital or treating facility first; however it is important to note that any physician, medical professional, or mental health professional who encounters a suspicious injury must ensure that the injury is reported to the appropriate authorities. At other times, the concern of reporting is more a result of ambiguity or vagueness in the information, which can cause hesitation to report the suspicious injury. In these incidents of doubt, the most salient point to remember is that the clinician is responsible for reporting suspicious injury, not proving or validating abuse. It is always better to report the suspicion than to ignore it. Most state agencies also have hotlines that are available to call 24 hours to ask specific questions regarding reporting suspicious injuries.[6] Although it is overwhelming to imagine that so much abuse occurs, statistics show that it does occur, not only with children but also with adults and our elderly population.

Intentional injuries can occur in the form of neglect, physical abuse, sexual abuse, and emotional abuse. All of these injuries can occur independently, but they often occur simultaneously.[7] Neglect is the most common form of intentional injury. Of the average 5.5 million referrals made to CPS each year, 64.5% of these children are neglected.[8] Physical abuse occurs in 25% of intentional injury cases.[8] More than 15% of victims of abuse suffer more than one type of abuse, and more than one-third of child fatalities are attributed to neglect (Fig. 62.1).[9] Burn injury is frequent in both neglect and physical abuse of children. Severe burns in children are between 10% and 12% of all intentional injuries.[10]

Since the last edition of this book, intentional injuries to adults have increased. It is frequently debated within the literature as to whether the increase is a valid increase or if there is an increase in reporting. Violence specifically against women and young girls has now become a universal phenomenon. The World Health Organization reported that, of the women who were partnered at some point during their lifetime, 15–71% reported experiencing physical or sexual violence by their partner.[11] Within this realm of violence against women and young girls, acid violence is the worst form of violence and violation of human rights.[12] Although steps are being taken to control the widespread free sale of acids to the public,[13] this act of violence is still on the rise and warrants discussion in the burn care literature and sensitivity to this overwhelming problem by all burn care professionals. Another vulnerable population of intentional burn injuries is the elderly. In the past 10 years, burns in the elderly have increased secondary to an increase in size of the aging population.

In this chapter, we have integrated our experience with current literature to classify risk factors in the total population and to propose validated therapeutic interventions to treat the burn wounds and the complex social and psychological familial concerns that both create injury and complicate the recovery and rehabilitation of the patient. It is essential that burn team clinicians understand their role and responsibility in assisting not only burn patients but the perpetrators as well because history and statistics have shown us that the outcome can be fatal if intervention and prevention methods are not implemented with sensitivity to maintain positive relationships with burn patients as well as with perpetrators.

The authors are well versed in clinical experience and research experience of child abuse and pediatric burn injuries; however our experience of intentional burn injuries within the adult population is limited. The literature and our

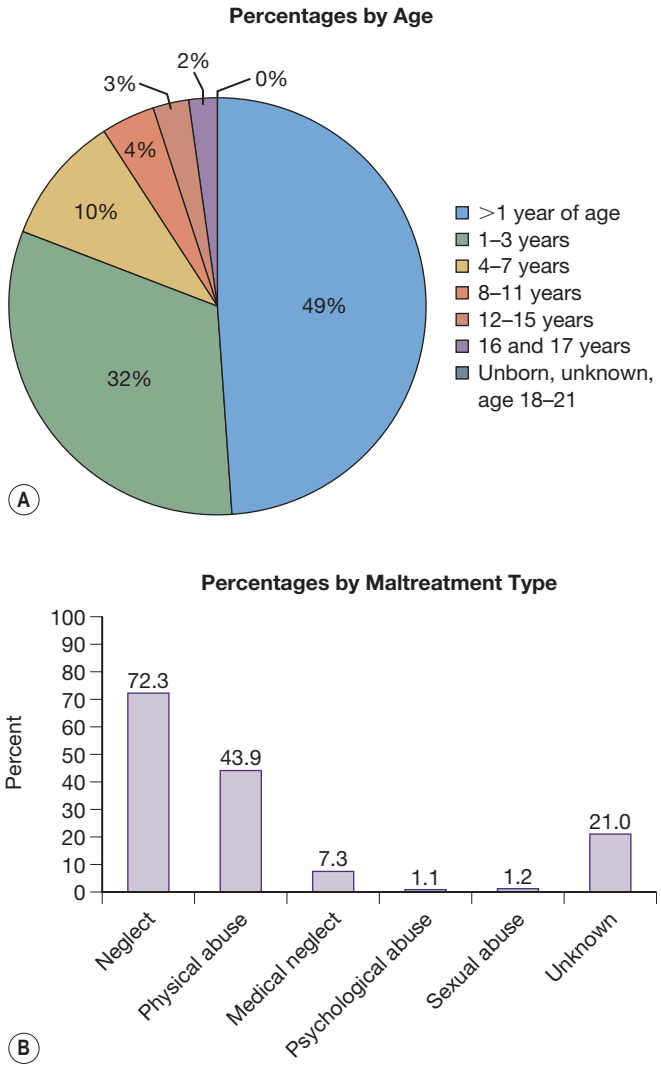

Fig. 62.1 Abuse and neglect fatality statistics. **(A)** Child abuse and neglect fatalities by age, 2006. **(B)** Forms of intentional injury that resulted in fatality. (From Child Welfare Information Gateway. June 2008 numbers and trends, child abuse and neglect fatalities: statistics and interventions. Available at: www.childwelfare.gov/pubs/factsheets/fatality.cfm.)

extensive knowledge of information regarding intentional injuries against children are reflected in this chapter. We have included the most recent literature on adult injuries, but it is not exhaustive. It is important to note that the pediatric population is not the only target for intentional injuries.

Prevalence Rates of Intentional Burn Injuries

Despite the improvement and use of smoke detectors, investment in sprinkler systems, and improvement in building codes in developing countries, burns continue to cause significant intentional and unintentional injuries. Smoking remains the leading cause of death by fire. Cooking is the number one cause of residential fires. Annually fire-related injuries claim more than 300,000 deaths and 10 million disability-adjusted life years worldwide.[13] Middle and low-income countries exceed 95% of fire-related burns.[13–15] Approximately half of these countries are in southern parts of Asia.[15] In the United States, burn injuries result in approximately 1 million emergency department visits and 50,000 hospital admissions, with a 5% mortality rate.[13] Fire and burns represent 1% of the incidence of injuries. Fatal home injury burns and fire deaths rank fifth and third, respectively, in the United States.[16] The incidences of the causes of burns are flame/fire 46%, scalds 32%, hot objects 8%, chemicals 3%, and other forms 6%. Fires/burns occur frequently in the home (43%), on the street/highway (17%), in occupational settings (8%), and in other settings (32%).[17] Burn injuries inflicted in Pakistan occur mostly to adult women: approximately one-third are secondary to stove burns and 13% are acid burns. Husbands inflict more than 52% of these injuries and in-laws one-quarter of the injuries.[18] Victims who are at highest risk of fire-related injuries and deaths are children aged 4 and younger, adults older than 65 years, African-Americans and Native Americans, and the poor or those living in rural areas.[16] A literature review of hospital-based studies of the prevalence of burn injuries in China revealed similar results with the most vulnerable being children younger than 3 years, males more than females, those living in a rural setting, and the incidence occurring between the hours of 17:00 and 20:00.[19]

PREVALENCE OF CHILDHOOD BURNS

Over the past 50 years, child abuse has been documented, especially in the United States. Child abuse characteristics are composed of physical abuse, neglect, sexual abuse, psychological abuse, and other, which include Munchausen by proxy and abandonment. Child abuse may present with multiple characteristics. Major forms of injuries to children include falls, poisonings, car accidents, foreign body, and fires/burns.[20] Ten percent of child abuse is burns, and 20% of burns are child abuse.[21] The child abuse death rate in the United States is approximately 1000 children annually,[18] with burns and scalds as the most frequent cause of death.[10] In China, the mortality rate from abuse ranges from 0.49% to 3.14%. In Hong Kong, it is 2.3%; in Singapore 4.61%, and in Iran 6.4%.[19] The lowest rates are in the United Kingdom and the highest rates are in the United States, where the majority of the studies have been completed.[10] In many cases of burn injuries, it may be difficult to conclude if the burn injury is an incidence of neglect, intentional, or truly an accidental event.[4] More recent studies[10,21–23] have begun to analyze hospital cases of burns to delineate if they are intentional or nonintentional. The characteristics of types of burns include scalding (70%), flame burns (50%), or electrical (3–4%).[19] Bathtub submersions peak at 6–11 months, then again at 12–14 months and remain high until 33–35 months of age.[20] Most studies calculate the mean ages of children with intentional burns at 2–4 years of age.[18] Boys are 2–3 times more afflicted than girls, with the youngest of multiple siblings suffering most often.[21] There is no ethnic predilection. Of children who are victims of physical abuse 10–12% suffer severe burns.[10] In 2007, Hicks and Stolfi[24] concluded that children with burn injuries are at risk for occult fractures at a significant rate. Therefore a skeletal survey should be routine in burn patients presenting to the emergency department, as

recommended by the American Academy of Pediatrics. Males are convicted at a greater rate than females, despite an equal rate as perpetrators.[25]

PREVALENCE IN ELDERLY

Over the past 10 years, prevalence data of burns in elderly have increased secondary to recent emerging studies in this area. As in pediatric burns, geriatric burns are higher in developed countries at a rate of 20%; in the developing world, the rate is 5%.[15] Results of the review of data from the U.S. National Burn Repository demonstrated an increase in the rate of elderly abuse from 1991 to 2005.[15,26] Of those burned, 14% are older than 55 years of age (with 6.2% between 55–64 years, 3.3% between 65–74 years, and 4.4% >75 years of age). There is a male predominance of burns of 1.4:1. However this decreases with age and is thought to be secondary to the decrease in life expectancy of males to females. The most common injuries are flame burns, accounting for 37%, and scalds at 22%. The TBSA was 9.6%, and the majority of injuries were residential.[15,26] In the United Kingdom, residential settings are the leading site for burn injuries to the elderly, at a rate of 18.6%. The occurrences had a 32% higher mortality rate and 33% more TBSA affected than like-sized burns in aged patients from other causes than abuse. Over a 4-year period, Bortolani and Barisoni[27] investigated 53 patients aged 60 and older who were admitted to a local Italian hospital. It was noted that 85% of these burns occurred in the home and 11% in nursing homes. Flame burns were the most common at 55%. The incidences were attributed to preexisting diseases in 85% of patients. These diseases included cardiovascular accidents, neurological problems, and diabetic comas.[27] In addition to illness, lack of adequate supervision is another major etiology for burns in this age group.[18] In the United States, residential care settings accounted for one-fifth of geriatric burns.[28]

With an increase in the aging population, there is concern about an increase in domestic elderly abuse and, proportionately, an increase in burn victims.[29,30] In the United States, elderly physical abuse was underreported, with a rate of 2.8% of total cases of abuse in 1988. However, in 1996, residential institutions estimated only one-fourth to one-fifth of abuse was reported. Another study, from Canada, estimated the prevalence of abuse at 1%.[28] The abuse is usually kept secret owing to guilt, shame, and fear of reprisal, especially if the perpetrator is the victim's adult child (Box 62.1).

The literature reports controversial results on the most likely perpetrator: spouse versus adult children. As in child abuse, disabled adults and those who suffer from dementia are at higher risk for abuse. Drug and alcohol abuse in caretakers also increases the rate of abuse. Other characteristics in caregivers are mental disorder, financial difficulties, and deviant behavior.[28]

Box 62.1 Premorbid Indicators of Intentional Burn Injuries of Adults

- Physical dependence
- Psychological dependence
- Accessibility as a target for abuse, as in institutional living or living with a caretaker
- Caretaker(s) with a history of substance abuse and/or other psychopathology
- Social isolation
- An injury that is not consistent with the story described
- Conflicting reports of the injury
- Scalds with clear-cut immersion lines and no splash marks
- Scalds that involve the anterior or posterior half of an extremity and/or the buttocks and genitals or a flexion pattern
- Other physical signs of abuse/neglect
- History of related incidents

Distinctive Characteristics of Perpetrators and Families

Perpetrators are frequently individuals responsible for the care and supervision of their victims. In 2007, one or both parents were responsible for 69.9% of child abuse or neglect fatalities.[31] More than one-quarter (27.1%) of these fatalities were perpetrated by the mother acting alone.[31] Child fatalities with unknown perpetrators accounted for 16.4% of the total.[31] According to the National Child Abuse and Neglect data system, in 2008, 56.2% of perpetrators were women, 42.6 % were men, and 1.1% were unknown.[32] Of the reported women perpetrators 45.3% were younger than 30 years of age compared to 35.2% of men younger than 30.[32] These percentages have remained consistent for several years in a row. Some 61% of all perpetrators were neglected as children.[1,31,32] Approximately 13.4% of all perpetrators were associated with multiple types of abuse.[1,31–33] Ten percent of perpetrators experienced physical abuse as children, and 6.8% were sexually abused as children.[33] Of the children who are abused, 80% were abused by their parents.[31–33] Other relatives accounted for an additional 6.5%.[31–33] Unmarried partners of parents were 4.4% of perpetrators. Of those parents who were perpetrators, more than 90% were biological parents, 4% were step-parents, and 0.7% were adopted parents.[32,33]

Other characteristics of perpetrators commonly include being adolescent parents, being a single parent, often maintaining inconsistent expectations for a child's development, experiencing a lack of external supports, stressors such as substance abuse, poor education (no high school diploma), unemployment, poor housing, mental illness, and being reliant on children for emotional support (Box 62.2).[34] Most fatalities from physical abuse are caused by fathers or other male caregivers. Mothers are most often held responsible for deaths resulting from child neglect.[35] In some situations, there are two "perpetrators," the actor and the overtly passive observer who does not stop the abuse.[36] Justice and Justice,[37] in their work with families who mistreat children, identified several erroneous belief systems that are commonly held by perpetrators; these are listed in Box 62.3. Since, as most authorities believe, violence is a multigenerational intrafamily pattern, then it is likely that the belief systems attributed to child perpetrators can be extrapolated to perpetrators of adult abuse as well.[36]

Often in homes where abuse occurs, there is little to no emotional support for the perpetrators. They are often dealing with tremendous life stressors and unfortunately

Box 62.2 Risk Factors for Abuse/Neglect by Burning

Forced-Immersion Demarcation

- Symmetrical, mirror-image burn of extremities
- Glove-like (burned in web spaces)
- Circumferential
- Minimal splash marks
- Uniform depth
- Full-thickness
- Clear line of demarcation, crisp margin
- Doughnut-shaped scars on buttocks/perineum (spared area forcibly compressed against container thus decreasing contact with hot liquid if container is not a heated element)
- Flexion burns, "zebra" demarcation to popliteal fossa, anterior hip area, or lower abdominal wall
- Injuries of restraint (e.g., bruises mimicking fingers and hands on upper extremities)[16]

Injury Demarcation, Other

- Incongruent with history of event
- Pattern of household appliance; note whether the burn presents as an even pattern versus a brushed, imperfect mark
- Scald
- Location of injury: palms, soles, buttocks, perineum, genitalia, posterior upper body
- Cigarette burn, if more than one on normally clothed body parts and if impetigo is ruled out

History of Injury

- Evasive, implausible explanation
- Incompatible with child's developmental age
- Changes in story; discovered to be burned
- Rule out dermatologic epidermolysis bullosa (EB), dermatitis herpetiformis, chemical burn due to analgesic cream, phytophotodermatitis,[17] and birth marks, including Mongolian spots[18]
- Undersupervised: inadequate monitoring, impaired person supervising, inordinately young babysitter (<12 years of age)
- Burn is older than history given
- Water outlet temperature greater than 120°F
- Mechanism of burn is incompatible with injury (e.g., exposure time, history of event, and degree of burn are inconsistent)
- Patient's per-event behavior displeasing to caregiver (e.g., inconsolable, failed to meet caregiver's expectations)
- Toileting events related to history of injury[19]
- Burn attributed to:
  - Child or patient, as per caregiver
  - Caregiver who is not present at the healthcare facility
  - Caregiver, as per patient
  - Delay in seeking medical treatment; note estimated time of delay

Developmental Associations

- Preverbal, nonverbal person
- Vulnerable person (e.g., special needs, failure to thrive, elderly)
- Caregiver expectations are inconsistent with patient's development; caregiver overestimates child's developmental skills and safety knowledge; caregiver unaware of patient's developmental capacity
- Patient has symptoms of mental disorder (e.g., ruminating, aggressive)
- Patient displays disturbing behaviors related to attachment (e.g., excessive crying, clinging, apathy/lethargy, excessively withdrawn, listless, unemotional, submissive, polite, fearful, vacant stare)
- Hypersexualized language or behavior as compared to same-age peers

Caregiver–Patient Relations

- History of interrupted caregiver–child bonding
- Adolescent caregiver(s) (e.g., child–child versus adult–child interactions)
- Strained interactions; inappropriate expectations of the patient by the caregiver
- Role reversal (rely on patient for support)
- Inappropriate or lack of caregiver concern:
  - Detached
  - Lack of sympathy
  - Lack of physical contact (e.g., fails to hold or pick up child)
  - Inebriated during visits
  - Infrequent visits

Other Physical Signs of Abuse or Neglect

- Unrelated injuries:
  - Fractures, dislocations; rupture to spleen, liver, or pancreas; point tenderness; impaired range of motion or function
  - Signs of poisoning
  - Ocular insult (edema, scleral hemorrhage, hyphema, bruise, blue sclera)
  - Swelling, bogginess, depressions, cephalohematomas palpable on head or increased intracranial pressure at fontanelle
  - Blood, infection, or foreign body in ear
  - Edema, bleeding, septal deviation of nose; foreign bodies in nose; cerebrospinal fluid rhinorrhea from nose
- Unrelated injuries involving the skin: hematomas, soft tissue swelling, lacerations, fingernail markings, scars, bruises (check behind ear), welts, rope burns, strangulation marks, bites, alopecia; note color, size, shape, and location of each (scalp most visible while shampooing)
- Abdominal tenderness, guarding, rebound tenderness, or bruises
- Cardiac instability, tachycardia, murmurs, flow murmurs secondary to anemia, or palpable rib fractures
- Dehydration or malnutrition; note weight, height, and head circumference
- Previous burns
- Unkempt (e.g., severe diaper rash, dirt under nails or in axillae, odoriferous, dirt on plantar surfaces of feet in cold weather)
- Inadequate or no immunization record
- Inadequate dental care (e.g., caries); trauma to lips, tongue, gums, frenula, palate, pharynx, or teeth
- Inadequate medical care
- Inappropriate dress
- Assess prior to invasive medical procedures
- Genital, urethral, vaginal, or anal bruising, bleeding
- Swollen, red vulva or perineum
- Foreign body in genital area
- Positive cultures for sexually transmitted diseases; if herpes develops, note whether lesions are on unburned body surface area, on genitals of type II
- Pregnant minor
- Recurrent urinary tract infections, streptococcal pharyngitis, abdominal pain

Family

- Caregiver abused or emotionally deprived during childhood
- Limited disciplinary practices (e.g., only uses physical punishment)

Continued

Box 62.2 Risk Factors for Abuse/Neglect by Burning—cont'd

- Lack of external supports; isolation
- Mental illness, substance abuse, criminal history
- Lack of financial self-sufficiency
- Poor employment history
- Dependent caregiver; unable to cope with daily responsibilities; unorganized
- Violent couples; impulsive, easily frustrated
- Previous Department of Protective and Regulatory Services involvement[20]
- Prior accidents to dependents
- Acute family stressors
- No primary caregiver

Box 62.3 Erroneous Beliefs of Abusers

Erroneous belief systems commonly contributing to the family system in which abuse occurs:[37]

- If my child cries, misbehaves, or does not do what I want, he or she does not love me and I am a bad parent
- My child should know what I want and want to do it
- My child should take care of me like I took care of my parents
- My spouse/lover should know what I want and meet all of my needs
- If I have to ask, it does not count
- You cannot trust anyone

resort to immature coping styles to deal with frustrations. Perpetrators resort to abuse as a result of complex behaviors derived from a dysfunctional family history, lack of education, desperation, and, at times, substance abuse. Children and elderly are usually dependent on the perpetrator; ironically, they are a source of stress and therefore become the victim of intentional injuries. Corporal punishment is "the use of physical force with the intention of causing a child to experience pain but not injury for the purpose of correction or control."[38] Some perpetrators will use this explanation as a form of justification for intentional injuries.[36] In young children learning toilet training, a hot bath to clean after a toileting accident is often a form of punishment. Usually the perpetrator's intent is to clean the child well, not to burn; however serious burns often occur. They often fail to seek appropriate and timely medical treatment for an injured child, not only because they fear punishment but also because of their learned helplessness and passivity. They discount the seriousness of the injury, as well as their ability to take care of the injury. "I didn't think it was that bad" is an explanation often given for delay in seeking treatment. By diminishing the significance, they relieve themselves of responsibility to act. When the perpetrator does take the child for help, the perpetrator commonly seeks first a relative or neighbor rather than a physician because perpetrators do not believe in their own ability to decide whether to seek medical treatment. Perpetrators are observed to interact inappropriately with their children because they are preoccupied with having their own needs met. A child who is hurt and demanding is unlikely to reward the perpetrator with feelings of comfort that the perpetrator seeks, and so the perpetrator withdraws from the child. If the child is quiet and compliant, the perpetrator may be observed to ignore the child and sit passively, watching television for long periods until some external force acts as a stimulus to motivate the adult into action.[36]

Indicators of Intentional Injuries

In approaching pediatric burn victims, indicators of possible inflicted burn injuries should be considered (Table 62.1). Patterns of scald burns are highly suggestive of inflicted injuries, and healthcare providers have a general agreement of these indicators (Box 62.2):[22]

a. In scald burns, it is implied that the absence of splash is suggestive of the victim being held down, although some children who jump into a hot tub of water may panic or freeze and not have splash burns. These scald burns have predominantly symmetric, clear upper margins. The burns usually involve lower extremities and the buttocks, without head and neck injuries (Fig. 62.2),[10] although Daria et al. 2004[23] describe six cases of submersion burns that involve the head and neck.
b. If there is uniformity of burn, consider that the patient was held still during the incident.
c. Symmetric bilateral burns (glove and stocking distribution) are highly suggestive of forcible immersion (Fig. 62.3B).
d. In submersion burns, there may be skin sparing secondary to joint flexion or the victim forcibly held against the receptacle. This gives an appearance of a "doughnut" or "halo sign."
e. In an Australian study authored by Heaton in 1989,[39] bilateral burns of extremities are between 2.4 and 4.8 times more common in inflicted burns.[22]
f. Accidental cigarette burns are superficial and ill defined. Yet inflicted wounds are superficial circular or ovoid macular wounds with distinct depigmented lesions and hyperpigmented edges.
g. Heated metal objects cause deeper burns (Fig. 62.3A).
h. Electric shock burns are revealed based on the size of the device and entrance and exit wounds. Areas will vary from full-thickness necrotic areas to superficial wounds that are erythematous. One cannot evaluate these lesions in isolation (Box 62.2). Review of medical records is necessary to assure the presence of a pattern of repeated abuse. Also be aware that perpetrators may frequent a variety of hospitals in the area to decrease suspicion by medical providers. Corroboration of history to physical exam is essential and may suggest indicators of intentional burns.

Table 62.1 Triage Tool for Diagnosis of Intentional Scalds

	Evaluate for Intentional Scald	Intentional Scald Should Be Considered	Intentional Scald Unlikely
Mechanism	Immersion		Spill injury; flowing water injury
Agent	Hot tap water		Non-tap water; other liquids (beverage)
Pattern	Clear upper limits; uniform depth scald symmetry (extremities)	Uniform scald depth; skin fold sparing; central sparing buttocks (doughnut ring pattern)	Irregular margin; irregular depth; lacks stocking distribution
Distribution	Isolated buttock/perineum, ± lower extremities; isolated lower extremities; rarely the face	Glove and stocking; 1 limb glove/stocking	Asymmetric involvement of lower limbs; head, neck, and trunk or face and upper body
Clinical features	Associated unrelated injury (recent or old fractures); history incompatible with examination findings	Previous burn injury; neglect/faltering growth; history inconsistent with assessed development	
Historical/social features	Passive, introverted, fearful child; previous abuse; domestic violence; numerous prior accidental injuries; sibling blamed for injury	Trigger, such as soiling/enuresis/ misbehavior; differing historical accounts; lack of parental concern; unrelated adult presenting child; child known to social services	

Adapted from Maquire S, Moynihan S, Mann M, et al. A systematic review of the features that indicate intentional scalds in children. *Burns* 2008;34(8):1072–1081.

Fig. 62.2 Newborns who were burned in hospitals by improperly trained hospital personnel.

Fig. 62.3 (A) Abuse: contact burn in which the markings of an iron are clearly visible. **(B)** Abuse: classic stocking pattern resulting from feet being immersed in very hot water. The initial history given by the mother of the 21-month-old infant was that an older sibling had turned on the hot water, and the patient herself dipped her feet into the tub.

Self-Inflicted Burn Injuries

One of the most violent means of suicide is self-immolation by burning. Self-immolation can also act as part of a deliberate self-harm syndrome consisting of continual, sudden urges toward self-harm.[21] There has been an increase in the literature on self-immolation, but it is unclear if this emphasis is a result of increased rates of occurrence or increased reporting.[13,41] Historically there is a debate as to whether self-immolations are more acceptable if they are religiously or politically motivated.[21,42–46] Characteristics of females who self-immolate include substance abuse, a lack of social support, younger age, and diagnosed eating disorders.[21] Males who self-immolate are also younger, with severe mental illness,[21] or pathological family dynamics, or possibly an adherence to fundamentalist religious convictions.[13] Regardless of sex, self-inflicted burn patients usually have some previous psychiatric problems, often depression or borderline personality disorder; previous failed suicide attempts with a poor response by others to suicidal ideation; and recent life stressors with feelings of helplessness.[21] One of the highest rates of this behavior is in Iran among young females in whom marital conflict is a significant risk factor. Others risk factors include low literacy, low socioeconomic status, limited access to mental health services, and posttraumatic stress disorder.[13]

Although self-inflicted burn injuries are less frequent in Western culture, studies report a rate of 0.5–2% in adolescents and up to 25% in adults.[21,47,48,46,49–54] In Africa, south Asia, and the Middle East self-inflicted burn injury rates account for up to 28% of all burn injuries.[55] There is an estimated range of self-immolation accounting for 9–32% of all suicides in India, Zimbabwe, and Iran,[21,56–58] with rates for Iranian and Brazilian women being as high as 46% of suicides.[21,59,60] Some studies have found that there are no gender differences in the rates of self-immolation,[61,62] but some have determined that it is most common in females,[63–65] specifically Asian and Latin females,[47,55,66,67] whereas others have found that it is more common in males.[49,68] Other risk factors for self-immolation in Western culture include previous psychiatric treatment, diagnosis of a psychotic disorder,[61,63,69,70] unemployment,[61,69,68] or severe relationship difficulties.[61]

The most common mechanism of self-immolation is flame as a result of fire accelerant such as kerosene, gasoline, or rubbing alcohol.[13,70] In a 2004 Finnish study, 43% of all patients used flame, but 93% of women with self-inflicted burn injuries used flame.[70] The reported mean TBSA among self-inflicted burn injuries is higher (median 42.2%; range, 22–79%) than other burn patients (median 36%; range, 11.8–77%). These burn injuries are usually deeper full-thickness burns with increased risk of inhalation injury, poorer long-term prognosis, and a higher rate of mortality.[21,49,58,59,63,64,66] Self-immolations are 1.5–1.7 times more frequent than reflected in current literature. This is an area where more studies are needed to identify more accurate prevalence rates and prevention interventions.

Clinical Evaluation of Suspicious Injury With Pediatric Patient and Family

The history of the burned child is of particular importance in assessing whether the burn is likely to be intentional or accidental. Evaluating for intentional burn injuries requires a multidisciplinary team effort (Box 62.4).

Box 62.4 Documentation for Reporting

In addition to the documentation of first-hand observations, the following tasks should be delegated:

- Examine the patient for other signs of maltreatment, including a skull and long-bone radiological scan. Clearly state that the radiology consultation is for assessment of occult trauma
- Photograph injuries and any possible evidence
- If the patient has been referred from another hospital, access information from the staff at that hospital to determine whether they identified suspicious aspects of the injury and whether the injury was reported to an investigating agency. If so, ascertain the number assigned to the patient's case by the investigating agency. This number is needed for subsequent calls related to the patient
- Interview the patient
- Interview the family members or caretakers individually and together for thorough histories of the event, being sensitive to differences in the story or changes across time
- Obtain a thorough family history, the patient's medical history, and the developmental capacity of the patient
- Gather other available collateral information (e.g., medical records from other places of treatment)

Created by Patricia Blakeney PhD and Rhonda Robert PhD, 2007.

PHYSICIAN ASSESSMENT

The physician–patient relationship is paramount in assessing patient injuries and providing an accurate assessment of an incident to determine if suspicious injuries are intentional or nonintentional. Obtaining a detailed history from the patient and the caretaker is foremost in assessing the creditability or plausibility of history to what is seen on physical exam (Box 62.2). It is essential that providers are familiar with child development in order to incorporate child development into the assessment process. Trust issues may interfere in obtaining a precise history. The assessment always requires an open mind for the possibility of intentional injury, which should be thoroughly investigated when clinical features are present in the history and examination. Features of the physical exam consist of identifying the pattern of burn injury, with the distribution and associated features being the more important aspects to distinguish. The reported method of injury must be clearly associated with the observed pattern of injury, burn depth, and appearance on physical examination (Box 62.2).[71] Children who are burned are also in a high-risk group of being subjected to other forms of abuse. Although a few studies have indicated that pediatric burn patients are at a lower risk for related fractures from abuse, approximately 18.6% of children in this subgroup had fractures on their skeletal survey.[72,73] Another study found that pediatric burns have a 14% risk of fractures.[24] This rate may be underestimated since all patients did not receive a skeletal survey. These fractures are occult and may not have physical evidence of their existence. Further evidence has also revealed that children with burns are less likely to be evaluated for fractures, reflecting the erroneous belief that they are a lower-risk group. All children 2 years and under should receive a skeletal survey on initial exam to denote concomitant new or old fractures.[72,73] The clinician must also be mindful at this time to assess for signs of abusive head trauma such as intracranial and retinal hemorrhage.[71]

A child who presents with suspected unintentional and intentional burn injury should be evaluated by a child abuse pediatrician or a pediatrician with experience in the evaluation of the causes and mechanism of burn injury. However such an evaluation should be done when the child is medically stable.[74]

The evaluation of burn injury should begin with a thorough history, which should be taken directly from a child who is verbal or developmentally matured enough to give the history and also from parents and caregivers who were present at and around the time of the injury. The history of the injury and the sequence of events should be as detailed and concise as possible.[75]

The developmental ability of the child, as well as home and social environmental factors, should also be taken into account.

The patient's past and current medical histories are also important factors to be considered. Additional specific questions should be asked depending on the type of burn injury. Ask about the temperature of the hot water setting at home in cases of scald burns and the duration of contact in cases of contact and scald burns.

The next step in the medical evaluation will be a complete physical examination. The physical exam should include a good assessment of the general presentation of the child, looking for signs of adequate nourishment, emotional status and general well-being, and hygiene.

If possible, a developmental assessment should be done, although in severe burns it is quite difficult to assess development, and the medical history should be relied on or the developmental assessment done later. All organ systems should be evaluated to look for bruises, fractures, head injury, and other signs of trauma.

The burn injury should then be specifically evaluated, looking at patterns, line of demarcation, distribution, planes of the body involved, size, and symmetry. Every injury should be well-documented, and photo documentation should be done ideally at the time the child is admitted or as soon as the child is stable.

After the child has been assessed other testing may be important. The American Academy of Pediatrics recommends that children younger than 2 years who present with concerns for physical abuse should have a skeletal survey. For children between 2 and 5 years of age, a skeletal survey may be done depending on the history and examination; however a skeletal survey is not indicated after 5 years of age.[76,79]

Skeletal surveys are important to diagnose subtle fractures such as classical metaphyseal lesion fractures and rib fractures that have a high specificity for abuse. Because such fractures can be subtle and may not be obvious in the first skeletal survey, a repeat skeletal survey needs to be done 10–14 days later to look for callus formation.[76,77]

Recent research shows that the incidence of fractures in children with inflicted burns is about 33% compared to those with accidental burns,[80] although some have reported the incidence of fractures in nonaccidental burns to be as high as 53% in children younger than 24 months.[77]

After the history, physical examination, lab and radiological investigations, and sometimes scene investigations have been done, the medical expert should then make an assessment of the injuries to determine if the history explains the mechanism and is consistent with the burn injury. The assessment should be made with no biased principles, and the physician or medical health professional should be focused on his or her role, which is mainly the care and protection of the child. It is not the role of medical personnel to find who may have caused the burn injury or to pass judgment on caregivers or the alleged perpetrators.[81]

Types of Burn

SCALD

Scald burn is the most common form of nonaccidental burn injury. The typical child who has sustained a nonaccidental burn injury has a history of being potty trained at around 2 years of age.[75,84] The burn mechanism is normally an immersion in hot water. These children present with a burn of uniform depth, with well-demarcated borders and an absence of the splash or splatter common with accidental burns. Nonaccidental burns often show bilateral symmetry and in most cases such burns also spare the flexors[83] (Fig. 62.4).

CONTACT

Contact burns are the second most common form of abusive burns.[84] Nonaccidental contact burns normally have very defined distinct borders. They could also assume the pattern of the instrument that may have been used to cause the burn.[86]

In nonaccidental cigarette burns, the burns are normally in clusters with ovoid to circular shape and with a circumference of 5–10 mm.[87] Reported mechanisms of contact burns include curling irons and steam irons.[86] Such burns normally leave the distinct pattern of the object used to cause the burn.

Fig. 62.4 Bilateral symmetry shown in non-accidental burns and in most cases such burns also spare the flexors.

Fig. 62.4, cont'd

CHEMICAL BURNS

These burns can be caused by alkali-based, acid-based, inorganic, and organic agents. It is important to discover the injury-causing agent so as to prevent further damage. Alkali burn injuries may seem innocuous at first but may produce deeper tissue injury and could produce further damage even after removal of the immediate cause of the burn.[85] Alkali burns may not be painful compared to acid burns, which produce painful deep ulcers. Chemical burn injury could be either from supervisory neglect or from an inflicted intentional injury.

Psychosocial Assessment

Multidisciplinary work is essential for appropriate management of children or adult burn/abuse victims. Psychologists are critical in the initial evaluation and to assist in interviewing, and social workers are advocates for referral and follow-up care. Both are skilled at assessing family dynamics and social situations in greater detail and should be your focal point for referral to appropriate government agencies. Psychosocial assessment and interview with the patient separately (when possible) from the caretaker will provide a more accurate picture of the injury events. Inconsistency is a marker of discrepancies in the history, which may alert an examiner to possible abuse. The patient and caretaker must have a detailed interview documented verbatim by the historian. Paraphrasing information increases the likelihood of personal interpretation of history. The presence of witnesses and the exact timing of events must be confirmed, and these persons must be interviewed to assess for correlation in narratives.[74] A thorough event reconstruction soon after admission should be conducted and documented. This limits the room the suspect has to alter the events and timeline related to the burn or the opportunity to collude with witnesses.[3] The pattern of circumstances is extremely important, with suspicions raised when the adult responsible claims not to have seen the incident, attributes the injury to a sibling, or presents late, or when relatives other than the adult supervising at the time of the burn bring the child for assessment.[21] The clinician conducting the interview must be well versed in child development to ascertain normal developmental responses to those that are suspicious of abuse. Observations of interactions and behavior are equally as important as the specific questions that are asked during the interview process.

Abused children often are under the age of 2, making them vulnerable to their caregivers. Other characteristics include inconsolable crying, difficulty in toilet training or associated toilet training accidents, insufficient or strained parent–child attachment, and inappropriate behavior such as apathy or apparent tolerance to invasive procedures. Severely abused children will demonstrate exaggerated responses by either being overly fearful or overly affectionate with the medical team. When requested to provide immunization records parents or caregivers suspicious of abuse will often fail to provide or will avoid providing accurate medical records and records of immunizations (Box 62.4).[3]

The interview with the child is an essential component to determining if the injury was intentional. The rapport that is established through a therapeutic relationship is the key factor to a successful interview. Warm-up questions or nonthreatening questions should be asked first to establish rapport: Ask "when is your birthday?"; ask questions about school or friends, or ask the child to verbalize a story of his or her best day. Once sufficient rapport is established, asking open-ended questions about the injury is most effective (i.e., "What happened? How did you get hurt?").[36] The child should be encouraged to tell the story freely. Specific questions for clarification should be asked only after the child has told the story. If the child seems unwilling to talk about what happened, the interviewer can suggest the child raise a hand or wiggle a finger to signal that they know something but do not yet want to talk about it. When interviewing younger children, short sessions with breaks will allow rapport-building and trust to develop so that child feels safe sharing his or her story.[36]

The suspicious injury assessment should be discussed confidentially with family members, including the suspected perpetrator.[36] Perpetrators should be allowed time to process their concerns in a nonjudgmental and therapeutic manner. The family should remain informed of the process and potential CPS interventions. It is important to share with families an understanding that often CPS is seen as a punitive agency but essentially the main goal is the safety and protection of all children. Sharing information will initiate a therapeutic relationship. Most perpetrators are reluctant to trust medical teams, especially when they feel as if they are being judged. Being honest about the process and the information shared with CPS minimizes mistrust. As stated previously, perpetrators often have limited emotional support. When an intentional burn injury occurs, psychologists are an essential component to providing the initial support and addressing the fears, sadness, and helplessness those perpetrators may feel. Regular psychotherapy sessions are critical to making a positive change in family dynamics.

Reporting Suspected Intentional Burn Injury

In 1967, state legislatures in every state had laws mandating that any reasonable suspicion of intentional injury be reported to the appropriate authorities.[36] In 1974, the Federal Child Abuse Prevention and Treatment Act was passed. These laws require professionals to report suspected intentional injuries to a child when there is sufficient information that would lead a "competent professional to believe maltreatment is reasonably likely."[36] It is important to be knowledgeable of not only state laws but also of local governing agencies' policies on reporting suspicious injuries. Most hospitals have risk management or legal teams that are well versed in the federal and state laws as well as in the policies, rules, and regulations of the hospital. Methods of communications regarding intentional injuries should be clearly outlined and reviewed prior to sharing any information regarding intentional injuries.

Providers who suspect abuse should report to the appropriate agency as designated by the state in which they

practice. As you interview, note the interaction between caregiver and patient. Providers should document inappropriate concerns, lack of sympathy, detachment, delay in seeking care, or use of drugs or alcohol (Box 62.2). If you suspect that inconsistency exists, without being confrontational, alert the caregiver and give him or her the opportunity to give a more truthful history. Detailed documentation of history and physical exam may be used in litigation charges and should be clear, concise, and accurate. It is imperative for clinicians responsible for reporting suspected abuse to be as accurate as possible because there are significant consequences for inaccurate assessment and diagnosis of suspected abuse. Some 50% of children who sustain intentional injuries have recurrent injuries that are eventually fatal.[3]

Ultimately it is not the hospital or any of the medical staff's obligation to prove that a suspicious injury was intentional. It is important to report the suspicion, ensure continuity of care, and cooperate with the legal process.[3] While the child is receiving medical treatment, it is imperative to keep accurate records and document all treatment and interactions among family members. The prosecuting attorney is responsible for proving intentional injuries; however medical records are often a key element. Physician reporting and cooperation are invaluable to legal prosecution. The physician's opinion on likelihood of intentional injury strongly influences CPS workers and prosecutors.[3] Salient to remember with intentional injury cases is that most attorneys have limited to no experience with burn injuries, and the expertise of medical investigators, burn psychologists, and social workers is the foundation for proving allegations and protecting the child from future injuries.

There are no federal programs to specifically address the reporting of suspected abuse in adults. All states have individual laws, reporting guidelines, and penalties for adult abuse. It is best practice to be aware of your state laws if you work with adults, but, if unsure, following the same guidelines as for children until the exact information can be obtained is acceptable. Most states have a statewide intake office that can be located online, and most states have online reporting. The National Center on Elder Abuse provides information and assistance on elder abuse, including a listing of state elder abuse hotlines. Child Help USA is a private charity that established and maintains the National Child Abuse Hotline (800)-4-A-CHILD (800-422-4453) and provides a listing of statewide reporting numbers at their website (http://www.childhelpusa.org/report). Telecommunications Device for the Deaf number is (800)-2-A-CHILD. The U.S. Department of Health and Human Services Administration for Children and Families provides a listing of statewide reporting phone numbers at their website (http://nccanch.acf.hhs.gov/topics/reporting/report.Cfm).

Clinical Interviewing With Other Vulnerable Populations

When interviewing vulnerable patients, it is important to provide a safe and confidential environment that is nonconfrontational and nonjudgmental. Developing rapport and trust is an essential component of the interview process. The older adult is likely to be dependent on the abuser in matters of daily living. Often the perpetrator is a family member or loved one. Whether the patient is able to express his emotions or not, he will likely experience fear, worry, shame, and a desire to protect the perpetrator. The therapeutic relationship developed will allow the patient to trust that the medical team will work in his best interest as well as the best interest of the perpetrator.

Maintaining Professional Relationships With Patient and Family

When approaching a child/adult who is an abuse victim, the provider must maintain professionalism and self-control and remain nonaccusatory. Clinicians within the healthcare profession are natural protectors of children with the desire to automatically align with the child. Addressing one's own feelings is vital to providing the best care for the patient. Establishing a therapeutic relationship with the family may be difficult, but it is imperative because many of these children are reunited with their family at discharge or at some point during outpatient burn care.

Future Burn Prevention and Child Safety

Burns and scalds are a significant cause of morbidity and mortality in children. Some studies have shown successful countermeasures to prevent burn- and scald-related injuries.[75] To prevent accidental burns, the American Burn Association Scald Injury Prevention Educator's Guide has published steps by which physicians can instruct their patients to assist in burn and scald prevention. Hot food and beverage scalds are the most common causes of scald injuries in both children and adults. Providing a safe cooking area and a supervised environment is foremost in prevention. Suggested examples are: do not carry hot liquids when carrying your child; place children in a playpen or high chair away from the stove; do not use child walkers; cook on back burners and remember to turn the pot handles to the inside; keep appliance cords coiled and out of reach from the counter; when removing lids, do not forget that steam can burn the face or arms; wear tight-fitting clothing or short sleeves when cooking; and, for those with mobility impairment, use a sturdy, large lap tray to carry hot liquids. Microwave scald burns have risen significantly since the 1980s.[16] Proper placement of the appliance, where the face is higher than the door of the microwave, is recommended. Children under 7 years of age should never operate this appliance. Never heat baby formula in the microwave due to unevenness of heating. Always allow microwave-cooked items to sit for 1 minute prior to opening. Prevent tap water scalds by setting hot water heaters below 120°F (Table 62.2). The American Burn Association reminds us that "Adequate and constant supervision is the single most important factor in preventing tap water scalds." Other tips

Table 62.2 Exposure Time to Receive a Severe Burn in Hot Water; Time and Temperature Relationship

Water Temperature		Time for a Third-Degree Burn to Occur
155°F	68°C	1 s
148°F	64°C	2 s
140°F	60°C	5 s
133°F	56°C	15 s
127°F	52°C	1 min
124°F	51°C	3 min
120°F	48°C	5 min
100°F	37°C	Safe temperature for bathing

Note: Downward adjustments to time needed for young children.

include placing a single-faucet handle always in the cold water position and avoiding sudden fluctuations in water temperature (e.g., flushing the toilet while showering). The CDC has free material that can be downloaded from the web (/safechild/FactSheets/Burns-Fact-Sheet-a.pdf).

Prevention of nonaccidental burn injuries is more difficult. Further research and education of physicians and maltreatment teams are imperative. Since the establishment of the National Burn Repository (NBR) by the American Burn Association, a Burn Registry was established to create a national database. Physicians need to recognize suspicious burns and document exam and history in detail. Further research will assist in identifying clearer indications and patterns to determine intentional injuries.

63 Functional Sequelae and Disability Assessment

KAREL D. CAPEK, BYRON D. HUGHES, and GLENN D. WARDEN

Introduction

Advances in acute burn care during the past 25 years in terms of decreased mortality and decreased length of hospital stay have been truly remarkable. Current and historical perspectives on burn mortality can be found in preceding chapters. In almost every burn unit in the United States, the length of stay has decreased from nearly 3 days/% burn to less than 1 day/% burn. The success can be stated simply: patients with larger, more severe burns are surviving.

But if patients with larger and more severe burns are surviving, this has created new problems for patients' quality of life. Although the problems are magnified in massively burned patients, they exist also in smaller burns. These problems are demonstrated in a pediatric burn patient with a 95% total body surface area (TBSA) burn (Fig. 63.1). Cultured keratinocytes were utilized to achieve wound coverage. The child survived; however, when we examined the patient's current and future reconstructive needs, they totaled 33 potential reconstructive procedures. Thus the reconstructive problems are monumental in a child with very few donor sites. With regard to survival, the results of this patient are impressive; however, we must ask the question: "Has the medical expertise in terms of survival progressed past the ability to reconstruct and rehabilitate patients?" Unfortunately the answer is clearly "yes." Are we returning our patients to a society that is not ready financially, psychologically, or socially to accept them? Again, unfortunately, the answer is clearly "yes."[1]

Under Titles II and XVI of the Social Security Act, adult disability is defined as "the inability to engage in any substantial gainful activity, by reason of any medically determinable physical or mental impairment(s) which can be expected to result in death or which has or can be expected to last for a continuous period of not less than 12 months." For children, the definition differs slightly, "a child under the age of 18 will be considered disabled if she or he has a medically determinable physical, mental, or combination of impairments that causes marked and severe functional limitations and that can be expected to cause death or last for a continuous period of not less than 12 months." These guiding principles of functional assessment require a further definition. "Medically determinable impairment" means that the impairment(s) can be demonstrated, witnessed, or otherwise known and described by some third-party means.[2] These may include laboratory tests, physical examination demonstrating signs of the underlying disease process, and disease-specific historical information elicited during the interview. When impairment results from two or more systems, the ratings should be combined according to a combined values chart or its underlying formula. Using the American Medical Association (AMA) formula, the first diagnosis-based impairment is subtracted from a 100% whole person, and each subsequent impairment is subtracted as a percentage of the remaining, or fractional, unimpaired person.[3] Disability ratings can only be performed after a patient has reached maximal medical improvement. This concept is unfortunately both subjective and undefined but retains its utility when applied with equal measures of common sense and medical judgment.

Postburn System-Based Disability Assessment

Description of an alleged impairment should begin before physician introduction. Careful observation of general appearance: how an individual is groomed, enters the building, comports himself while waiting, interacts with clinical staff during check-in, and completes initial paperwork all provide useful, global insight into how his life has been impacted by burn injury and how he has adapted to it. A whole person's impairment depends on disruption of organ system function. For each system, impairment is categorized into five classes: 0 (no impairment), 1 (minimal), 2 (moderate), 3 (severe), and 4 (very severe). Generally, these correspond to function and symptoms, where 0 is no symptoms despite strenuous activity, 1 is symptoms only with strenuous activity, 2 is symptoms with normal activity, 3 is symptoms with minimal activity, and 4 is unabated symptoms. In cases where an objective measure is widely accepted to correlate with experiential symptoms, this objective measure becomes the key factor (e.g., see the section on respiratory function, which uses the results of pulmonary function tests as a key factor).

This classification allows assignment from no impairment to complete impairment of the system being evaluated, which can be expressed as a percentage of whole-person impairment. Within each diagnosis-based impairment class, impairment can be modified up or down based on additional clinical information or supplementary diagnostic tests. These vary somewhat for each condition (for full details please refer to the individual chapters in the most recent edition of the AMA's *Guides to the Evaluation of Permanent Impairment*). The assessment of typical postburn sequelae is described in the following sections.

CONSTITUTIONAL

Body mass, composition, and growth curves in children provide important objective data regarding the overall magnitude of the postburn systemic insult. The weight trend,

Fig. 63.1 A pediatric burn patient with a 95% total body surface area burn.

particularly compared with a preinjury weight, is helpful in estimating the loss of lean body mass, although confounding by body compositional changes does occur. In general, loss of 10–30% of body mass correlates with increasingly severe manifestations of malnutrition and catabolism, namely impaired wound healing, pressure sores, and pneumonia. Losses approaching 40% of preinjury body mass (in survivors seen for disability assessment) indicate a near-fatal systemic insult of malnutrition combined with postinjury hypermetabolism.

While the gold standard of body compositional analysis is potassium-40 scintillation counting coupled with deuterium oxide dilution measurement of total body water,[4] whole-body dual energy X-ray absorptiometry (DEXA) provides a useful and more readily available surrogate. Whole-body DEXA scans provide bone density measurements of the axial and appendicular skeleton, as well as assessment of peripheral and visceral fat mass, bone mass, and extremity/central lean mass.[5] Bone metabolism[6–10] is markedly disturbed after severe burn injury; accordingly growth arrest is seen in growing (prepubertal) children.[11] This is attributable to stalled endochondral bone formation. Patients are also prone to fracture from trivial trauma such as ground-level falls, and fracture healing is slowed.

SKIN/INTEGUMENT

As the organ most visibly affected by burn injury, photodocumentation of affected areas can provide efficient insight into the magnitude of the injury and the status of the healing process. Scars from healed burn wounds or skin grafts and donor site morbidity are described by TBSA and location. It is also important to note associated venous congestion, tissue edema, chronic wounds, pain, itch, tissue disfigurement, and distortion of adjacent unburned mobile structures (nipple, umbilicus, and/or genitalia) by burn scar contraction. Large burns (>20% TBSA) can result in homeostatic impairment of the skin. Manifestations may include subjective heat intolerance, impaired thermoregulation, and loss of sweat function in the scars, or cold intolerance owing to loss of adipose tissue insulation. The latter is of particular concern after deep or infected burns with fascial excision or other significant adipose tissue débridement in the course of burn care. While a goal of burn care is rapid, durable wound closure, chronic wounds still occur after burn injury. If present, these should be described including size, depth, location, exudate/odor, and status of the healing process/granulation tissue. Previously applied wound therapies should be described. If a wound has been present beyond 3 months, a more detailed assessment of the reasons for failure of healing is warranted (including malnutrition, pressure, infection/colonization, osteomyelitis, loss of sensation, tension, and lack of blood flow). This assessment may include a search for neoplasia (Marjolin's ulcer) and related examination of the draining lymph nodes because nonbasal cell skin cancer (not in remission) is assigned 58% whole-person impairment.[12] The claimant's history is the key factor in classifying nonfacial skin/scar-related impairment, focusing on the impact of the skin-related conditions on an individual's ability to perform activities of daily living. Whole-person impairment resulting from nonface skin disorders can range from 0% to 58%.[12]

FACIAL INJURIES, SCARS, AND EAR/NOSE/THROAT PROBLEMS

Burn scars involving the face can be a significant cause of impairment. Beyond aesthetics, these may include cicatricial microstomia (causing weight loss and malnutrition), loss of facial expression, and nasal deformity/tissue loss with associated airway dysfunction and loss of humidification. Air passage deficits, including nasal injuries and vocal cord paralysis, are rated from 0% to 58% whole-person impairment based on the key factor of degree of dyspnea and interference with daily or work activities.[13] Voice and speech impairment is rated at 0–35% of the whole person, based on the key factors of speech audibility, intelligibility, and functional efficiency of speech in everyday communication.[13] Ear loss, in addition to the aesthetic deficit, can compromise sound localization/lateralization and make it difficult to wear glasses or similar headgear that rests on the ears. Auditory function may be compromised in several ways following burn injury. Significant blast injuries are associated with tympanic membrane (TM) rupture. Middle ear infection, often with TM perforation, may complicate convalescence from severe burns; multidrug-resistant organisms are usually observed, and clearance can require prolonged treatment. Resulting TM scarring may reduce auditory acuity. Several ototoxic medications (especially aminoglycosides and furosemide) are routinely used during critical care of the severely burned patient. The key factor for hearing evaluation is decibel threshold sum audiometry using 500, 1000, 2000, and 3000 Hertz sounds. Whole-person impairment from binaural hearing loss ranges from 0% to 35%, with the latter value reflecting complete hearing

loss.[13] Facial disfigurement is rated separately from overall skin assessment, and the key factor determining classification is the degree of facial anatomical distortion, loss of expression/facial features, and the degree of difficulty experienced by the patient in social settings due to facial disfigurement. Whole-person impairment resulting from facial scars/disfigurement can range from 0% to 45%.

MUSCULOSKELETAL

Burn-related amputations are not infrequent, especially in the setting of electrical injury. If an amputation is present, the requisite description is straightforward, including the level of the amputation, the condition of the stump (note if chronic wound present), any prosthetic used, how well it works for the patient, and specific (work and home) activities that are difficult or require adaptation due to the amputation.

The main cause of musculoskeletal impairment after burn injury is scar contracture across joints. In the acutely injured state, patients typically assume a "position of comfort." Contraction of the burned joint may reduce the area of the wound to heal but at the cost of losing range of motion with scar formation. The use of splinting, exercise, and release with tissue interposition have all been shown to mitigate this problem, but rarely is function completely restored to the preburn state. In describing scar contractures, particularly involving joints, one may note that the resting position is often abnormal. Range of motion, strength, associated chronic wounds or ulcers, and pain/tightness at the scar also provide helpful medical evidence of impairment. The description of specific daily living or work activities that the patient finds difficult due to specific scars/contractures is needed to communicate the experiential severity of impairment.

Prolonged immobilization and excessive use of static splints may also lead to joint fibrosis and impaired range of motion. Heterotopic ossification, generally occurring in patients with burns greater than 30% TBSA, can cause near complete loss of joint mobility.[14] When it occurs, the joint becomes immobilized in the position in which it was maintained. It causes significant pain, and the lost range of motion is generally refractory to surgical intervention and rehabilitation. For example, at the elbow, the ulnar nerve at the cubital tunnel can be affected.

Muscular conditions of systemic import may accompany burn convalescence. Sarcopenia is increasingly diagnosed after critical illness, sepsis, and prolonged immobilization.[15] Rhabdomyolysis and compartment syndromes may lead to the rapid loss of mass of involved muscles. Especially common after electrical injury, these may exacerbate the muscle wasting and skeletal muscle protein catabolism due to the burn injury proper. Loss of lean muscle mass leads to decreased strength and endurance and can contribute to metabolic derangements including altered glucose homeostasis and decreased insulin sensitivity. Muscle bulk can be assessed by the examiner and extremity circumference measurements reported if they appear grossly abnormal. Ultrasound is increasingly utilized to quantitate the degree of sarcopenia (e.g., midfemur vastus lateralis thickness), but its role in routine disability assessment is not yet widely established.[16–19] The key factor for musculoskeletal impairment classification is the diagnosis itself, supplemented with the "functional history," and comprises the extent to which the diagnosis-defined problem interferes with vigorous activity, work, daily living, and basic functioning. It also considers the extent to which another person is required to accomplish these tasks. Because of the complexity in rating nonamputation impairments of the extremities, the reader is advised to obtain and refer to the most recent edition of the *Guides to the Evaluation of Permanent Impairment.*[20]

HAND FUNCTION

Hand function is both uniquely important to daily and work activities and frequently impaired by burn injury and scars. Loss or deformity of digits leads to a variety of deficits. Complete loss (amputation) results in the following impairment ratings:

- Ring/small finger: 10% of hand, 9% of upper extremity, and 5% whole-person impairment
- Index/middle finger: 20% of hand, 18% of upper extremity, and 11% whole-person impairment
- Thumb: 40% of hand, 36% of upper extremity, and 22% whole-person impairment
- Hand: 90% of upper extremity and 54% whole-person impairment
- Entire upper extremity: 60% whole-person impairment.[20]

Flexion contracture or boutonniere deformity digit(s) leads to impairment in dexterous movements, and extension contracture compromises grip strength and carrying tasks. Scoring is more complex for partial losses and functional impairments but may not exceed the impairment rating for amputation.[20] Due to the hand's complex tissues and their response to splinting, immobilization, and vasoactive medications it is not uncommon for muscle, tendon, and bone/joint involvement to be demonstrable in addition to the obvious skin/soft tissue cicatrization.

In the lower extremity, amputation results in the following impairment ratings:

- Lesser toe: 3% of foot/ankle, 2% of lower extremity, and 1% whole-person impairment
- Great toe: 17% of foot/ankle, 12% of lower extremity, and 5% whole-person impairment
- Foot/ankle: 70% of lower extremity, and 28% whole-person impairment
- Entire lower extremity: 40% whole-person impairment.

For nonamputation impairment at the upper and lower extremities, if none of the diagnosis-based grids reflects the patient's impairment (as is often the case with significant musculoskeletal compromise after burn injury), then impairment can be rated according to range of motion testing. A comprehensive description of this process is beyond the scope of this chapter, but can be found in Rondinelli et al.[21]

An assessment of gait and balance (i.e., heel/toe, tandem gait, and Romberg tests) provides insight into the coordinated function of the nervous and musculoskeletal systems. Impairment of the ability to respond quickly to changing conditions (general weakness, loss of balance, or

unsteadiness) can impair the ability to safely function in physically demanding occupations. Exertional tolerance, although subjectively reported, can be assessed by asking how far the patient can walk without resting or how many flights of stairs can be climbed without stopping. The reason for exertion limitation (e.g., shortness of breath, musculoskeletal cramps, general weakness, joint pain, chest pain, back discomfort, or other) often provides important insight into the dominant underlying disease state.

NEUROLOGICAL

Both focal and global nervous system problems are possible after burn injuries. Traumatic brain or spinal injury may be seen in high-energy automobile crashes, blast injuries, and escape-related injuries. Burns sustained in closed-space fires are frequently accompanied by the inhalation of a cocktail of toxins and combustion byproducts. These cause inhalation injury (discussed later) but carbon monoxide, cyanide, and other metabolic poisons may also cause global hypoxic insults (classically the hippocampi are most vulnerable to hypoxia, with impairment in learning and memory). Cerebral edema often accompanies carbon monoxide poisoning or hypoxic insult, and herniation syndromes may lead to neurological devastation. Cardiac arrest may also accompany severe burn injury (usually hypovolemic) with hallmark cerebral watershed infarcts between the distributions of the anterior, middle, and posterior cerebral arteries. Hypoxic and ischemic insults may lead to alterations in consciousness and awareness. Impairment is rated 0–100% of the whole person, with continuous impairments (e.g., nonepilepsy) rated higher, from 31% to 100% of the whole person.[22] Alternatively, if consciousness and awareness remain intact, alterations in mental status, cognition, and highest integrative function may be present after traumatic injury or severe central nervous system (CNS) insult. Resulting impairment is rated from 0% to 50% of the whole person, based on mental status exam and interference with activities of daily living, occasionally supplemented with neuropsychiatric testing. Individuals who have suffered an electrical injury may develop a condition characterized by progressive degeneration of fine and gross motor coordination. Resultant complications can range from inability to perform work-related tasks safely to an inability to perform the routine activities of daily living. It is a disease process that takes place over a significant period of time and may worsen after an individual has returned to work. It can be particularly vexing to differentiate this entity from the malingerer, and the objective neurological exam findings must be cataloged in each case. A polyneuropathy of critical illness is also described and should be considered when prolonged ICU care was needed for recovery. A prolonged systemic inflammatory response syndrome, hyperglycemia, corticosteroids (which are endogenously elevated for >12 months after burn injuries), and the use of neuromuscular blocking agents (paralytics) have variously been implicated in its pathogenesis.

Focal peripheral nerve lesions are also possible owing to postburn compartment syndromes. In the upper extremity the ulnar nerve is particularly vulnerable within Guyon's canal and at the cubital tunnel, while the median nerve is vulnerable at the carpal tunnel. If a compartment syndrome is present for 4–6 h without adequate release, irreversible nerve damage may occur anywhere within the affected compartment(s). Fortunately the dire sequelae of contracture and complete defunctionalization of the upper extremity described by Volkman are infrequently encountered owing to rapid escharotomy and fasciotomy of impending compartment syndromes as a routine part of burn center care.[23] The rating of impairment owing to peripheral nerve lesions is based grossly on sensory and motor findings, and the reader is advised to refer to the latest edition of the *Guides to the Evaluation of Permanent Impairment* for both the upper and lower extremities.[20,24]

Characterization of gait, station, balance, sudomotor function, strength, deep tendon reflexes, and sensation (including as needed pain/temperature, light touch/two-point discrimination, and vibratory/joint position sense) deficits should be done; a detailed neuro exam may be supplemented with electromyography or nerve conduction studies if needed.

CARDIOVASCULAR/METABOLIC

Postburn hypermetabolism has been well described in multiple preceding chapters. Impairment may result from decreased exercise capacity (VO_2 peak), in turn related to increased basal energy expenditure. Tachycardia and elevated resting energy expenditure frequently persist for more than 12 months after major burn injury. Although pharmacologic treatment may ameliorate aspects of postburn hypermetabolism, restoration of preinjury metabolism occurs slowly and often incompletely. The stress of major burn injury (and frequently sepsis) may also cause cardiac dysfunction.[25] Significantly elevated catecholamine levels and a chronic high-output state contribute to myocardial remodeling; a depressed ejection fraction, myocardial fibrosis, and diastolic dysfunction are increasingly appreciated via echo in survivors of major burn injuries. Objective evidence of the magnitude of a burn survivor's cardiovascular and metabolic derangement are given by pulse, resting respiratory rate (and depth of respiration), blood pressure, jugular venous pressure/waveform as assessed vertically from the sternal angle, presence of hepatojugular reflux, and precordial palpation. Resulting impairment is classified using the New York Heart Association (NYHA) Functional Classification of Cardiac Disease. Whole-person impairments range from 0% to 65%, and objective testing, such as echo (ejection fraction and diastolic dysfunction based on left atrial E-A waves) and exercise testing (VO_2 max or METS), are used as the key factors. The exercise test results are categorized corresponding to NYHA functional classes, which provide an objective measure of functional status.[26]

RESPIRATORY

Burns that occur in an enclosed space, such as a building structure, often result in some form of inhalation injury to the respiratory system. Impairment may be limited to a temporary need for ventilator support or extend to permanent respiratory disease. Chronic and recurrent respiratory infections and pulmonary insufficiency may limit an individual's ability to perform his or her previous work,

especially when toxic chemicals or dust are present in the workplace. Exposure to irritating gases can also worsen preexisting asthma or result in irritant-induced asthma. Although this form of reactive airway disease usually resolves with time, some individuals may have persistent respiratory impairment that may also require a change in vocation in order to avoid continued exposure to irritants and exacerbation of symptoms.

Furthermore, patients with severe inhalation injuries may require a tracheostomy long after the burn has healed. Closure of the stoma is often delayed due to chronic airway complications or need for future reconstructive surgeries. Tracheal stenosis is not an infrequent complication of tracheostomy and causes increased work of breathing that is exacerbated with exertion and accompanied by stridor. Burns/scars of the trunk and chest wall, especially if circumferential, can impair chest wall mobility resulting in dyspnea and related symptoms. An assessment of chest wall motion, breath sounds,[27] adventitious sounds,[28] stridor, inspiratory/expiratory time and flow,[29] clubbing/cyanosis, and pulse oximetry provide noninvasive medical evidence of pulmonary function. However, the classification of impairment related to pulmonary problems is primarily through pulmonary function tests. These include spirometry, arterial blood gas analysis, carbon monoxide diffusion limit,[30] and exercise testing maximal oxygen uptake (VO_2 max). These tests provide objective descriptions of a patient's respiratory problem(s) if correctly performed and are the key factors determining impairment class.[31] Pulmonary impairment ranges from 0% to 65% whole-person impairment.

EYES/VISION

Chapter 43 covers burn-related eye pathology in detail. The principal visual problems seen after burn are corneal ulcer/scar (after ocular surface infection/exposure), cataract (after electrical injury), and anterior ischemic optic neuropathy (due to orbital compartment syndrome). The key factors in determining visual impairment are distance visual acuity and visual fields. While diagnostic eye care is more concerned with the vision of each individual eye, binocular vision is more important for functional status. The distance visual acuity of each eye and binocular vision is converted into a visual acuity score. The functional acuity score is three times the binocular visual acuity score, plus the right and left visual acuity scores divided by 5. Thus the score is weighted 60% binocular, and 20% for each individual eye. A similar adjustment is made for visual field defects if present. These scores are used to calculate visual system impairment, which can be converted into whole-person impairment ranging from 0% to 85%.[32]

RENAL/GENITOURINARY

Renal failure and genital/perineal burns constitute a major burn-related impairment. Whole-person impairment resulting from kidney disease ranges from 0% to 75% based on frequency/severity of symptoms and need for dialysis. Penile, scrotal, and testicular impairments are each rated separately, although each can comprise 0–15% whole-person impairment. The key factors are sexual function for penile impairment and physical exam findings for testes and scrotum (separately). Physical findings are the key factor for vulvar and vaginal impairment, which ranges from 0% to 20% of the whole person.[33] Unique to burn convalescence, severe scarring of the perineum, buttocks, or gluteal cleft may impair sitting, voiding of urine and stool, and hygiene.

GASTROINTESTINAL

The digestive system is not usually a problem except in those individuals who have had superior mesenteric artery syndrome, cholecystitis, pancreatitis, or peptic ulcer disease during the acute admission. The postdischarge clinical course of these individuals is unpredictable. Upper GI impairment (including esophageal problems, peptic ulcer, and pancreatitis) ranges from 0% to 60% of the whole person, considering frequency and severity of symptoms and need/frequency of treatment. Weight loss below ideal body weight is an important consideration in more severe impairments.[34]

ENDOCRINE

Burn convalescence is complicated by a hyperadrenergic state characterized by elevated catecholamine levels and cortisol. The pathophysiology is described in Chapter 23, along with numerous references. Whole-person impairment from adrenal cortex disorders ranges from 0% to 20% based on signs, symptoms, biochemical abnormalities, and burden of treatment. Although no therapies are currently standard for postburn hypercortisolism (best assessed by 24-hour urinary cortisol), the physical stigmata of moon facies, peripheral muscle wasting, central obesity, and lipodystrophy are familiar to the burn surgeon. Adrenal medullary excess is assessed separately from the adrenal cortex. The postburn alterations in adrenal medulla function and resulting catecholamine excess are also covered in Chapter 23, and numerous references documenting the extent/duration of catecholamine excess postburn are also given. Whole-person impairment resulting from adrenal medulla hypersecretion ranges from 0% to 60%, with the key factor being the presence of symptoms and efficacy of blocking agents. After burn injury, the nonselective β-blocker propranolol is usually able to reduce tachycardia, although supranormal doses (up to 4 mg/kg per dose) may be necessary. Symptoms of catecholamine excess after major burn injury tend to be moderate to severe and may last for several years postburn injury. Stress-induced diabetes is seen after severe burn injury, although the observed elevations in glycosylated hemoglobin are usually mild to moderate. Biochemical evidence includes fasting glucose, insulin levels, and glucose tolerance testing. Impairment from diabetes ranges from 0% to 28% of the whole person, and the rating uses severity and complexity of the required treatment as the key factor. Central hypogonadism has also been described in burned men,[35] and the role of androgen deficiency/replacement during burn recovery is an area of active investigation. Impairment resulting from states of gonadal hormone deficiency or excess is classified according to the key factors of biochemical evidence, physical symptoms, and impact on fertility. Whole-person impairment from gonadal disorders ranges from 0% to 15%.

HEMATOLOGICAL AND LYMPHATIC

Anemia frequently accompanies burn injuries and is of multifactorial etiology. The reader is referred to Chapter 22 for further descriptions of the related pathophysiology. Impairment resulting from anemia is classified according to exertional symptoms experienced by the patient and frequency of need for transfusions or other therapies. Anemia can cause whole-person impairment ranging from 0% to 75%, although the problems typical of burn convalescence are generally in the 0–15% range.[36] Postburn immunosuppression is also discussed in the above-referenced chapter. Although the magnitude of immune suppression is an important determinant of survival,[37] it tends to be self-limiting, with resolution occurring concurrently with wound closure. Significant blood-borne infections (hepatitis, human immunodeficiency virus, cytomegalovirus, and others) do occasionally complicate burn convalescence owing to significant transfusion and allograft needs in major burns. Trauma/burns are a risk factor for venous thrombosis. Whole-person impairment resulting from thrombotic problems ranges from 0% to 40% and is classed using the frequency and timing of thrombotic events as the key factor.[36] Full-thickness burns, particularly of the lower extremities, will also cause damage to the lymphatic system. Such injured individuals often demonstrate a lack of normal lymphatic drainage, resulting in chronic edema and the development of stasis ulcers. There can be little or no improvement expected posthealing. External support in the form of elastic garments is necessary to help replace the normal activity of the lymphatic system in reabsorption of fluid. These individuals frequently have difficulty in standing for long periods of time or working in a hot and humid environment.

PSYCHOLOGICAL

The psychological impact of burn injury is discussed in Chapter 65. Impairment may result from mental problems predating (and occasionally causing) the burn injury or be related to the injury and treatment. Substance abuse, suicidal ideation, and mood disorders are all common comorbidities in burn patients. They may predispose the patient to risk-prone behaviors, impair the ability to escape injury, or even prompt self-harm such as self-immolation. If present, an understanding of the patient's impairment requires documentation of symptoms and signs, including previous suicide attempts, psychiatric hospitalization, and self-injuries. The time course, frequency, and severity of suicidal ideation, previous traumatic injuries, and substance use should be detailed. Flat or expansive affect, flight-of-ideas, loosened associations, and level of psychomotor activity all comprise signs (medical evidence) that help assess impairment. After burn injury and acute hospitalization, both acute and posttraumatic stress disorders are frequent. An abnormally high level of anxiety is also present, perhaps owing to the prolonged sympathetic hyperactivation that accompanies burn injury. A description of the content, frequency, and intrusiveness of flashbacks and sensation of anxiety is helpful in gauging the patient's burden and level of impairment. Impairment is calculated as the median value of scores obtained from the global assessment of function, brief psychological rating scale, and the psychiatric impairment rating scale. Whole-person impairment from mental and behavioral disorders ranges from 0% to 50%.[38]

OVERALL QUALITY OF LIFE

Survey instruments have been constructed in an attempt to measure quality of life and subjective disability.[39] Of these, the World Health Disability Assessment Scale II measures generic function and is useful for comparison across disease states. The Burn-Specific Health Scale-Brief is, as the name suggests, constructed to capture the specific difficulties experienced by burn survivors and is useful in comparing within a population of burn survivors. In a cohort of 50 large pediatric burns, greater TBSA, male sex, increasing age at burn, burn after school entry, and survivors transitioning to adulthood were all associated with lower quality of life using both of these scales.[40] From 1994 to 2014, the Burn Model System Database (established by the National Institute on Disability, Independent Living, and Rehabilitation Research) has enrolled more than 2000 children and almost 3500 adults. More than 33 survey instruments have been administered within this population to better understand and quantitate the experience of the burn survivor. In 2016, publications resulting from this endeavor were comprehensively reviewed.[41] While these demonstrate progress toward quantitation and understanding of postburn quality of life, as suggested at the start of this chapter, these measurements have not been optimized and accepted as routine standards in clinical burn follow-up. As the use of these scales is mainstreamed, it may be instructive to compare experiential patient quality of life with whole-person impairment ratings.

64 Management of Pain and Other Discomforts in Burned Patients

WALTER J. MEYER III, J.A. JEEVENDRA MARTYN, SHELLEY WIECHMAN, CHRISTOPHER R. THOMAS, and LEE WOODSON

Introduction

The words "burn injury" trigger, for almost anyone, immediate and vivid images of excruciating pain and suffering. Children are conditioned from early childhood that burn injuries are painful and can cause great harm. At the time of the first edition of this book there was still debate about the importance of pain management in the burn survivor. Many practitioners believed that the treatment of burn injury pain, especially in children, was more dangerous than leaving it untreated. The past 20 years has shown that children's pain can be effectively and safely managed with significant benefits in recovery and long-term outcomes.[1,2] There are now data showing that even premature babies have significant pain that needs to be addressed.[3]

A series of therapeutic approaches have been developed to approach both pain and its associated anxiety. There is justified concern about opiate and benzodiazepine dependence and abuse, but this is offset by the importance of treating pain aggressively. In addition to pain and anxiety, practitioners are now focused on pruritus as well. Scales have been developed to measure pain, anxiety, and itch separately.

Pathology of a Burn Injury Pain and Pain-Generating Mechanisms

Pain is the most frequent complaint of burn-injured patients.[4] Injury-induced nociceptive responses can be described as hyperalgesia and allodynia. Hyperalgesia is increased nociceptive response to painful stimulus (e.g., pinprick). Allodynia is exaggerated pain to nonpainful stimuli (e.g., touch). All burn injuries are painful. Even first-degree burns can produce at least mild pain and discomfort, especially when something such as clothing rubs against the burned area (allodynia). Even the slightest change in air currents moving past the injured/exposed skin can cause a patient to experience excruciating pain. The loss of protective covering of the epidermis and the associated inflammation leads to sensitization of the nerve endings. Studies of humans and monkeys confirm that burn injuries not only make the injured area but also the surrounding tissue more painful.[5–7] Second-degree, moderate to deep partial-thickness burns result in variable amounts of pain depending on the amount of destruction to the dermis. In addition, as the inflammatory response progresses, the release of cytokines and chemokines increases the pain not only in the burned area but also in the surrounding tissues by the activated peripheral circulating macrophages and the central nervous system microglia.[5]

Areas of deeper partial-thickness and full-thickness burns may display a confusing pattern of pain over the first few days. These areas may show little or no response to sharp stimuli such as a pinprick initially, yet a patient may complain of deep, severe pain related to the inflammatory response. In a full-thickness burn, the dermis is completely destroyed along with its rich network of nerve endings. This leads to an initial response of a completely anesthetic wound when a sharp stimulus (e.g., pin prick) is present on the dead skin. Over time, patients begin to complain of a dull or intense pain during manipulation of these areas (e.g., dressing changes). Once the devitalized tissue (i.e., eschar) sloughs and is replaced by granulation tissue, the patient again experiences the sensation of sharp pain to noxious stimuli. Thus it appears that, in all types of burn injury pain, there is an inflammatory and neuropathic component both resulting from injury to tissues and to sensory nerves endings. As to which of these (inflammatory vs. neuropathic) components contributes more to the nociceptive responses is still not understood.

Additional Factors Contributing to Pain Generation

Ptacek et al.[8] found that although there was a general trend for pain to decrease over time in patients with small or superficial burns, there was also considerable variability in the course of pain among adult survivors after major burns. Persons with large burns showed a higher affective (suffering) component to the pain, but there was no reliable correlation between the pain scores and burn size. Quite in contrast to that report, studies in children have shown that the intensity of pain increased as the burn size increased.[9] Whether this is related to the increased anxiety of children is unclear. Other reports confirm that pain intensity at rest was correlated with psycho-affective responses such as anxiety, depression, anorexia, fatigue, and helplessness.[10] Choinière et al.[11] also noted that pain at rest was significantly and positively related to levels of anxiety or depression (i.e., with elevated anxiety or depression, pain scores at rest increased). Depression also plays a similar role in the enhancement of pain.[12] Pain leads to depression, and depression increases the perception of pain.[13,14] Confusion therefore can occur concerning the amount of pain expressed by burn patients on the role played by psychiatric disorders that are concomitantly present in any form of

injury versus injury-induced biochemical changes at the local and central nervous system level. Treatment of anxiety with benzodiazepines may have either beneficial or paradoxical effects on anxiety and pain.[15] Clinical observation and rodent studies indicate that although benzodiazepines acutely potentiate the analgesic effects of other opiates, the prolonged administration of benzodiazepines together with opiates can induce tolerance or even hyperalgesia.

Another factor that contributes to pain is procedures. Baseline pain (pain at rest) is invariably present in most burn patients. This baseline increased nociception can be aggravated by procedural pain (hyperalgesia) induced by dressings changes, physical therapy, and other procedures. Procedural pain is the most intense burn injury pain that is undertreated.[16,17] Thus the anticipation of pain related to procedures (e.g., wound care) that occurs at least once daily can increase a patient's perception of pain, which in turn can lead to greater anxiety. This reaction may explain some findings that suggest that pain increases over time in burned patients.[18–20] There could also be another component—namely, tolerance to analgesics and/or opiate-induced hyperalgesia (see later discussion)—that explains the increase in pain over time.[7] Finally, exaggerated adrenergic stimulation with release of catecholamines is part of the pain and stress response. Stress of any form has paradoxical effects on pain, initially causing stress-induced analgesia and then later exacerbation of pain, a feature known as "stress-induced hyperalgesia.[21–23] Thus the stress of burn injury, with its concomitant release of catecholamines and adrenoceptor stimulation, leads to exaggeration of pain.[21–23]

Pain as a Function of the Healing Process

As deep dermal or full-thickness burn wounds heal, either by primary intention from excision and grafting or by secondary intention through granulation tissue and scar formation, the injured neural tissue is reorganized.[17] Reflex neural function returns to grafted burn skin approximately 5–6 weeks after the burn has been covered by autografted skin.[20] Active vasodilatation, vasoconstriction, and pain sensation all return at this time.[24] These functions also return to the burn wound that heals through scar formation but may take up to 6 months for complete neural reorganization. This could be an additional basis of neuropathic pain at the burn wound site and in surrounding tissue. Despite the healing of tissues, the memory of any form of trauma-induced pain lasts for a prolonged period. In other words, subsequent (e.g., reconstructive) surgery on this area leads to exaggerated nociceptive responses sooner and longer lasting than that seen at initial injury.[32] This memory seems to be maintained by innate immune cells (macrophages and microglia), which seem to be already primed because of previous injury and become activated sooner with release of inflammatory cytokines and chemokines.[26]

Although rare, causalgia, dysesthesia, and phantom pain syndrome can sometimes develop in healing skin. Phantom limb sensation and pain are more common following amputation, which is often associated with large burn injury or electrical injury.[267] The incidence of these chronic pain syndromes seems to be related to the healing process. Burns that have been excised and grafted on a clean and uniform vascular bed rarely develop one of these chronic pain syndromes. Wounds that heal by granulation and scar formation seem to be more apt to develop a chronic pain problem because of the continued stimulation of nerve fibers in the area with enhancement of the hyperalgesia. Skin biopsies of granulation tissue have clearly shown neuronal tissue entrapment.[20] Pain in scar tissue subsides over time as the scar tissue matures.

Tolerance to Opiates and Opiate-Induced Hyperalgesia

Opioids are highly effective analgesics and are the mainstay for treatment of moderate to severe burn pain.[24] Continued use of opiates can lead to burned patients developing tolerance to their analgesic effects. There is a pharmacokinetic component to the tolerance to opiates: the clearance and the volume of distribution of many drugs are increased over time, resulting in lower therapeutic concentrations.[27] The protein binding of opiates is also increased in burned patients, resulting in a lower free fraction available to act on target μ-opioid receptor. The most important reason for the tolerance is indeed related to μ-opioid receptor changes induced by the opiates.

Opiates signal their beneficial analgesic effects by intercellular coupling to G-proteins. Just like any other G-protein coupled receptor (e.g., adrenoceptor), the repetitive administration of an agonist (e.g., epinephrine or opiate to adrenoceptor or opiate, respectively) leads to desensitization of the receptor in which the receptor responses are attenuated with each subsequent administration.[28] The attenuated response is related to phosphorylation and not to down-regulation of receptor. The continued administration of opiates will, with time, result in down-regulation of the opiate receptor number.

Both the desensitization (phosphorylation) and down-regulation of opiate receptors lead to tolerance to opiates. Recent studies indicate that continued administration of opiates also induces increased nociceptive behaviors (hyperalgesia and allodynia: a.k.a. opiate-induced hyperalgesia [OIH]).[17] Tolerance can be overcome by increasing the doses of the opiates, but OIH is made worse by increasing opioid administration. Studies in burn patients confirm OIH when pre- and intraoperative use of opiates resulted in worse postoperative pain.[28] Opiates, similar to bacterial peptides, lead to activation of innate immune responses (activation of macrophages and microglia) with release of inflammatory cytokines and chemokines. Attenuation of microglial activation has been shown to decrease OIH, with improved control of pain.[26]

Measurement of Pain in Burned Patients

Although pain cannot be measured directly, it can be quantified by using one of the standardized tools described here. Using reliable and valid tools allows us to gauge the effectiveness of our treatment for any one patient. Assessing pain on a scheduled basis and using the same tool for each

assessment gives us information about how pain is experienced by a single patient throughout burn treatment; we can note patterns that emerge and schedule medications accordingly. Furthermore standardized tools allow us to compare the pain management of one patient with another, as well as of one burn unit pain management regime with that of other burn units in order to determine the effectiveness of protocols for pain management. Another important reason for assessing pain regularly and in a standardized way is that it communicates to the patient that we believe he or she has pain and that we are trying to do something about it. This communication reassures the patient, thereby reducing the likelihood that the patient will escalate pain, anxiety, and other related behaviors.

Gracely[3] reviewed a number of objective modalities for the measurement of experimental pain. He notes that "pain arises from and is modulated by, a number of mechanisms. These mechanisms are not static but change over time and involve all levels of the central nervous system. In an attempt to understand these mechanisms, several experimental tools have been employed to further elucidate the exact pathways involved in pain transmission and to better understand the therapies used to relieve pain."

Some of these tools are cortical evoked potentials, functional brain imaging (positive emission tomography [PET]), functional magnetic resonance imaging (fMRI), source analysis of evoked activity, and electrophysiological recording from the human brain. As noted by Gracely, comparing these measures with verbal judgments of pain magnitude validates these physiologic measures: "This implicitly elevates subjective judgment to the level of a validation standard."[3] Clinical measurements of pain must continue to rely on standard subjective measures. A tool to use in the clinical setting must be quick and easy to use and useful for frequently repeated assessments.

A major concern in the clinical setting is the use of a consistent pain measurement tool before and 1–2 hours after the administration of a pain-relieving medication. For procedural pain management, the same tool should be used to measure pain at the beginning of a procedure, during the procedure, and post-procedure in order to measure the effectiveness of the pain management regimen used for procedural pain.

PAIN MEASUREMENT TECHNIQUES FOR ADULT BURNED PATIENTS

A variety of pain measurement techniques have been used with adult burned patients. The more common measures include adjective scales (Table 64.1), numeric scales (i.e., rating pain on a scale of 0–5, 0–10, or 0–100), and visual analog scales (Fig. 64.1). Each of these scales measures the sensory component of a patient's pain. Adjective scales and numeric scales are quick and easy to administer because they do not require a visual representation of the scale. The visual analog scale requires a visual representation of the scale to be presented to a patient. Patients must mark or point to the place on the scale that represents their level of pain. This presents a problem for a patient whose hands are burned, so some investigators have used a technique of sliding a line or color strip along the scale with instructions to a patient to direct the movement of the slide, stopping at the point representative of the patient's pain. The visual analog scale has been used in a number of studies with a variety of patient samples and has been shown to be a valid method of measuring the sensory component of a patient's pain. The demonstrated validity of the scale allows for comparisons of visual analog pain assessments between studies with different patient samples. However the visual analog scale is not interchangeable with the graphic numeric rating scale.[29]

Table 64.1 Adjective Scales in English and Spanish.

0	No pain	0	Nada de color
1	Slight pain	1	Dolor leve (ligero)
2	Moderate pain	2	Dolor moderado
3	Severe pain	3	Dolor severo

Fig. 64.1 Visual analog scale (VAS) for children to rate their levels of pain. (From the Varno/Thompson Pediatric Pain Questionnaire. With permission from the American Society for Clinical Pharmacology and Therapeutics.)

Motivational-affective and cognitive-evaluative components of pain are most frequently measured using the McGill Pain Questionnaire (MPQ).[30] The MPQ consists of 20 sets of adjectives that describe all three components of pain: sensory, affective, and evaluative. Qualitative profiles and quantitative scores for each dimension as well as a total pain score can be derived from the selected adjectives. The MPQ has been translated into several languages and has been shown to be a reliable and valid measurement tool. Since it takes 10–20 minutes to administer, it may not be as useful for frequent, repeated measurements. Many studies have employed this measurement on a daily basis to measure either overall or resting pain. Gordon et al.[31] in a prospective multicenter study, asked 40 adult burned patients to rate their pain on four scales. These scales were a visual analog scale, an analog chromatic scale,[32] an adjective scale, and a faces scale.[33] At the end of the study patients were asked to choose their preferred scale. Patients preferred the faces and analog chromatic scales. Although further research is needed to validate these findings, the preference of patients is another variable to be considered.

PAIN MEASUREMENT TECHNIQUES FOR PEDIATRIC BURNED PATIENTS

The measurement of children's pain is much more complex than it is for adults, especially for preverbal children. The American Academy of Pediatrics and the American Pain Society issued a joint statement in 2001 that included the recommendation that, in a hospital setting, "ongoing assessment of the presence and severity of pain and the child's response to treatment is essential."[34] The assessment of pain in children has included physiologic measurements, behavioral assessment, and patient reports of pain. The physiologic indicators that have been evaluated are heart rate,[34]

respiratory rate,[35] blood pressure,[35] endocrine changes,[35,36] and changes in Po_2.[37] None of these shows promise as an indicator for measuring pain in sick children because all are affected by a variety of stressors, metabolic changes related to a burn, and medications in addition to pain.

Behavior scales have been devised to measure pain by providing standardized instructions and guidelines for observing behaviors thought to be specific to pain. A number of investigators[38–43] have looked at infants' cries as measurable behaviors that can be observed in order to evaluate pain. Although these studies demonstrate that length of cry, pitch, intensity, and other characteristics of crying may be used to evaluate pain in infants, the analyses of crying are very time-consuming and require elaborate audio equipment. Izard et al.,[44] Craig et al.,[45] and Granau and Craig[42] have attempted to code facial expressions as measures of pain in infants. Their system characterizes nine facial actions involved in the expression of pain, but its use requires videotaping and detailed analyses of an infant's facial movements. Although this method offers excellent research applications, it, like the detailed analyses of crying, is too cumbersome and not appropriate for the clinical setting. On the other hand, the studies do provide clinicians with information about various facial reactions, as categorized by Granau and Craig, which may be helpful in the clinical identification of pain in infants. Other investigators have devised multidimensional scales that include length of cry, facial expressions, and behavioral states in order to measure pain in infants.[46–48] These scales are easier to use and allow an observer to assess pain as either present or absent without further quantification.

Examples of observational scales that allow for quantification and may be used with toddlers and preverbal children are the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)[49] and The Observer Scale.[50] The CHEOPS is a scale of six behaviors, each scored on a numeric range; it yields a total numeric score for pain. This scale has been shown to be valid and to have good interrater reliability. The Observer Scale is another standardized instrument that categorizes overall pain or comfort behaviors on a scale of 1–5. The five categories are laughing, euphoric; happy, contented, playful; calm or asleep; mild-moderate pain—crying, grimacing, restlessness, but can be distracted with toy, food, or parent; and severe pain—crying, screaming, and inconsolable.

Pain during procedures is especially important to assess. In 1997, the FLACC scale was developed for postoperative pain.[51] This has now been applied for pain related to dressing changes on burn wounds. This scale is now documented to reflect patient pain intensity as well as nurse clinical experience.[52]

A burn-specific observational tool was developed by Barone et al. at Shriners Hospitals for Children-Cincinnati.[53] The Observational Pain Assessment Scale (OPAS) is useful in children 0–3 years of age. The scale is depicted in Table 64.2.

Research suggests that simple self-report scales can be used with preschool children. Examples of such scales include the Oucher Scale (photographs of children with various facial expressions).[54–56] Drawings of faces[19,57] have also been used with preschool-aged children[58] and school-aged children (8 years).[59] Preschool children have also used the Poker Chip Tool,[60] color scales,[61,62] and a thermometer[62] to report the degree of pain or hurt. These simple tools allow a preschooler to report pain and are easy to use. One caution with the face scales is that a practitioner must help a child differentiate between physical pain and sadness unrelated to pain. Since there is no evidence that any one of these is more valid than another, it is recommended to pick one and use it consistently. When self-report scales are used in conjunction with observational scales, a practitioner gets a better picture of a child's response to pain and pain therapies.

A school-aged child's cognitive development allows for more abstract thinking. In addition to the Faces Pain Rating Scales, which they enjoy,[19] they can use simple numeric scales 0–5 in the early school years (ages 7–8)[63] and more complex scales 0–10 or 0–100 in the later years (age 9–12). Visual analog scales anchored with happy and sad faces[62] and simple adjective scales[62,64] also can be used with this age group. In addition to self-reports of pain, observational scales such as the CHEOPS[40] or the Procedure Behavior Check List[65] can be used with a school-aged child. Again, the important issue is to use one selected scale consistently since no one has been shown to be more valid than others.

Adolescents can think abstractly and can quantify and qualify phenomena and so can use the same scales as adults. One concern with adolescents is that when they are ill they tend to regress and thus may require the use of a simpler scale during such times.[66]

Table 64.2 Observational Pain Assessment Scale (OPAS)[44]

Assess each of the areas identified in the "Observed Behavior" column rating each behavior using the 0, 1, or 2 rating. Add the ratings together for each observed behavior. Document your total score.

Observed Behavior	0	1	2
Restlessness	Calm, cooperative	Slightly restless, consolable	Very restless agitated, inconsolable
Muscle, Tension	Relaxed	Slight tenseness	Extreme tenseness
Facial Expression	No frowning or grimacing, composed	Slight frowning or grimacing	Constant frowning or grimacing
Vocalization	Normal tone, no sound	Groans, moans, cries out in pain	Cries out, sobs
Wound Guarding	No negative response to wound	Reaching/gently touching wound	Grabbing vigorously at wound

Intubated and sedated children provide more challenges in the assessment of pain. The more disabilities that a child has and the more medications that are being given to the patient create challenges to the clinician. A 2-year-old child who is blind, with only one extremity that is functioning and on numerous medications presents a huge assessment challenge to the clinician. Table 64.3 presents a list of clinically useful tools according to patient age.

"Pain is what the child says it is."[67] What about the case where the nurse documents a lower number than the child says because the nurse believes the child is over-rating the score? Reiman et al.[68] surveyed nurses' knowledge and attitudes regarding pain and their ability to manage pain. The modified Pediatric Nurses' Knowledge and Attitude Survey Regarding Pain tool (PNKAS – Shriners Version 2002) needs further validation but demonstrates the need to consider the healthcare provider's attitude and knowledge of pain.

Measurement of Anxiety

Anxiety is measured in a variety of ways. In 2000, Robert et al. surveyed 64 burn treatment centers to determine how they evaluated and treated anxiety, especially in children.[69] They found that most centers did not use standardized measures of anxiety. Based on that survey and other information, the Shriners Hospital for Children in Galveston has been using the Fear Thermometer adapted by Silverman and Kurtines[70] from the Walk's Fear Thermometer[71] (Fig. 64.2).

Taal and Faber introduced a tool to measure burn-specific pain anxiety (BSPAS).[72] It uses a five-item scale used to measure anxiety associated with anticipated procedural pain in adult patients.[73] Initial reliability, validity, and utility studies have been completed.[73,74] A similar tool is needed for children.

Measurement of Itching

Itching is very common in burn survivors. Even in small burns, the prevalence is 35% with moderate pruritus and 14% with severe, and, in many cases, the pruritus impacts daily living.[75–77] Another series of 510 burns reported a prevalence of 87%.[78] The severe itching of burn scars and wounds has not been discussed much in the literature, but clinicians can testify that this phenomenon is a very serious problem. Patients who experience such itching often excoriate new grafts or recently healed skin, thus enhancing their susceptibility to infections. The measurement of itching has been part of a number of scales that focus on all the problems that the patient has, such as the Patient and Observer Scar Assessment Scale (POSAS)[79] and the Assessment of Health Outcomes in Children with Burn Injury.[80] When pruritus is severe, patients can focus on nothing else. Until very recently there have not been any tools focused on measuring itch. Now, Field et al.[81] reported using a visual analog scale of 1–10 to assess itching. Pat Blakeney and Janet Marvin at the Shriners Hospital for Children in Galveston developed an instrument to measure itch called "itch man" (Fig. 64.3). This instrument was based on a patient's drawing of his experience in the hospital.[82] Children seem to be able to relate to "itch man," and validation has been completed.[83] Several scales have been developed for adults to use. One from Belgium has been translated and validated in English and seeks to measure all the aspects of itching and how it relates to other types of variables.[84] Another coming from the dermatologic literature measuring itching in five dimensions is named the 5-D itch Scale.[85]

In summary, symptom assessment and management are very important in burn care. The experience of pain may affect the perceptions of other symptoms, including anxiety, fear, or itch. Each symptom should be assessed within the context of other symptom assessments. There are many measurement tools for pain, anxiety, and itch assessment across the life span that can be useful to the clinician and the researcher. Further studies need to be completed in all these areas.

Treatment Considerations

Once pain has been assessed and quantified, treatment can be considered. Three modalities of treatment are effective

with pain secondary to burn injury: surgical, pharmacological, and behavioral.

SURGICAL TREATMENT OF PAIN

In burn patients, pain is predominately related to the open wound. Once the wound is closed, the pain subsides. The use of resection and grafting of open burn wounds significantly reduces burn pain. Open wounds should be grafted as soon as they are clean enough to do so. Even temporary coverage with cadaver skin or pigskin reduces pain in the area of the burn. In the case of second-degree wounds, the use of Biobrane, Opsite, Tegaderm, Dressilk, Polymem, Copoymer, Acticoat, Mepilex AG, Duoerm, or other wound-covering dressings almost immediately eliminates pain at the burn wound site.[86–95] Biobrane has also been used for toxic epidermal necrolysis and was found to reduce pain significantly; Duoderm is a similar but cheaper product than Biobrane and has the same beneficial effect on pain. Cultured allogeneic keratinocyte sheets accelerated healing and thereby reduced pain and suffering compared to Opsite treatment. The cultured keratinocyte sheets cut healing time in half. Pain assessment as early as day 3 revealed lower pain scores in those sites treated with keratinocyte sheets. Less costly dressings include honey because it provides the synergistic interactions of a moist environment, antibacterial activity, and antiinflammatory action and thereby promotes healing.[96–98]

Negative-pressure wound dressing therapy is a relatively new approach to the closure of wounds. As a byproduct of that treatment, Fischer et al. claim less pain but give no data.[99] Other new techniques include laser treatment of scars. The CO_2 fractional photothermolysis treatment of scars does reduce scars and pain. On the other hand, it reduces neuropathic pain by 54% and pruritus by 49%.[100]

The newest approach to reducing the pain of a scar is the use of fat grafting. It was initially developed in animals and more recently used clinically in humans.[101] The fat decreases local neuroinflammation.

TOPICAL AGENTS

Aloe vera has been used as a home remedy for burns for many generations, and several recent studies have examined its efficacy more thoroughly. Maenthaisong et al. conducted a systematic review and meta-analysis and concluded from the published studies of first- and second-degree burns that aloe vera was more effective than Vaseline gauze alone.[102] In that study, aloe use was associated with a shorter healing time by 8.79 days. A more recent randomized controlled study in 2009 by Khorasani et al. confirmed the greater efficacy of aloe over silver sulfadiazine.[103]

In contrast, topical morphine was not very effective in reducing the pain of partial-thickness burns.[104] The final word on the effectiveness of topical heparin is still out.[105]

Physical coverage of the burn wound decreases pain. For example, blisters left intact lead to less pain,[106] but this practice is questionable because of possible infection associated with the blisters. One additional issue concerning procedures is the amount of pain created by removing a dressing from the burned area. These removals are usually facilitated by soaking the dressings off, but the soaks are sometimes painful. Some newer dressings are easy and painless to remove, and moist, exposed-burn ointment dressings[107] are being developed to further reduce pain.

Acticoat was found to be much less painful than silver sulfadiazine in the treatment of partial-thickness burns by Varas et al.[108] Several new lipido-colloid dressings seems to show promise for reducing pain.[109, 110] Cellulose dressings also reduce pain.[111] Several new products are adherent to dry skin but not moist skin and therefore much less pain than has been reported to be associated with silver sulfadiazine.[112,113] Suprathel is a reabsorbable skin substitute that goes even further to reduce the pain of dressing by eliminating the need for dressing changes.[114]

A more novel technique of painlessly cleaning the burn wound is to use an ultrasound mist, and there are two short reports advocating this.[115,116]

PHARMACOLOGICAL TREATMENT OF BURN PAIN

Optimal pain management for burn patients requires a multidisciplinary approach and individualized therapy. However pharmacologic management of burn pain is the mainstay of therapy. General rules are helpful in governing the use of pain medication. The first tenet is that if the patient says he or she is having pain, he or she is suffering. The second tenet is that analgesics are most effective when given on a regularly scheduled basis (not "as needed" or PRN). The third tenet is that, when avoidable, pain medication should not be given as an intramuscular injection since injections themselves cause pain and anxiety. In addition, initial physiological changes associated with large burns make uptake from injection sites erratic and unpredictable. Last, dose and type of medication should be reevaluated frequently during the hospital course to make sure pain is

continuously controlled and that the patient is experiencing no serious side effects.

Dramatic physiological changes associated with large burns produce significant pharmacokinetic and pharmacodynamic alterations that affect drug selection and dosing considerations.[117] Two metabolic and hemodynamic phases are recognized following major burn injury. An initial burn shock (ebb) phase with decreased circulating blood volume, decreased cardiac output, and increased systemic vascular resistance is followed after approximately 48 hours by a hyperdynamic/hypermetabolic (flow) phase with increased cardiac output and decreased systemic resistance, increased oxygen consumption, and intense catabolism. These changes in cardiac output and organ perfusion also affect hepatic and renal drug clearance in a biphasic fashion. For example, during the ebb phase, hepatic and renal blood flow may be reduced enough to impair drug metabolism and excretion. Conversely, during the flow phase, increased hepatic blood flow enhances clearance of drugs such as fentanyl and propofol that are efficiently extracted by the liver.[118] Likewise renal excretion of some drugs may be increased enough to require alteration of the dose. Furthermore loss of plasma proteins through open wounds and extensive edema due to massive fluid resuscitation profoundly alter drug distribution and binding to plasma proteins. Sympathetic tone and drug exposure during the hospital course alter the up- and downregulation of various drug receptors. Perception of pain is enhanced by anxiety. Devastating burn injuries produce intense anxiety that can be exaggerated or reduced by the effectiveness of pain control. All these factors ultimately affect responses to analgesic (and other) drugs in ways that are often unpredictable. Patient response should be closely monitored and drug selection and dosing adjusted carefully to avoid undertreatment or complications of overdose.

OPIOIDS

Opioid analgesics have been the mainstay of burn pain drug therapy.[119] Burn pain is not a single entity but is experienced in several distinct ways: background, breakthrough, procedural, and postoperative pain. Drug selection and dosing are very different for each of these clinical situations. There are several opiate drugs with widely different pharmacokinetic profiles. This allows selection of an agent with speed of onset and duration of action appropriate to specific clinical needs. For background pain, slower onset and long duration of action are suitable. For patient-controlled analgesia (PCA), a rapid onset is desirable. For procedural pain, it is best that the drug effect (and adverse effects) not last much longer than the procedure. A variety of routes of administration are also possible with this large group of drugs. In most cases, it is better to give a sufficient dose to control pain over its recommended length of action rather than smaller doses more frequently. This problem occurs frequently when physicians are reluctant to prescribe the recommended dose for pain.

The use of opiate analgesics is often limited by their adverse effects. Continuous use may be limited by pruritus or constipation. Higher doses needed for intense pain associated with procedures may cause unsafe depression of respiration. Use of adjuvant drugs and a multimodal approach to pain control can increase the quality of pain control in part by reducing the dose and thus the adverse effects of opiates needed.

Morphine

Morphine has been described as the gold standard for treating burn pain and remains the first choice in many burn units. Time to peak effect and duration of action for morphine are appropriate for treating background and breakthrough pain most of the time. Although morphine is often used with PCA, some clinicians prefer drugs with quicker on–off kinetics, especially for painful procedures. The active morphine-6-glucuronide metabolite of morphine is excreted in urine and can accumulate in patients with renal failure.[120]

Chronic treatment with opiates will result in tolerance and increasing dosage requirements to control pain. Opiate tolerance is accompanied by an increased sensitivity to pain. The central mechanism of this hyperalgesia appears to involve glutamate transmission mediated by N-methyl-D-aspartate (NMDA) receptors. In addition to tolerance to narcotic analgesics, some patients experience a phenomenon referred to as OIH. OIH differs from tolerance in that, where patients tolerant to morphine respond to larger doses, with OIH, increasing doses of morphine are associated with increased pain.

OIH associated with burns has been reviewed by Holtman and Jellish.[121] Although it may at times be difficult to distinguish opiate tolerance from OIH, deteriorating pain control despite large increases in morphine dosage is suggestive of OIH. One benefit of a multimodal approach to pain control is that it allows lower doses of opiates, which also reduces the risk of OIH. When OIH is suspected, the dose of morphine must be reduced, and additional changes in drug therapy are needed to compensate for the reduced effect of morphine. All patients with OIH will not respond in the same manner to pharmacological interventions. A switch to methadone has been reported effective in patients poorly controlled by morphine. This benefit has been explained by NMDA receptor antagonism by methadone. α-2 Adrenergic agonists, as well as low-dose ketamine have also been found effective. Additional agents included in multimodal strategies to reduce narcotic analgesics are benzodiazepines, acetaminophen, gabapentin, and pregabalin.

Fentanyl

Fentanyl is a potent synthetic opiate with a relatively rapid onset of action and a shorter duration of effect than morphine. The relatively rapid onset and shorter duration of action with bolus doses make fentanyl a suitable choice for analgesia during painful procedures and with PCA. An oral transmucosal dosage form is also available and has been found effective in pediatric patients during procedures.[122] With continued infusion, however, the drug accumulates, and, due to its long context-sensitive half-time, prolonged infusions can delay extubation of ventilated patients. This can be prevented by the daily wake-up protocols practiced in many ICUs. Discontinuing sedation in ventilated patients can also be associated with significant morbidity, such as unplanned extubations. A benefit similar to daily wake-up protocols but without associated morbidity is also possible with a protocol of daily assessment of sedation and dosage adjustment.[123]

Remifentanil

Remifentanil is an ultra-short-acting opioid with a rapid time to peak activity (90 s). Elimination is very rapid by nonspecific esterases in blood and tissue, which give it a context-sensitive half-time of approximately 4 min without regard to duration of infusion.[124] The pharmacokinetic properties of remifentanil make it appropriate when rapid emergence is desired. The abrupt recovery from remifentanil analgesia has been associated with hyperalgesia. This can be prevented by concomitant doses of α-2 adrenergic agonists, ketamine, or a longer-acting opiate prior to termination of infusion.[125]

Alfentanil

Alfentanil has a short time to peak effect similar to remifentanil (90 s) and shorter duration than fentanyl. With a Vd of less than one-fourth that of fentanyl, alfentanil also has a faster clearance and shorter half-life.[126] These properties make it suitable to provide analgesia for brief procedures and to infuse for longer procedures and yet provide relatively rapid recovery. The pharmacokinetics of alfentanil are especially suited for PCA. Sim and others[127] used alfentanil alone with PCA for burn dressing and wound care with excellent satisfaction of patients and nurses.

Methadone

Methadone is a synthetic opiate that combines μ receptor agonist, NMDA antagonist, and amine uptake inhibition properties.[128] Preclinical studies have shown that through its NMDA receptor antagonist action, methadone inhibits morphine tolerance and hyperalgesia.[129] These properties make it theoretically suited for treating burn pain by reducing the risks of central sensitization of pain and OIH. In clinical studies there appears to be a lack of cross-tolerance with morphine. There are multiple reports of improved pain control in patients switched from morphine to methadone.[130,131] The mean bioavailability is about 80% after enteral administration. Its onset of action is more rapid than morphine after intravenous injection due to its higher lipid solubility. Its elimination is quite variable but significantly longer ($t_{1/2}$ 7–65 hours) than that of morphine ($t_{1/2}$ 1.7–3.3 hours).[128]

BENZODIAZEPINES

Significant burn injuries are associated with considerable anxiety and psychological stress. Pain sensation is enhanced by anxiety and, in some cases, pediatric patients for example, even complete elimination of pain does not make procedures stress-free. Reducing anxiety can reduce narcotic requirements for pain control. Benzodiazepines are the most commonly used anxiolytic agents used in burn centers. Pharmacokinetic considerations influence the choice of benzodiazepines in burn patients. Martyn et al. evaluated the clearance of diazepam[132] and lorazepam[133] in burned patients and in nonburned controls. Diazepam is metabolized by P450 oxidases (phase I reaction), and its metabolism and clearance were depressed in burned patients. In contrast, lorazepam is metabolized by conjugation (phase II), and its clearance is slightly enhanced in burned patients. These results suggest that although the clearance of diazepam may be unpredictably slow and accumulation of doses may be possible in burned patients, this is not the case with lorazepam. As a result, treatment of burn patients with lorazepam should be more predictable than with diazepam and therefore more controllable and effective. Diazepam has a relatively long half-life and is biotransformed to active metabolites. Midazolam is a shorter-acting agent suitable for brief procedures or infusion and is the most frequently used sedative in U.S.-based burn centers.[134] Midazolam undergoes extensive first-pass metabolism by intestinal and hepatic tissues after oral administration. However its major hydroxylated metabolite, α-hydroxymidazolam, is at least as potent as midazolam.[135] Lorazepam has a duration intermediate between midazolam and diazepam. Lorazepam is metabolized by glucuronidation to inactive metabolites, and, because of this, it is often preferred for anxiolysis in burn ICUs.

NONOPIATE ANALGESICS

Acetaminophen is a nonantiinflammatory antipyretic analgesic. Although its analgesic action is too weak to adequately control pain of more than minor burns by itself, acetaminophen acts synergistically with more potent analgesics and is an important component of multimodal pain protocols. When used in this manner acetaminophen reduces the dose requirements of opiates. It is effective when given alone for minor burns. Meyer et al. found that 10–15 mg/kg of acetaminophen given orally every 4 hours was effective without producing toxic plasma concentrations.[136]

Nonsteroidal antiinflammatory drugs (NSAIDs) also possess significant analgesic and antipyretic action and are also antiinflammatory agents. They are not used routinely in burn patients due to additional adverse effects. NSAIDs have been found to promote acute kidney injury in hypovolemic patients through inhibition of prostaglandin synthesis, which reduces renal blood flow due to constriction of afferent renal arterioles.[137] Increased bleeding due to an antiplatelet effect is another concern.

ANTICONVULSANTS

Drugs originally intended as anticonvulsants have also proved helpful in pain management protocols. Gabapentin and pregabalin are such drugs that have been found to be effective for the management of neuropathic pain.[138,139] Since neuropathic pain and narcotic-induced hyperalgesia appear to share pathophysiological etiologies, it is likely that drugs effective against neuropathic pain should also facilitate pain control by reducing hyperalgesia associated with narcotic administration. The proposed mechanism is not established, but there is preclinical evidence that these drugs reduce central sensitization through an interaction with spinal voltage-gated calcium channels.[139] Van Elstraete and colleagues found that although gabapentin did not affect the initial analgesic effect of fentanyl in rats, it did prevent, in a dose-dependent manner, the delayed hyperalgesia associated with fentanyl administration.[140] In a clinical study Rimaz et al.[141] reported that a single preoperative dose of gabapentin given prior to burn surgery decreased

the postoperative PCA morphine consumption. These drugs are often used as part of a multimodal pain control protocol.

KETAMINE

Ketamine is a potent analgesic with many characteristics that make it suitable for treating burn patients. It has been used extensively alone and in combination with other drugs primarily for controlling pain during procedures related to burn care, but also low-dose infusions can improve pain control in some patients tolerant to morphine. It has been administered orally, intramuscularly, and intravenously. Ketamine causes pain when administered intramuscularly or through a peripheral intravenous catheter. It also causes tachycardia and hypertension, which may be poorly tolerated by older patients with hypertension or coronary artery disease. These side effects can be reduced by concomitant administration of an α_2 adrenergic agonist. Ketamine has been avoided in patients with increased intracranial pressure because it has been reported to cause increased cerebral blood flow that might further increase intracranial pressure. More recent evidence contradicts this warning. Clinical and experimental data suggest that, especially for patients who are mechanically ventilated, ketamine may offer neurological protection, decreased intracranial pressure, and improved cerebral perfusion.[142]

In doses above 1–2 mg/kg intravenously ketamine produces a dissociative state that renders the patient insensible. At the same time, respiratory drive, airway patency, and airway reflexes are preserved.

Ketamine has an extensive record of safety in pediatric emergency departments even when given without regard to prandial state.[143] This combination of features is especially beneficial in pediatric patients who can experience intense psychological stress and may be combative even if all pain is prevented. A more bothersome problem is delirium during emergence. Midazolam is often described as a remedy, but dexmedetomidine may be more effective.[144] It is best that midazolam be co-administered with ketamine to avoid this complication. Ketamine sedation can be associated with increased salivation that can make laryngospasm more likely but, in contrast to laryngospasm caused by inhalation agents, laryngospasm with ketamine is largely self-limiting.

α_2 AGONISTS

The use of α_2 adrenergic agonists has increased dramatically for perioperative and ICU applications.[145] These drugs are used for both sedative and analgesic properties. For these applications α_2 agonists' predominant effect is mediated by central inhibition of norepinephrine release. This action results in sedation and reduction of sympathetic tone. Peripheral release of norepinephrine is also inhibited. If blood pressure is maintained by increased sympathetic tone, as with decreased circulating blood volume, administration of clonidine or dexmedetomidine can cause hypotension.

Clonidine is available for oral or intravenous use. When administered by mouth or nasogastric tube, clonidine has an approximately 85% bioavailability. Dexmedetomidine is available as a solution for injection and can also be administered as an intranasal mist.[146] Clonidine is the more inexpensive of the two agents.

The analgesic action of dexmedetomidine and clonidine is weak, and these drugs are most effective as adjuvants. They reduce dose requirements for narcotics and counteract opiate-induced hyperalgesia. Compared to clonidine, dexmedetomidine is a more selective adrenergic agonist and has a higher affinity for the α_2 receptor. The elimination half-life for dexmedetomidine is much shorter than clonidine's (2 hours vs. >12 hours).[147] Intravenous infusion of dexmedetomidine allows more precise titration of sedation to the patient's needs but is more expensive.

Among the advantages of α_2 adrenergic agonists are the lack of effect on airway patency, respiratory drive, and airway reflexes. Dexmedetomidine is especially effective in combination with ketamine. Dexmedetomidine limits the hypertension and tachycardia associated with ketamine, which can be problematic in older patients. In addition, dexmedetomidine also potentiates the analgesic effect of ketamine and in this way reduces the dose of ketamine needed.

PROPOFOL

Propofol is a nonbarbiturate intravenous anesthetic without analgesic activity.[148] Advantages include rapid onset of action and a rapid emergence with little cumulative effect after prolonged infusion.[149] A disadvantage is pain when administered through a peripheral vein. It is most commonly used for induction and/or maintenance of general anesthesia. Propofol has also been used in sub-anesthetic doses along with an analgesic drug for sedation during stressful procedures.

Under certain conditions and with limited duration propofol is given by intravenous infusion for sedation of intubated patients requiring mechanical ventilation in the ICU. Ronan and others found sedation of intubated patients to be superior with propofol than with midazolam infusion in terms of speed of wake-up and quality of sedation.[149] The rate and duration of propofol infusion should be limited, and patients receiving propofol should be closely observed for signs and symptoms of propofol infusion syndrome (PRIS). This is a rare but serious and often fatal complication of propofol. PRIS has a variable clinical presentation but includes combinations of metabolic acidosis, arrhythmias, rhabdomyolysis, renal failure, and other disorders. The total cumulative dose is the main risk factor for PRIS, and the U.S. Food and Drug Administration (FDA) recommends a maximum dose rate of 4 mg/kg per hour, but case reports have included dose rates lower than this.[150] Some intensivists limit propofol to provide sedation during weaning of longer-acting agents or for relatively short-term infusions of 24–48 hours.

In doses that result in loss of consciousness (general anesthesia) propofol causes loss of pharyngeal tone, which may cause airway occlusion.[151] It also causes reduction of respiratory drive and loss of airway reflexes, making patients vulnerable to hypoventilation or apnea, aspiration, and laryngospasm. Hypotension is also associated with these doses. As a result, propofol in these higher doses should only be administered by personnel with formal anesthesia

training or by credentialed personnel who are part of a care team designed to provide sedation for procedures.

NITROUS OXIDE

Nitrous oxide is the only nonhalogenated anesthetic gas still in clinical use. Its low potency requires 50–70% inhaled concentrations to provide significant analgesia. Filkin and Marvin have reported effective analgesia during burn wound care with self-administered nitrous oxide.[152] More recently, Ozil et al. used 50% nitrous oxide in combination with morphine premedication to provide analgesia for 33 children with small (<10% TBSA) burns.[153] In these cases pain scores and patient/parent satisfaction were favorable.[205] Do Vale et al. found that the use of fentanyl was not reduced by using nitrous oxide.[154] A brief intermittent exposure to nitrous oxide and chronic exposure to trace amounts appear safe, but repeated exposure to higher concentrations can result in significant hematopoietic and neurological toxicity. This results from oxidation by nitrous oxide of the cobalt in vitamin B_{12}, which impairs its coenzyme function. Synthesis of methionine and tetrahydrofolate needed for DNA synthesis and metabolic reactions involving methylations is inhibited by nitrous oxide inactivation of vitamin B_{12}. Clinical presentation mimics pernicious anemia, with megaloblastic anemia and subacute combined degeneration of the spinal cord. Hayden and colleagues reported a case of myeloneuropathy in a burn patient chronically exposed to high concentrations when he was given 50% nitrous oxide in oxygen to self-administer ad lib over approximately 4 months.[155,206] Chronic exposure also is possible for workers chronically exposed to nitrous oxide. Sweeny et al. found bone marrow changes consistent with nitrous oxide toxicity in three of 21 dentists who used nitrous oxide for sedation and analgesia for their patients during long procedures.[156,207] Ambient nitrous oxide concentration were as high as 4,600 ppm in their work areas. With modern scavenging systems, operating room personnel are not considered at risk. If nitrous oxide is used for analgesia for burn patients, adequate consideration must be given to chronic exposure of personnel.

Initial Injury

Although areas of full thickness burn injury are initially insensate, Singer and colleagues[157] reported that only 25% of patients presenting with isolated full-thickness burns had pain scores of 0; that is, were painless. Of all other patients with partial or partial plus full-thickness burns, 18% were also painless. The differences in the frequency of painless wounds between these two groups were not statistically significant. These observations suggest that most patients with full-thickness burns have significant pain.

If possible, intramuscular injections should be avoided. Not only is the injection painful, but, during the early stages of major burns, absorption from tissue sites is highly variable and unpredictable. With decreased intravascular volume and cardiac output, tissue perfusion may be low and absorption poor. Later, with fluid resuscitation, drug may enter the circulation as tissue perfusion is restored. This can combine with any sedative or analgesic drugs given later and lead to oversedation and respiratory depression.

In the case of second-degree wounds, the use of wound-covering dressings almost immediately eliminates pain in the burn wound site. As an example, Schwarze and colleagues compared the clinical efficacy of two synthetic burn wound dressings, Suprathel and Omiderm. Both were highly effective in reducing pain. Omiderm was more cost effective, but Suprathel was slightly more effective in reducing pain (10-day average visual analog score [VAS] pain score was 1.0 for Suprathel, 1.59 in the Omiderm group).[158]

Although the most widely followed burn shock formula, the Parkland formula, recommends 4 mL/kg per percentage of TBSA burned, Engrav and colleagues reported in 2000 that many burn centers were administering considerably more fluid than this and that patients were experiencing serious morbidity from overresuscitation.[159] This trend of administering increasing amounts of resuscitation fluids has been termed "fluid creep" by Pruitt and is associated with significant morbidity due to fluid overload. The mechanism of this phenomenon has not been established, but Sullivan and colleagues found an association of increased fluid volumes administered with increased doses and variety of narcotics given to burn patients.[160] They suggested that higher doses of narcotics could contribute to hypotension and increase the fluid needs of these patients. Saffle examined factors associated with "fluid creep" and reasoned that it is unlikely that narcotics contribute significantly to the practice of administering larger volumes of fluid to burn patients.[161]

Background and Breakthrough Pain

Pain perception and analgesic requirements for burn injuries vary widely. Adequate pain control requires that each patient be continuously assessed for pain and anxiety. For a variety of reasons the simplest effective treatment plan is optimal. Often morphine in combination with a benzodiazepine is adequate. However the advantages of a multimodal approach to pain control are generally accepted, especially for patients with moderate and severe pain. The use of multiple drugs with different mechanisms of action provides synergistic effects that improve pain control and allows the use of lower doses of opiates. For this reason the addition of scheduled doses of acetaminophen and gabapentin may reduce OIH and neuropathic pain. Cuignet et al. reported that if 2400 mg of gabapentin is given to adult burn survivors per day, the amount of morphine needed is less and the pain control better.[138] An unexpected finding was that improved pain scores and reduced morphine requirements persisted after treatment with gabapentin was stopped.

During the acute phase of recovery from burn injuries patients with good pain control often experience transient periods of sudden intense increase in their pain. This is referred to as *breakthrough pain*. A pain management plan must include orders for as-needed or p.r.n. doses of an analgesic. The intensity of breakthrough pain is usually so great that an opiate is required.

One technique that can accommodate both background and breakthrough pain is PCA. PCA requires patient

cooperation, which means that the patient is able to understand and perform tasks necessary to self-administer the medication. When hands are burned and the PCA pump cannot be activated manually by the patient, a foot pedal can be used. When neither of these options is possible, protocols have allowed a nurse to activate the pump at the patient's request. To avoid overdose when PCA is used to cover postoperative pain or background pain in the burn ICU, it is important that family members or other visitors do not activate the PCA for the patient. Nilsson and colleagues evaluated the use of PCA with morphine to control burn-related background pain and pain associated with mobilization.[162] Background pain was adequately controlled, but even a double PCA dose given in anticipation of mobilization was not sufficient to control the associated increased pain. Although subcutaneous administration is generally to be discouraged in burn patients, Shipton and others reported safe and effective control of background pain with PCA morphine administered subcutaneously.[163]

Fear related to a traumatic injury and apprehension associated with pain enhance the perception of pain and make it more difficult to control. Pain is most effectively treated if aggressive measures to control pain are accompanied by consideration for the patient's anxiety. Complaints of pain should not be attributed solely to anxiety, however.

Patterson et al.[164] reported that in a double-blind placebo-controlled study of 79 patients, 1 mg lorazepam significantly reduced procedural pain ratings in those patients with high baseline pain, but did not reduce baseline trait anxiety. In a survey of the use of antianxiety drugs in burned children, 72% received lorazepam at a dose of 0.03–0.05 mg/kg or higher every 4 hours for much of their initial hospitalization.[165] Lorazepam provided aid in anxiety control with essentially no side effects.

Occasionally the quality of pain control will deteriorate to the point that changes in drug dose or selection must be changed to maintain adequate analgesia. A variety of mechanisms can account for difficulty or deterioration of pain control by standard protocol (Table 64.4). Also, intubated patients requiring mechanical ventilation present an additional challenge for managing pain control.

Burn patients poorly controlled with increasing doses of morphine have benefited from substitution of methadone.[130] As discussed earlier, in addition to μ opiate receptor agonist activity, methadone is an NMDA antagonist and inhibits amine uptake similar to tricyclic amines.[166] These properties reduce central sensitization and hyperalgesia that are not sensitive to morphine. Methadone reduces a neuropathic component of pain that often develops with healing of burn wounds.

Table 64.4 Factors Complicating Quality of Pain Control

- Repeated pain of daily wound care
- Intubation for mechanical ventilation
- Physical therapy range of motion and exercise therapy
- Postoperative pain
- Wound infection
- Tolerance to narcotics
- OIH
- Development of neuropathic pain
- Exaggerated anxiety
- Post-traumatic stress disorder

α_2 Adrenergic agonists represent another class of drugs that may dramatically improve pain control in patients no longer controlled with morphine. Clonidine has been found effective specifically in burn patients poorly controlled by large doses of morphine.[167] Clonidine is inexpensive, and bioavailability is very good when given via nasogastric tube. Fagin and colleagues compared sedation of burned pediatric patients with midazolam or dexmedetomidine infusions. Patients receiving dexmedetomidine were treated for an average of just over 3 weeks. They found sedation more effective with dexmedetomidine and with less hypotension.[168] Caution is necessary when giving α_2 adrenergic agonists to acute burn patients, however. If the patient is hypovolemic and blood pressure is maintained by increased sympathetic tone, administration of clonidine or dexmedetomidine can result in hypotension. In pediatric patients this may be treated by volume administration, but adults, especially those with coexisting disease, may need prompter treatment with vasoactive drugs while hypovolemia is corrected. Dexmedetomidine can also be helpful when increased doses of morphine are ineffective. It is more expensive than clonidine but sedation can be more easily titrated with alterations of rate of intravenous infusion.

Not all patients respond in the same manner to analgesics, and it is necessary to have alternative choices when pain control is especially challenging. Ketamine is an effective NMDA receptor antagonist, and, as a result, it can reduce central sensitization and improve analgesia for patients with neuropathic pain or who are experiencing OIH. Subanesthetic doses (0.1–0.3 mg/kg as bolus or 0.1–0.3 mg/kg per hour infusion) have been found to improve pain scores and reduce perioperative narcotic requirement.[169] We have found low-dose ketamine infusion helpful in patients with poorly controlled pain and inadequate response to methadone and α_2 adrenergic agonists (unpublished observation).

Analgesia for Procedures

Burn patients require frequent painful procedures to facilitate healing of their wounds. Among others, these include initial wound débridement, daily dressing changes, range of motion and exercise therapy, wound staple removal, and placement of intravascular catheters. Providing safe and effective sedation and analgesia for these procedures can be challenging for a number of reasons (Table 64.5).

Poorly controlled pain can make it difficult to accomplish a procedure effectively or safely and increases anticipatory anxiety, which can impair patient compliance and may contribute to behavioral morbidity such as post-traumatic stress syndrome.[170] Effective pain control in adults can often be sufficient to reduce anxiety. In pediatric patients, however, anxiolysis is also needed. For especially stressful procedures, most pediatric patients must be rendered insensible. For this reason, the popular term "conscious sedation" is inaccurate and misleading when treating pediatric patients. A very young patient who is aware of the procedure will resist enough to make the procedure difficult or less safe, and the anxiety associated with this experience makes future

Table 64.5 Challenges of Sedation and Analgesia for Burn Procedures

- Intense but brief pain requiring rapid onset and short duration of drug effects to avoid overdose or delayed recovery
- Lack of intravenous access, especially for outpatient care
- Nutritional requirements for large burns preclude frequent fasting periods for deep sedation
- Exaggerated anxiety states
- Staffing resources may limit availability of personnel credentialed to provide deep sedation

Table 64.6 Risks of Deep Sedation for Burn Procedures

- Decreased respiratory drive (hypoventilation or apnea)
- Upper airway obstruction
- Difficult airway (difficult intubation and/or difficult mask ventilation)
- Decreased airway reflexes
- Aspiration after emesis
- Cardiovascular depression

procedures more difficult. The level of sedation and analgesia required in this situation cannot accurately be described as "conscious sedation." A more accurate descriptive term is "moderate or deep sedation for procedures." The depth of sedation must be individualized depending on the intensity of the pain associated with the procedure and the patient's maturity, level of anxiety, and pain tolerance.

Clinical needs of patients presenting for burn procedures vary widely from outpatient care of small superficial burns to inpatients with extensive burns who require intensely painful dressing changes and wound care. Additionally, availability of staff credentialed to provide deep sedation varies from hospital to hospital. In Europe and elsewhere many burn centers are staffed by anesthesiologists who can provide general anesthesia at the bedside. In the United States burn centers are staffed by surgeons, and, with some exceptions, anesthesiologists may not always be available for these procedures outside of the operating suite. It is not possible to describe a protocol that is appropriate for all centers. Each institution must recognize the challenges faced in controlling pain during burn procedures and plan care to address these challenges with the resources available.

Minor injuries treated with outpatient procedures may need very little medication for preparation. Children may benefit from low doses of benzodiazepines and/or opiates. More extensive outpatient procedures become progressively more problematic as the intensity of pain and associated anxiety increase. Several effective protocols for delivery of moderate sedation for procedures have been published involving a variety of drugs and routes of administration.[122,127] The ideal pharmacological treatment would be easily administered in a palatable form, produce intense analgesia with a rapid onset, have a relatively short duration of action, and produce minimal side effects. Most drugs in current use will produce prolonged sedation when given in doses that prevent most of the intense pain during wound care. On a daily basis, this prolonged period of sedation can interfere with nutritional support and other therapies. In the outpatient setting without an intravenous catheter, the most common technique is to give a preprocedural fixed dose of an analgesic with or without an anxiolytic by the oral, transmucosal, or intranasal route. Fentanyl citrate is available as a flavored Oralet to administer by the oral transmucosal route. The oral transmucosal route has the advantage of direct absorption into the systemic circulation, which bypasses the first-pass hepatic clearance effect and improves its bioavailability.

Sharar and colleagues have compared oral transmucosal fentanyl citrate with hydroxymorphone[122] and oxycodone[171] and found similar analgesic and sedative efficacies. Humphries et al. found oral ketamine to be effective.[172] In pediatric patients prior to dressing change, Borland and colleagues compared analgesia and sedation with morphine administered orally and fentanyl given intranasally.[173] Although both were effective, intranasal fentanyl was more palatable and had a much more rapid onset. Although these regimens provide significant analgesia, pain control is often not optimal. It is difficult to provide sufficient analgesia with enterally administered drugs to control intense pain without unacceptable risk of adverse effects, especially prolonged sedation. Remifentanil administered intranasally is an attractive alternative. Remifentanil is an ultra-short-acting opioid rapidly metabolized by plasma esterase.[174] In our institution 5–10 μg/kg of intranasal remifentanil enhanced the effectiveness of oral transmucosal fentanyl as judged by pain scores and the subjective evaluations of nurses and patients (unpublished observations) and did not delay recovery. The ultra-short duration of action allows rapid recovery, which reduces risks of sedation and may improve patient satisfaction.

When patients have an intravenous catheter in place there are many more treatment options that allow more profound analgesia, more rapid onset with shorter duration of action, and, depending on which drugs are administered, reversal of drug toxicity with antagonists. Sedative and analgesic drugs can be given as a bolus with supplemental doses given as needed, as an infusion to be titrated or supplemented with bolus doses, and by PCA. Infusion of short-acting opiates such as remifentanil or alfentanil is a logical choice.

Deep sedation can be associated with the risk of serious adverse events, including mortality (Table 64.6). These include airway obstruction, depressed airway reflexes and respiratory drive, and hemodynamic instability. Loss of consciousness with most sedatives causes reduced pharyngeal tone and airway obstruction of varied degree depending largely on the patient's anatomy.[151] If this is not recognized or attempts to open the airway are not successful (operator skill or difficult patient anatomy), hypoxia can result. An airway exam is a critical part of the preprocedure evaluation, and a sedation plan must take into consideration potential difficulties with airway and respiration. Obstruction due to laryngospasm can be very difficult to relieve and, in extreme cases, may require muscle relaxation and intubation. Hypoxia can also result from hypoventilation due to depressed respiratory drive. If airway reflexes are depressed, aspiration of gastric contents may occur when passive reflux or active vomiting occur. In addition, deep sedation can cause loss of sympathetic tone or direct cardiovascular depression. These effects can lead to morbidity due to hemodynamic instability (Table 64.7).

Table 64.7 Organizational Recommendations for Provision of Moderate or Deep Sedation for Procedures

1. Preprocedural evaluation of the patient, including airway exam
2. A documented plan for sedation and monitoring
3. Availability of equipment for continuous monitoring of breathing effort, airway patency, oxygenation, and circulation
4. A designated practitioner with documented airway skills whose primary responsibility is to administer the sedative drugs and monitor the patient during the procedure and during recovery
5. Personnel administering and monitoring sedation cannot be the same individual performing the procedure and can do other tasks only for brief intervals
6. Resuscitation equipment must be immediately available

Ketamine has been widely used as a sedative and analgesic for painful procedures in burn patients. The properties of ketamine described above make it a nearly ideal drug for use during stressful procedures, especially for children. As Ketamine has recently been described as possibly the first choice for anesthesia in burn patients.[175] Several qualities make ketamine an effective drug for stressful procedures. It is a potent analgesic, and its inhibition of NMDA receptors reduces hyperalgesia associated with morphine tolerance.[176] Increased salivation with ketamine can be controlled with glycopyrrolate.

The combination of an opiate with a benzodiazepine is another common choice for sedation and analgesia. Adverse events associated with deep sedation with these agents during endoscopy[177] led the Joint Commission to set guidelines for sedation that included restrictions regarding who can administer deep sedation. A controversy developed since the American Society of Anesthesiologists (ASA) defines general anesthesia as a condition induced by medication that results in the patient's inability to respond purposefully to verbal communication.[178] Since hospital guidelines restrict administration of general anesthesia to anesthetists, this interpretation precludes personnel other than anesthetists from administering deep sedation. Requiring the presence of an anesthesiologist or certified nurse anesthetist during moderate or deep sedation creates problems in that there are not enough anesthetists available to provide coverage for all procedures and the added professional fees significantly increase the costs of these procedures, often, it is argued, without proportional added benefit. Numerous studies have demonstrated that with competency-based credentialing along with appropriate planning and organization, moderate and deep sedation can be administered safely by nonanesthetists.[179,180] Components of a suitable program are listed in Table 64.7. Currently (Joint Commission update from July 10, 2010), Joint Commission standards require that personnel "permitted" to administer sedation must be able to rescue patients from the effects of sedation that intentionally or unintentionally result in a state of general anesthesia. These standards leave it up to each organization to decide how to determine which personnel are permitted to administer moderate or deep sedation. Regional regulations as well as interpretation vary and change over time. To be compliant, each institution must examine current regulations to determine which personnel are permitted to provide sedation and monitor patients during procedures. Departments of anesthesia are a logical and convenient resource for training, organizing, and monitoring sedation programs. In our institution (Shriners Hospital for Children, Galveston), competency-based credentialing for sedation privileges requires knowledge of hospital policy regarding sedation guidelines, current advanced cardiac life support (ACLS) or pediatric advanced life support (PALS) training, passage of a written exam over self-study didactic material, and successfully managing the airway of a minimum of five patients in the operating room under general anesthesia each year. Educational material, supervision of airway training, and oversight of adverse events is provided by personnel from the anesthesiology department. Medication errors and adverse events are monitored, and adverse events are to be reviewed during monthly hospital morbidity and mortality conferences. Owens described the safe and effective implementation of a similar protocol at the Northern California Shriners Hospital (Table 64.8).[180]

PCA is a technique that can effectively avoid many problems associated with titrating sedatives and analgesics during stressful procedures since the patient remains conscious and in control of dosing. Requirements and limitations of PCA were described earlier. During procedures rapid and intense changes in pain level are experienced. Adequate control in these circumstances requires a rapid onset of effect. Narcotics such as remifentanil, alfentanil, and fentanyl are more appropriate. A number of studies have described a variety of PCA protocols for burn procedures. Prakash and others performed a dose-response study with fentanyl with burn patients during dressing change.[181] They found that after a loading dose of 1 μg/kg the optimal demand dose was 30 μg with a 5-minute lockout period. Sim and colleagues gave a 1 mg loading dose of alfentanil followed by an infusion of 200–800 μg/h. Demand doses of from 200 μg to 400 μg with a lockout time of 3 minutes produced comfort and mild sedation during dressing change.[127] Nilsson and others compared analgesia with a mixture of propofol and alfentanil administered either by PCA or titrated by an anesthesiologist.[182] Patients preferred PCA to titration by an anesthesiologist in spite of the fact that PCA doses were lower and bispectral index scores (BIS) higher than when the patients were sedated by an anesthesiologist. Coimbra and others used BIS scores to individualize PCA propofol doses for patients during burn dressing changes.[183]

Itch Medications

Itch is one of the most common sequelae of burn injury.[184] Field et al. reported that pruritus occurs in 87% of patients who have a burn injury.[185] Itching will often last for many years.[186] Although it is thought to be secondary to the injury of the skin, the possibility that morphine is adding to the itch needs to be kept in mind. Itch can definitely influence the quality of life and duration of rehabilitation required. Scratching further injures the skin, leading to graft loss and skin breakdown requiring sometimes further grafting. In addition, it is very common for the patient to have a significant problem exercising or sleeping if the itching is intense. Several classes of medications can be used to treat itch but very few real comparative studies have been done. The approaches to treatment are as varied as the presumed causes of the itching.[187] Pruritus associated with burns is

poorly understood, so blocking histamine, kinins, proteases, prostaglandins, substance P, and serotonin (5-HT) release and receptors have all been tried. The first line of defense is a series of moisturizing body shampoos and lotions to alleviate itching due to dry scaly skin. If these measures are inadequate in providing relief, Preparation H, which contains a local anesthetic has been advocated. In contrast topical benzocaine is not effective in treating itching even though it reduces pain.[188] Topical steroids are not usually used until the skin is well healed because of the infection risk. They are effective in controlling the itching. Only a small area of skin should be treated with steroids in order to reduce the risk of systemic adrenal suppression. Antihistamine creams such as Benadryl (diphenyl hydramine) are available. Other topical medications include colloid and oatmeal baths.[189] Newer topicals are tricyclic antidepressants such as doxepin.[190,191] The major side effect of this preparation is that too much is absorbed, with resultant oversedation. Several nonpharmacologic approaches have been used. Massage seems to have a very beneficial effect.[185] In addition Hettrick et al. reported that transcutaneous electrical nerve stimulations (TENS) considerably reduced the perception of itching in nine adult patients compared to controls.[192] The most recent is the use of pulse dye laser[193] and electroacupuncture treatment[194] to reduce pruritus in burn scar. Silicone gel sheeting has been reported to also be effective.[195]

Usually the antihistamines are given orally. Using only one antihistamine results in complete relief for only 10% of patients.[196] Diphenhydramine PO 1.25 mg/kg every 6 hours is often the first oral medicine used because of its sedative effect as well as helping control the itch. A few children respond better to loratadine, which is much longer acting. If itch is not well controlled using only one, then another class of antihistamine can be added, such as hydroxyzine PO 0.5/kg every 6 hours. Last, if the itch is still not well controlled, an antiserotonergic agent, such as cyproheptadine 0.1 mg/kg every 6 hours, can be added, scheduled so that one of the medications is given every 2 hours. This is targeted against the 5-HT_3 receptors. Care must be taken to not use the cyproheptadine with patients who are on serotonergic antidepressants.

Gabapentin (10–35 mg/kg per day in divided doses) is becoming a reliable safe standard for treating severe itching following burn injury.[197] The typical individual dose is 5 mg/kg during the day and 10 mg/kg at bedtime. Comparative studies using gabapentin have demonstrated its efficacy. Goutos et al. demonstrated that it was usually more

effective than antihistamines.[198] In the experience of the Shriners Hospital in Galveston, a daily dose of 30 mg/kg is often needed in three divided doses. Recently a retrospective study was done with pregabalin with promising results. For many of those who fail gabapentin therapy, pregabalin has been found to be effective.[199]

Another new class of medications to be used in chronic itching is naltrexone. First LaSalle et al.[200] reported some improvement in itch with naltrexone. Then Jung et al.[201] reported a significant decrease in itching sensation and scratching from 9 to 5.9 on a 10-point scale after 2 weeks of treatment with 50 mg of naltrexone at night, when it was given with the usual antihistamines. Side effects of headache and nausea were noted in many of the patients.

Development of Protocols for Comfort

Interest in pain management of burned patients has been a high priority in the treatment of burns only in the past 10–15 years. Several institutions have developed pain and anxiety management protocols. In 1995, the *Journal of Burn Care and Rehabilitation* published a special issue devoted to then-current practices of systematic treatment of burn pain. In the first edition of this book in 1996, we reported the initial use of a burn pain protocol at the Shriners Burns Hospital in Galveston; the protocol currently used there is reviewed and updated every few years.[2] In 1997, a Boston group headed by Tompkins published a 3-year history with a similar protocol.[202] They incorporated a distinction in treating ventilated acute patients differently from nonventilated acute patients. Most recently a national consensus on pain management has been reached. Ulmer[203] brought these recommendations to the attention of the burn community in a 1998 article. The most recent version of the Shriners Burns Hospital protocol is shown in Table 64.9 and includes management of the most common discomforts of burned patients. It is extremely important to continue to improve these protocols as more is learned about the treatment of pain in burn injury.

Nonpharmacologic Therapies in Burned Patients

As discussed, there is a strong interaction between psychological and physiological factors contributing to the pain experience. Anxiety in particular is prevalent in patients with burn injuries and is known to exacerbate acute pain. Nonpharmacologic therapies play an important role in addressing the psychological factors that exacerbate pain as well as having a direct impact on the pain itself.[204]

In American Burn Association practice guidelines for the management of burn pain, Faucher and Furukawa in 2006 argued for the use of nonpharmacological techniques as part of the standard of care for burn centers.[205] In understanding how nonpharmacologic approaches can be used with burn pain, it is important to discuss how behavioral principles contribute to the patient's experience.[206] In terms of classical (stimulus–response) conditioning, patients (particularly children) often develop a conditioned anxiety response to stimuli associated with painful burn procedures. One study demonstrated that the simple event of seeing a healthcare worker who is wearing scrubs was enough to elicit a fearful response in burned children.[207] In terms of operant (reinforcement) conditioning, patients can be thought to gain reinforcement by avoiding or escaping painful procedures, perhaps by screaming enough to terminate treatment, or to obtain some sort of reinforcement from the staff by showing pain behaviors. Between the stimulus that precedes pain and the pain response that follows, there is the cognitive processing of pain. Such cognitions can be modified, as can behavior, and can influence how much pain a patient experiences. Classical and operant conditioning principles and modifying internal cognitions have a bearing on how nonpharmacologic approaches are applied to burn pain. A series of articles by Thurber and Martin and colleagues[208,209] provide an extensive discussion of the theory and application of such principles to controlling pain during pediatric wound care.

Classical Conditioning

If the stimuli associated with a painful procedure have been conditioned to evoke anxiety or pain, then a logical goal is to reduce the impact that the stimuli have on the fear/pain response. An obvious environmental intervention is to make the wound care procedure setting as minimally threatening as possible. For children this might involve making the hydrotherapy tank a "bath tub play area" with age-appropriate floating toys and the like. Cheerful or relaxing music, a warm room, and pleasing art on the walls can also lessen the threatening nature of a typical tank room. Providing the patient with choices in music or art gives a greater sense of control over the procedure. Some clever children's hospital staffs have turned their magnetic resonance imaging (MRI) scanner into a "cave in a jungle"; obviously such a setting will be less threatening to a child than the typical scanner. Similar principles can certainly be applied to burn care.[208,209]

There are other implications from classical conditioning, the most important of which is that the best way to prevent a conditioned pain response is to optimize pain control in the first place. By aggressively and proactively treating pain, the contributions of conditioned anxiety will be minimized. Conversely, once a patient undergoes a procedure with inadequate analgesia, concomitant anxiety can be extremely difficult to treat. Since it is rare that a child who requires wound care would not find the setting anxiety-provoking, burn units will often use an anxiolytic at the first dressing change to prevent this anticipatory anxiety.

Any attempts to enhance a patient's control over the situation can minimize anticipatory anxiety. Patients tell us that the hospital environment, unlike any other environment, strips a person of control. A functioning, independent adult prior to an injury is suddenly dependent on others for almost all aspects of care, including when and what they eat, what medications they will be taking, the painful procedures they will undergo, and their daily schedule. In addition, burn care can be quite complicated, and the medical information that patients are required to process can be overwhelming. When an adult or child feels out of control, anxiety increases. We can enhance a patient's sense of control over the hospital environment by allowing them to have input into their care as much as possible. For

Table 64.9 Shriners Hospitals for Children (Galveston): Comfort Protocol for Children

BACKGROUND PAIN

Inpatient

Consciousness should be noted on the vital signs flow sheet.

- IV Morphine dose: 0.03–0.06 mg/kg/dose IV q2–4h (scheduled while awake)
- PO Morphine dose: 0.1–0.3 mg/kg/dose PO q4h (scheduled while awake)

Note: Begin bowel prep program simultaneously with beginning opioids: prune juice, docusate, etc.

- If requires longer-acting pain medicine
- Methadone dose: 0.1 mg/kg/dose PO q6–8h, then reduce frequency to q12h to taper off

Outpatient:

- Oral acetaminophen 15 mg/kg/dose PO q4h
- Tramadol 1–2 mg/kg/dose q 4–6 h
- If inadequate, add hydrocodone 0.2 m/kg usually in combination with acetaminophen
- Ibuprofen PO 10 mg/kg/dose PO q6h
  - The antiplatelet effects of ibuprofen last as long as the drug is still in the body.

Pre-Wound Cleaning:

- Oral transmucosal Fentanyl (Actiq) dose: 10 µg/kg/dose rounded to nearest available dose. Oral transmucosal Fentanyl is available in 200 µg, 400 µg, and 600 µg doses
- IV Morphine dose: 0.03–0.06 mg/kg/dose IV q 2–4 h (scheduled while awake)
- PO Morphine dose: 0.1–0.3 mg/kg/dose PO q4h
- PO hydrocodone 0.2 m/kg usually in combination with acetaminophen 10–20 mg/kg
- Benzodiazepam added: diazepam 0.1 mg/kg or lorazepam 0.05 mg/kg.

Pre-Rehabilitation Therapy:

- At request of therapist, PO hydrocodone 0.2 m/kg usually in combination with acetaminophen 10–20 mg/kg given with diazepam 0.1 mg/kg

Postoperative Pain:

Option A:

- IV Morphine via PCA pump (if >5 years), total dose 10–20 mg/kg per 4 h.

Option B:

- Attendant administered bolus, slow IV push morphine 0.03–0.05 mg/kg per 2 h (hold if level of responsiveness is decreased)

Neuropathic Pain

- Pain which is described as tingling, or burning in nature; like fire ants or ants walking with cleats; due to nerve entrapment, nerve damage, and venous congestion
- Pain often does not respond to opiates
- PO gabapentin (Neurontin) 100 mg, 300 mg, 600 mg
- Gabapentin dose: 5–30 mg/kg/dose q8h
- PO pregabalin (Lyrica) 50 mg, 100 mg
- Not indicated for small children
- Begin with 50 mg tid; then titrate up to 100 mg tid.
- PO amitriptyline 0.5–2 mg/kg. Do not advance to 2 mg/kg without checking blood level. Do not give with fluoxetine or sertraline; check PR interval on EKG

ANXIETY

Inpatient

- Before using anxiolytics address pain management
- PO lorazepam 0.05 mg/kg/dose q4h (scheduled while awake)

Outpatient

- If muscle relaxation is also desired, PO diazepam 0.1 mg/kg/dose q8–12h

ACUTE STRESS DISORDER OR POST-TRAUMATIC STRESS DISORDER SYMPTOMS

- PO Fluoxetine usually administer in the morning

≤20 kg	2.5 mg
≤40 kg	5 mg
>40 kg and <60 kg	10 mg
>60 kg	20 mg

- PO imipramine 1 mg/kg and increase slowly to 3 mg/kg as needed after checking concentration (usually used in young children where duloxetine could not be easily dosed)
- PO sertraline 1 mg/kg. Available as a 25-mg, 50-mg, and 100-mg tablet. Begin with 25 mg once daily; titrate dose as needed
- Approved for children 6 years old and older

Note: watch for serotonin syndrome characterized by agitation, confusion, rapid heart rate, dilated pupils, twitching muscles, muscle rigidity, heavy sweating

MANAGEMENT OF AGITATION AND HALLUCINATIONS NOT ASSOCIATED WITH ASD AND PTSD:

- PO risperidone (Risperdal)
- Children <5 years: Oral initial dose 0.1–0.2 mg once daily at bedtime
- Children ≥5 years and adolescents: Oral initial dose 0.2–0.5 mg once daily at bedtime; may titrate to the lowest effective dose every 1–2 days
- PO quetiapine (Seroquel)
- Children ≤10 years and adolescents ≤17 years: 25 mg twice daily on day 1; increase to 50 mg twice daily on day 2, then increase by 100 mg daily (administered twice daily) each day until 200 mg twice day is reached on day 5. May further increase up to 600 mg daily in increments of ≤100 mg daily. Usual dosage range: 400–600 mg daily; maximum: 600 mg daily

MANAGEMENT OF SLEEP NOT ACCOUNTED FOR AS ASD OR PTSD:

- Instruct in sleep hygiene
- Rule out pain and anxiety and itching
- PO Benadryl 1– 2 mg/kg at bedtime
- PO melatonin 0.01 mg/kg or 3 mg at bedtime
- PO zolpidem (Ambien) 5 or 10 mg with side effect of sleep walking
- PO Trazodone 1.5–2 mg/kg/dose qh

Reference: *Pediatric and Neonatal Dosage Handbook*, 21st Edition, Lexi-Comp

example, adults and adolescents may be able to work with the nurse to determine the day's schedule, to specify techniques that they have found make wound care go more smoothly, to choose to eat in the cafeteria instead of having meals served in their room, and to choose the music played during wound care. Children should be offered "forced choices" as often as possible to create a sense of control. Forced choice is a technique whereby a child is given two reasonable options and allowed to choose the one they prefer. For example, a child might be given a choice of whether to have wound care before lunch or after lunch, or whether he or she prefers to take medicine with apple juice

or milk. The key is to only provide two options and to ensure that the healthcare provider and parent are agreeable to whichever option is chosen. Kavanaugh has described how giving children more control during procedures can reduce the effects of learned helplessness and enhance pain tolerance.[210] He reported that children who were provided with the opportunity to participate in and make decisions about their wound care showed lower depression, anxiety, hostility, and stress scores than did controls.

Finally, psychological preparation can also play an important role in enhancing control and minimizing anticipatory anxiety. Patients can be provided with procedural or sensory preparatory information.[211,212] When providing procedural-based preparatory information, patients are explained the mechanics of their procedure (e.g., "we will unwrap your bandages, wash your wounds and débride necrotic skin, apply silver sulfadiazine cream, and then rewrap your dressings"). When providing sensory information, patients are prepared about what they might feel during a procedure ("You will likely feel a pulling sensation as we remove your dressings and a stinging sensation when we wash your wounds with an antiseptic"). Such information is usually helpful to patients, but it must be emphasized that some patients prefer to have as little information as possible, given their particular coping styles. It is best to follow a patient's lead in determining how much detail to provide when explaining upcoming procedures.[206]

One study found that a multimodal approach that combines procedural preparatory information and distraction was more effective at reducing pain, distress, and length of treatment than distraction alone.[212]

Another approach based on classical conditioning is relaxation training. Patients can be taught deep relaxation and imagery prior to undergoing painful procedures. The rationale is to counteract the anxiety stimulated by preprocedural stimuli with the relaxation response. If anticipatory anxiety is minimized with deep relaxation, the potential for a cyclical interaction between anxiety and acute pain is reduced. Recent topographic electroencephalographic (EEG) mapping during relaxation and imagery has shown changes in EEG activity that are similar to stage 1 sleep. Imagery also appears to activate the hippocampus, which is involved in emotion regulation.[213,214] Clinicians have also reported success with administering massage therapy on nonburned areas immediately prior to wound care.[215] Children who received 15 minutes of massage therapy reported lower pain scores during wound care than did a control group. A number of studies have applied relaxation training and stress inoculation techniques, as well as some of the behavioral techniques discussed later, to reduce burn pain.[216–224] One study even found that the simple technique of jaw relaxation practiced 20 minutes prior to dressing changes can significantly reduce pain and anxiety during and after the procedure.[225]

Operant Conditioning

The consequences that patients receive for showing pain can have implications for pain control. Since almost all burn procedures are extremely aversive, it will be the natural tendency of patients, particularly children, to be motivated to escape such events. Staff members who allow patients to terminate procedures might be reinforcing and potentially exacerbating such escape behaviors. When left unchecked this process can lead to a distressed patient becoming combative rather than tolerant of procedures. While such avoidance behavior should (more importantly) alert the staff that analgesia is inadequate and that the many potential pharmacologic protocols discussed earlier should be invoked, it can also occasionally suggest a need for further limit setting. Rewarding a patient with rest once a stage of wound care is completed, rather than stopping the procedure based on pain behavior, can be a useful means to minimize such escalating behavior. Children can also be given a predetermined number (usually five is adequate) of "timeout cards" that they can present at any time during wound care, each worth a 1-minute timeout or rest period. Once the cards are used up, they no longer have any timeouts. This technique can enhance their sense of control over the environment as well as ensuring that rest periods do not reinforce pain behaviors. Again, however, the goal of a burn team should be to provide enough preparation and analgesia in a preemptive fashion that the need for such escape behaviors does not develop in the first place.

Operant conditioning also has implications for the manner in which patients receive pain medication. When patients are medicated in response to pain behaviors, they are potentially receiving social reinforcement in terms of attention from the staff as well as the euphoric effects that the drugs might cause. This is one reason that, as mentioned earlier, it is far preferable that patients are medicated at regular time intervals rather than in response to their pain; the latter encourages them to complain more often in order to get the reward.[226] A similar application of operant principles is particularly important for the patient who excessively complains about pain out of emotional dependency needs, attention seeking, or in seeking the euphorigenic properties of the pain medications. In such patients, provided that adequate levels of pharmacologic analgesia have indeed been established, it may be important to extinguish pain behavior by ignoring it and simultaneously engaging the patient in distraction unrelated to pain. This is a model more consistent with that used for chronic pain but one that is occasionally useful for burn patients who seem to overreact independent of how aggressively pain is managed.[227]

Another common application of operant principles has to do with "token economies" for children. It can be extremely useful to reward children for successful completion of procedures by using star charts, prize boxes, or reinforcement schedules of this nature. Thus a child, upon completing a procedure, may receive a star in a grid that covers a week of burn care. Older children can use an accumulation of points to purchase a desired reward. Courage beads have also become popular in pediatric hospital settings. Differently colored beads are assigned to various painful or unpleasant procedures (e.g., wound care, physical therapy, X-ray, blood draws, etc.). Each time a child completes one of these unpleasant procedures, he or she receives a corresponding bead and adds it to a necklace. Both boys and girls have responded positively to these necklaces and often wear or display them as a source of pride. It is important that children are rewarded for completing procedures

rather than for "being brave" as the latter can serve as a subtle form of punishment to children; in other words, reinforcement should not be withheld if children act out and have a bad day during wound care as long as wound care is completed.[208,209]

One final application of operant principles that is borrowed from the chronic pain literature is the use of a quota system that rewards activity with rest. This is particularly useful with patients who are overwhelmed by therapies or who appear to have poor motivation. Patients complete predetermined quotas of activity that are within their capacity and then are allowed to rest. A baseline assessment determines what is within their capacity. For example, a patient who is trying to walk with burned legs might be instructed to walk until tired for three therapy sessions. The distance walked is recorded for those three sessions, the average is taken, and 80% of that average becomes the starting point. For example, the patient walks 50, 150, and 100 feet during three sessions. The average is 100 feet, and 80% of that is 80 feet. This (80 feet) becomes the starting point. Patients start at 80 feet and increase that amount by 5% (about 5 feet) each session. If they fail to meet a quota, they return to the last successful one. However they also quit when they reach the goal. They do not keep exercising even when they are having a "good day." This addresses the problem of pacing and overfatigue. Ehde, Patterson, and Fordyce have reported the successful use of the quota system with a number of patients with burn injury, both in terms of increasing therapy performance and reducing depression.[228]

Cognitive Interventions

How patients think about their pain can be regarded as a modifiable behavior and, in turn, can influence the degree of suffering they experience. As such, an important nonpharmacologic approach is to draw out the thoughts patients have about their pain and teach them to modify these thoughts accordingly. A particularly salient example is catastrophizing about pain. Catastrophizing thoughts include those such as "I cannot stand this pain," "I will never get better," or "The pain means I will die." Such catastrophizing thoughts have been associated with greater amounts of pain and less favorable health outcomes in a variety of studies. Patients can be taught to challenge and reinterpret such thoughts. Along the same lines, it can be useful to teach patients to reinterpret the meaning of their pain sensations. For example, the appearance of skin buds and enhanced pain sensation may indicate that a wound is healing and skin grafts may not be necessary.[206]

Under the rubric of cognitive interventions patients may be taught techniques to enhance their ability to cope with pain. Positive self-talk and imagery designed to facilitate coping during periods of pain are examples of this. Thurber and colleagues have described the *two-process model of control* as it relates to controlling pediatric burn pain.[209] In terms of primary control, the patient attempts to modify the objective conditions of the painful procedure, such as negotiating how and when a dressing change will take place. In secondary control, the patient makes adjustments so that he or she can better tolerate the difficult procedures (e.g., positive self-talk vs. catastrophizing). Thurber et al.[209] and Martin-Herz et al.[208] have published a two-part series on a conceptualization of psychological approaches to burn pain, as well as specific examples for treatment. Crucial in choosing an approach is the assessment of a person's coping strategies. Simply, most adult and pediatric patients have coping styles that fall on an approach-avoidant continuum. At one end of the continuum is the avoidant coping style in which patients prefer to turn away or be distracted during painful procedures. Any distraction technique described in this chapter would be appropriate for this group of patients. On the opposite anchor of the continuum are those with an approach coping style who seek information and like to be involved as much as possible in their care. In this group, having them participate in wound care and giving them as much information as they request will help to decrease their anxiety. If they are told to close their eyes, turn away, and distract themselves from the procedure at hand, their anxiety will only increase.

Distraction is another cognitively based approach to pain control. Processing pain requires a certain amount of conscious attention, and distracting such patients' attention can enable them to tolerate pain better. Movies, music therapy, and games have all been used with some success as distraction techniques for burn pain.[221,223,229] Music has the additional benefit of inducing a relaxation response.[220,230] One study found that music therapy significantly reduced pain and anxiety levels and muscle tension before, during, and after dressing changes.[231]

Augmented Reality

Another form of distraction-gaining attention is the use of *augmented reality* or *virtual reality* (VR) technology. Several researchers have reported on the use of immersive VR as a powerful analgesic.[229,232–242]

VR can immerse patients' attention in a computer-generated world and engage them in interaction with that world. These investigators indicate that VR can significantly reduce pain during wound care and physical therapy,[232] even relative to computer game distraction and television.[233,243] Recently Morris et al. conducted a systematic review on the use of VR distraction for reducing both pain and anxiety in acute burn pain.[244] They found nine studies that met their rigorous inclusion criteria. Results showed that VR distraction is most often used for burn wound care and physical therapy and as an adjunct to pharmacotherapy. When compared to pharmacotherapy alone, it appears that VR distraction is superior in reducing pain. Other interactive video-gaming technology that tracks body movements has also been shown to enhance participation and reduce pain and anxiety during physical therapy.[245,246]

Finally, one randomized controlled trial looked at the used of augmented reality in reducing acute procedural pain in burn patients.[247] Augmented reality overlays virtual images onto the physical world, rather than creating a complete immersive virtual world as in traditional virtual reality. They randomized 42 children between the ages of 3 and 14 years into either the experimental or control

condition and found that augmented reality significantly reduced mean pain scores. This technique shows promise as well.

Hypnosis

Hypnosis involves a blend of relaxation, imagery, and cognitive-based approaches. This technique deserves special attention because there are a number of reports on its use with burn pain, and, when it is effective, its impact on burn pain can be quite dramatic. There are more than 100 anecdotal reports in the literature indicating that hypnosis can dramatically reduce pain, and at least a dozen have been done with pain from burn injuries; however such studies lack control groups, standard measures of pain, or information about pain medications.[248] More recently, tightly controlled studies with reliable measures of pain have supported hypnosis as an effective nonpharmacologic approach to burn pain.[249,250] Patterson and Jensen have reported 12 controlled studies on chronic pain and 17 with acute pain indicating pain reduction; indeed, this modality is becoming far more scientifically acceptable.[251]

Patients with burn injuries are ideal candidates for hypnosis for a number of reasons. In a review of such factors, Patterson et al. listed motivation, regression, dissociation, and hypnotizability as factors that promote hypnotic analgesia on the burn unit.[252] Specifically patients who are faced with the excruciating nature of burn pain are motivated to engage in techniques such as hypnosis. The nature of a burn and its resulting care can cause a patient to become emotionally regressed (i.e., more dependent on the burn staff) and dissociated (i.e., removed from their emotions), and both of these factors seem to be associated with hypnotizability. Such factors likely account for the frequent dramatic effects that are seen with hypnosis during burn care. On the other hand, hypnosis clearly will not benefit some burn patients, and the degree to which patients are inherently hypnotizable (or not hypnotizable) almost certainly has some bearing on this issue.[252]

The protocol used by Patterson and colleagues[243–251,253–255] is to provide hypnosis prior to wound care and have nurses provide standard post-hypnotic suggestions during wound care. This approach is efficient for both the hypnotist and the nurses. Patterson et al. have recommended that hypnosis used in this fashion be an adjunct to, rather than replacement for, pain medication.[250] A randomized controlled trial by Wiechman et al. used this protocol for burn wound pain and found that hypnosis significantly reduced the affective component of pain when compared to an attention-only control group.[256] Furthermore Shakibaei et al. conducted a randomized controlled trial of hypnosis for reducing pain and flashbacks in burn patients.[257] They also showed that the hypnotherapy group had significantly lower pain ratings and fewer flashbacks than did the control group.

VIRTUAL REALITY HYPNOSIS

More recently, investigators have combined immersive VR with hypnosis in order to control burn pain. This approach has the advantage of not requiring a trained hypnotist to be present and appears to work as well as "live hypnosis."[255,257] The technology simply requires patients to open their eyes and watch the induction presented to them; minimal cognitive effort or skill is required. Delivering hypnosis in this way addresses several concerns of standard therapist-induced hypnosis. First, this standardized procedure allows for greater use in that it does not require a trained therapist to be present at each session. Second, with the visual images in front of them, it decreases the extent of cognitive effort required. This is important for patients who are taking opiate medications and cannot concentrate as effectively. It also helps those who are lower in visual imagery skills and therefore unable to visually imagine the scenes described by the therapist during traditional hypnosis. One clinical case series of 13 patients used hypnotic analgesia delivered through VR technology for patients with burn injuries. Pre- and postprocedure pain ratings were collected from patients undergoing painful wound care procedures over a 3-day period. There was a decrease in reported pain and anxiety, the need for opioid medication was cut in half, and there were no undesirable side effects. No randomized controlled trials have yet been published.

OTHER APPROACHES

There is some evidence that TENS can be effective with burn pain,[258] but we are aware of only one study of this nature. Massage therapy has been reported to be useful in reducing burn pain.[259] We are unaware of any studies on the efficacy of acupuncture on burn pain although this modality has been useful in controlling pain from a variety of different etiologies. The acute nature and variable distribution of burn pain may make acupuncture a challenging modality to apply to this problem.

For patients in the post-hospital, long-term rehabilitation phase, nonpharmacologic approaches from physical and occupational therapists become critical. Stretching, strengthening, increasing activity, and hot/cold therapy may all become instrumental in enhancing pain control during the rehabilitative stage.

EMPIRICAL SUPPORT

Recently there have been several rigorous systematic reviews of studies that have focused on both pediatric and adult nonpharmacological pain management strategies. In a review of risk factors for anticipatory distress to painful medical procedures, Racine and colleagues found 77 articles that addressed this issue. Their review concluded that the factors most relevant in increasing anticipatory distress in children undergoing painful medical procedures are child psychopathology, difficult child temperament, parental distress, previous painful events, a parent's anticipation of distress, and anxious disposition in parents. Many of these factors are amenable to intervention with the techniques mentioned in this chapter. It appears that parents' presence during painful procedures is neither inherently good nor bad, but is instead entirely dependent on the characteristics of the parents and their ability to provide a calming presence. A focus on training parents in distress-reducing behaviors is warranted.[260] Hanson, Gauld, Wathen, and MacMillan conducted a systematic review of nonpharmacological interventions for acute procedural pain in pediatric patients with

burn injuries.[261] Using a systematic review of methods of the U.S. Preventative Services Task Force, they found 12 articles that met the study criteria and seven of the 12 articles were rated as "fair or good." They categorized these 12 articles into child-mediated interventions, parent-mediated interventions, and healthcare provider-mediated interventions. Of the child-mediated interventions, both VR distraction and stress management showed promising effects. Of the healthcare provider interventions, massage therapy and optimizing patient control during wound care were effective at relieving wound care pain when compared to a control group. Parent-mediated interventions were not found to be effective, and, in fact, one study showed an increase in childrens' distress when parents were present.[262] Although the study designs in these interventions were rated as poor, the findings are consistent with those reported by clinicians, in that parental presence during painful procedures can either help or hurt a child depending on the parents' affect and ability to soothe their child. This is a difficult intervention to study, but one that deserves more attention in this era of family-centered care and the emphasis on increased parental involvement in a child's care. It would be a tremendous benefit to the field if we could determine which variables are necessary to facilitate a positive parental presence and which variables serve as barriers to the success of this practice. Hanson et al.[261] acknowledged that it is very difficult to conduct randomized controlled trials with adequate sample sizes in this population, but we must strive to find empirical support for the techniques that we choose.

De Jong et al. also conducted a systematic review of the literature for nonpharmacological interventions for acute burn pain in adults.[263] They found that hypnosis was the most frequently studied intervention and that the majority of the studies on hypnosis showed a beneficial effect when compared to a control group. They concluded that hypnosis seems to have a strong impact on the affective component of pain. Their review also showed beneficial effects of distraction relaxation and found that any technique that enhances a patient's control over the situation is beneficial.

The authors of these systematic reviews provided directions for future researchers that would advance our knowledge of the effectiveness of nonpharmacological interventions. These suggestions included the need for large sample sizes, documentation regarding study response rates and randomization methods, experimental control for premorbid psychosocial variables, details on instructions given to patients, cost outcomes, and assurance of treatment integrity/adherence.[261,264]

Conclusion

The state of the art in burn pain management would seem to be based more on personal bias and tradition than on a systematic, scientific approach. In addition, the number of pharmacokinetic studies of pain-relieving drugs of any kind in young children is virtually nil. Since approximately 35% of all burn injuries occur in children under 16 years of age, with a great majority of these occurring in children under 2 years of age, we have almost no information on which to base the use of pain-relieving drugs in burned children. It is no wonder that Perry and Heidrick[264] found great disparity in what burn care staff would order or administer to a young child as compared to an adult with burns of similar size and area of distribution on the body. More pharmacokinetic studies in both adults and children with burn injuries must be initiated.

Similar to the lack of conclusive data about the use of the various opioids or anxiolytic agents is the scarcity of scientific data to recommend any of the nonpharmacologic techniques. However significant progress has been made just since the previous edition of this book 5 years ago. Most burn centers recognize anxiety as contributing to patient discomfort and are beginning to treat both anxiety and pain. Standardized protocols such as the guidelines (see Table 64.9)[2] modified for starting doses of medication from the Shriners Burn Hospital in Galveston are being disseminated. Nonpharmacologic techniques are more frequently included in a center's repertoire of tools for managing anxiety and recognized as a definite adjunct to pharmacotherapy. The major problem currently with these techniques is that they are personnel intensive and therefore are often not offered or reimbursed in the current managed care environment in the United States.

How, then, can we provide the "best" pain management for a burned patient? Probably the first answer to that question is vigilance in assessment and flexibility in treatment. Patients show great individual variation in their responses to the variety of agents and modalities presented. A successful approach with a burned patient requires that healthcare personnel understand the pain associated with the different depths of wounds, the phase of the healing process, and the components of the pain response. For the burned patient during the initial 3–7 days, the more superficial areas give rise to moderate or severe pain, while the full-thickness areas contribute less to the overall pain response.[11] Although moderate to severe pain is usually related to procedures or physical therapy, background pain (or pain at rest) is usually described as mild or very mild but may be exacerbated by emotional concerns and anxiety. By the second week post-burn, the moderately deep partial-thickness burn with its multitude of skin buds accounts for the majority of the moderate to severe pain. In many burn centers, deep dermal and full-thickness burns are excised and grafted between the third and tenth days post-burn. Although this often eliminates the severe pain associated with wound débridement during the second and third week, donor sites are often as painful as the areas of more superficial burns were initially. Dressing changes 3–5 days post-grafting also may be accompanied by the removal of sutures or staples, a procedure that is usually described by patients as excruciatingly painful. By the third or fourth week, if the wounds are not mostly healed, anxiety and depression may cause a patient to perceive increased levels of pain. And, within a single phase of recovery and within a single patient, pain frequency and intensity will vary from day to day. A fixed and inflexible approach to treatment is likely to overmedicate on one day and undermedicate the next.

To avoid over- and undermedication in adults, regimens that allow patients to control their own therapy seem most appropriate. This is very important for adults and teenagers, but children also can benefit from having this control. PCA can be used safely by many children and should not be

disregarded as a tool on the basis of age alone. For procedural pain, patient control regimens may include self-administered nitrous oxide, PCA, hypnosis, a variety of behavioral approaches, or a combination of these approaches. For background pain, the best control seems to be the use of slow-release opioids or other pain cocktails given on a nonpain contingent basis (i.e., scheduled every 4–6 hours) with the flexibility to supplement this with p.r.n. or "as-desired" medication. Another approach is to use PCA with or without a continuous low-dose infusion of narcotics. A variety of nonpharmacologic therapies may also help relieve background pain. Again, the most important aspect to remember with all of these regimens is flexibility. The other obvious aspect is to remember that a patient is not only the best person to assess his pain, but he is also the best to evaluate the success of the therapies provided.

As challenging as managing comfort is for the healthcare provider, it is equally important to the burned patient. Recent studies suggest both physiologic and psychological reasons to successfully manage pain. Kavanagh et al.[265] demonstrated that pain in a burned patient adds significantly to the physiologic demands caused by stress. Schreiber and Galai-Gat[266] as well as Ptacek et al.[8] have shown that successful pain management can significantly reduce the occurrence of psychological disorders such as post-traumatic stress syndrome.

Burn care professionals who desire to keep their patients as comfortable as possible can perhaps best prepare themselves by learning to:

- watch and listen to their patients with vigilance;
- use a standardized assessment tool for measuring discomfort on a scheduled basis as well as during moments when the patient is complaining, either verbally or behaviorally, pre- and post-administration of treatment;
- know how discomforts are likely to change as the patient recovers;
- include a variety of pharmacologic and nonpharmacologic methods for managing discomfort and be prepared to change as the patient's needs change;
- feel comfortable with a process that never ends, but which can bring many moments of relief for the patient and satisfaction for the caregivers.

65 Psychiatric Disorders Associated With Burn Injury

J. F. AILI LOW, WALTER J. MEYER III, MIMMIE WILLEBRAND, and CHRISTOPHER R. THOMAS

Introduction

All members of the burn treatment team should have a basic knowledge of psychiatric problems because they commonly occur and often play a central role in burn recovery. It is useful to have mental health professionals as integrated members of the team because their expertise and skills are often needed in the management of patients with burns to screen and identify problems and to assist in the treatment of the multitudes of psychiatric and psychological issues concomitant to burns.

Preexisting psychiatric disorders and symptoms are relatively common in the histories of burned patients and frequently appear to have contributed significantly to the etiology of the injury itself.[1–4] The converse is also true.

In addition to premorbid disorders, a number of patients will develop psychiatric symptoms during acute treatment for burns, as also can be seen after other major trauma.[4] Pain, itching, and stress during hospitalization can contribute to problems during acute treatment, such as sleep disorders and depression, starting a vicious circle. Dissociation and anxiety experienced during the burn have been shown to predict later psychopathology.[5,6] While it is understandable to expect patients with major burns to be at risk, even minor burns can result in significant psychological distress and psychiatric symptoms.[7]

At present, there is no profile that can reliably predict and identify which patients will suffer psychiatric symptoms following burns. Furthermore, there is a clear risk that patients will not actively seek help for psychological distress or psychiatric symptoms, and this can have a strong effect on outcome and rehabilitation. All members of the burn team should be aware of this risk and be observant of signs or symptoms.

This chapter will focus on the recognition and treatment of common mental disturbances that can be expected to occur in patients suffering serious burns. This includes specific attention to both pediatric as well as adult patients, and it is important to be aware that symptoms and signs may differ between ages. Also, preexisting psychopathology may alter the expression of a patient's distress and complicate medical management of the patient.

In the following text ICD-10 codes can be found in parentheses after each diagnosis.

Preexisting Factors

Psychiatric morbidity greatly increases the risk of sustaining an injury, either directly (e.g., self-inflicted burns or suicide attempts) or indirectly through problems in impulse control (e.g., conduct disorders), by reducing vigilance or affecting judgment (e.g., substance abuse disorders, depression).[1,7,8] The knowledge of preexisting psychiatric problems is important for burn care mainly for two reasons: first, to better understand and identify psychiatric symptoms occurring during treatment and to recognize them as ongoing or reactivated problems instead of reactions to the injury; and second, to increase awareness of potential difficulties during rehabilitation (for a comprehensive review refer to McKibben et al.[1]).

Patients with preinjury psychiatric disorders have been observed to require longer hospitalization, they more frequently experience complications during treatment and problems with rehabilitation and postburn adjustment, and they have a higher risk of developing other psychiatric disorders (e.g., posttraumatic stress disorder; PTSD).[2–4,9–13]

Psychiatric morbidity is common in burn patients. Two-thirds of all patients with burns have a lifetime history of at least one psychiatric disorder, 50% had a psychiatric disorder in the year before injury, and one-third have an ongoing psychiatric disorder at the time of injury.[1] Patients with preexisting psychiatric morbidity have a higher risk of sustaining a preventable injury, and, in individuals with psychotic disorders, self-inflicted burns are overrepresented.[1]

The most frequent preexisting psychiatric disorder in burn patients is the mood disorder major depression, which is present in up to 42% of individuals, a proportion much higher than in the general population.[1] Smoking (i.e., substance use disorder, tobacco use disorder; Z72.0 or F17.2x), has been shown to increase the risk of burns; smoking more than 10 cigarettes a day increases the risk of burns by up to sixfold.[1] Similarly, other substance use disorders (e.g., the stimulant drug methamphetamine or the use of highly volatile and flammable substances) increase the risk of sustaining a burn.[1,14]

Personality disorders are also overrepresented in burn patients compared to the general population, and persons who score high on the personality traits neuroticism and extraversion appear to have a higher risk of injury.[1] In addition, persons with dementia have a higher age-standardized incidence rate of burns than do those without dementia (22.7 vs. 14.2 per 100,000 inhabitants), and they have a longer length of hospital stay.[15]

Disorders in Children and Adolescents

Psychiatric morbidity can increase the risk for burns in children and adolescents, and specific psychiatric disorders

have been found to occur more frequently in pediatric burn survivors than in the general population. Commonly pediatric burn survivors may not exhibit symptoms of prior psychiatric disorders during the acute phase of treatment due to the impact of injuries and other treatments. When symptoms are evident, continuation of prior treatment or implementation of indicated treatment for a preexisting psychiatric disorder may not only control symptoms but also facilitate patient participation and cooperation with acute care and long-term rehabilitation.

Repeated inhaling of psychoactive volatile hydrocarbons from, for example, glue, fuels, or paint ("sniffing") can be classified as inhalant use disorder (F18.x). This disorder can result in burns because many of the substances are flammable. Inhalant use disorder is most common in adolescents, whereas prevalence declines rapidly in adulthood.[16]

Across cultures attention-deficit/hyperactivity disorder (ADHD, F90.x) in children has a prevalence of about 5%.[16] One of the key features of ADHD is impulsivity (i.e., actions without forethought), which can expose the individual to high-risk situations, and children with ADHD have repeatedly been shown to be at greater risk for burns.[17–19]

Conduct disorders (F91.x) encompass repetitive and persistent behavioral patterns of violations of social norms and rules. Childhood-onset conduct disorder often is concurrent with ADHD, and individuals displaying this subtype (in contrast to adolescent-onset type) often display physical aggression; thrill-seeking and recklessness are frequent personality features.[16] In this context, playing with fire and fire-setting can be symptoms of conduct disorder[16] and can result in burns. Conduct disorders have a prevalence of around 4%, and the childhood-onset subtype has a worse prognosis with risk for adulthood psychiatric morbidity.

In contrast, pyromania (F63.1) is a specific conduct disorder in which deliberate and purposeful fire-setting occurs not as an aggression but in a setting of tension or affective arousal. This repeated fire-setting behavior increases the risk for burns, both for the individuals and those around them. Possibly the prevalence of pyromania may be underestimated; it has been observed that a slight majority of individuals with pyromania restrict their fire-setting to controlled situations, such as controlled fires on their own property, and therefore can remain "undetected."[20] The prevalence of pyromania as a comorbidity has been found to be 3–7%.[16,20] There is limited knowledge about the time course of pyromania. It has been postulated that the disorder is rare in children and begins in late adolescence but that some individuals "switch" to other impulsive, reward-seeking behaviors.[16,20]

Social Considerations in Pediatric Burns

Clearly parental and family characteristics can increase both the risk for burns in children as well as influence their subsequent recovery and outcome. The presence of child abuse or neglect can directly result in pediatric burns.[1,21,22] The presence of parental anxiety, depression, poor coping skills, or lack of social support at the time of injury are associated with poorer functional outcome in pediatric burn survivors.[23,24] Possibly high parent state anxiety in combination with ineffective coping strategies rather than family functioning or burn severity can be most predictive of pediatric burn outcome.[25]

Parents face numerous emotional challenges not only due to the psychological trauma of their children's burns, but also during subsequent treatment and recovery. Parents report more feelings of anxiety and being stressed, depressed, and guilty than the normal reference population even in areas unrelated to their children.[24,26] These stresses can result in psychiatric disorders in parents up to 2 years after the injury, with mothers at greater risk for developing mental health problems and depressive and posttraumatic stress symptoms.[27–29] Increased risk for depression was associated with having an only child or multiple offspring injured and with complicated burn injuries (secondary infection or amputation). Larger burns and the presence of parent–child conflict, parental dissociation, or PTSD symptoms in the child are strongly correlated with parental PTSD symptoms.[30–32] This emphasizes the need for psychological attention to parents of burned children, as well as to the children themselves. As child and parent ratings do not always match, recent studies suggest that burn centers adopt a family perspective and include assessments of both parents and children.[32]

Self-Inflicted Burns and Suicide Attempts

The proportion of self-inflicted burns differs across the world: whereas it is between 1% and 9% in North America and Europe with no clear gender distribution, self-inflicted burns are a major cause of burns in females in the Middle East, Africa, and south Asia, with a prevalence of up to 28%.[33,34] Of patients with self-inflicted burns, those attempting suicide are more likely to have larger burns and longer hospitalizations than those with the intent of self-mutilation.[33] Across cultures psychiatric morbidity is an important additional risk factor, often in conjunction with social stress factors such as marital problems or unemployment.[1]

In-Hospital Contributing Factors and Disorders

Several problems during acute burn treatment can affect the course of treatment and the eventual outcome after burns. Pain, itching, and sleep disorders are caused by both the injury and its treatment. High levels of stress and anxiety may contribute to the development of psychiatric morbidity (e.g., PTSD). In patients with substance-related disorders (F10.x–F19.x), withdrawal symptoms can occur during acute care, and patients with preinjury substance abuse have a higher risk of developing psychiatric symptoms during and after acute care. There is evidence that, in the case of comorbidity of PTSD and substance-related disorders, concurrent treatment of both disorders is necessary to achieve improvement.[35]

After the initial postburn period patients will undergo a series of operative procedures or dressing changes interspersed with physical therapy. Constant pain or the sure knowledge of repeated painful episodes in the near

future and feelings of anxiety and powerlessness are predominant[36–38] because every movement, even shifting position and change of bedclothes, is painful. Therefore treatment and the experience of hospitalization may be as traumatic psychologically as the original burn. Patients who experience high levels of pain not only have a higher risk of poor adjustment and psychiatric problems after discharge, but wound healing also can be affected due to stress.[38,39] Furthermore, high levels of stress, anxiety, and PTSD decrease pain tolerance.[37]

Itching is a common problem during wound healing and scar maturation, and it can cause considerable distress and anxiety.[40,41] Persistent itching can disrupt sleep, which increases stress levels and also impairs everyday functioning and participation in rehabilitation.[42] Anxiolytic, antidepressant, and antipsychotic agents have been used successfully to reduce itch.[41]

Significant sleep problems are common during and after treatment for acute burns.[43–45] The noise and light on the unit and interruptions for treatment will disrupt sleep.[46] Pain, anxiety, and itching can disrupt sleep or affect sleep quality. Symptoms of stress and PTSD (e.g., nightmares) can both cause awakening and a fear of going back to sleep.[44,47] Pain severity during hospitalization has been shown to predict insomnia after discharge, and insomnia in turn predicts long-term pain.[45] Burn patients who experience poor sleep at night will also have lower pain tolerance during the day.[47]

IN-HOSPITAL DISORDERS

Disorientation, confusion, delirium, transient psychosis, depression and anxiety, stress, and sleep disorders are commonly observed during acute burn treatment.[3] Causes of these symptoms are multifactorial: hypoglycemia, sepsis, and/or a variety of other organic problems can contribute. The altered state of consciousness may be transitory, wax and wane over several days, or, with large burns, persist for weeks.

A significant number of burn survivors will experience acute or posttraumatic stress disorder symptoms, including intrusive memories of the injury, during their acute recovery.[1,48,49]

Symptoms of depression and agitation related to excessive pain will subside with adequate pain management. The experience of pain has been found to be a mediating risk factor for PTSD in both pediatric and adult burn patients.[38,50] The recurrence of pain in a scar area following laser treatment or with wound cleaning can lead to recurrence of the PTSD symptoms associated with the original pain.

After severe burns patients are at risk for the development of substance abuse in the wake of PTSD,[3,35] but the use of opioids and other pain medication will not cause dependence per se if adequately administered and tapered when pain levels decrease.[37,51]

Symptoms of delirium and transient psychosis rarely occur among children under the age of 10 years.[52] True hallucinations are uncommon in children, but, when they do occur, the most likely cause is stress, followed by pain and medications.[53] In young burn patients sepsis and metabolic conditions are a more frequent cause of hallucinations than are psychiatric disorders.

In contrast to delirium and psychosis, burn encephalopathy is often observed in children,[54,55] characterized by lethargy, withdrawal, or coma. Electroencephalograms (EEGs) in such cases typically reveal diffuse, nonspecific slow waves. Causative factors probably are the same as those for delirium.[56]

Even young children can experience severe anxiety following burns, with up to a third of patients reporting symptoms of acute stress disorder (ASD) in the immediate aftermath of burns.[57] Mediating factors for the presence of anxiety symptoms appear to be size of burn, parental stress, and the experience of pain. High resting heart rate, poor body image, and parental stress symptoms have been found to be significant risk factors in development of ASD in children.[58]

Similarly to adults, pain in children appears to dramatically increase the risk for developing anxiety symptoms and subsequent anxiety disorders, and appropriate pain management can reduce or resolve anxiety symptoms.[59,60]

DELIRIUM

Delirium (F05) is a state of acute brain dysfunction, and, in burn patients, it is important to consider that it can both be due to the trauma itself as well as a symptom of substance withdrawal. It is a transient and usually reversible syndrome with disturbance of consciousness and cognition compared to previous levels of functioning. Hallucinations and delusions can occur, and patients in delirium can become suicidal or combative. Early symptoms can be restlessness, anxiety, disorientation, or sleep disorders.

Delirium in burn patients has been found to occur more often in individuals with a history of substance abuse or other psychological problems and with larger burns.[61,62]

Other potential causes of disorientation, hallucinations, and agitation may be medications used in the treatment of the acute burn patient, sepsis, and metabolic conditions.[62] These hallucinations can blur the line between delirium and ASD. Sleep deprivation has also been discussed as a cause for delirium in ICU patients.[63]

Acute Stress Disorder and Posttraumatic Stress Disorder

In the course of the progression from the *Diagnostic and Statistical Manual of Nervous and Mental Disorders,* Fourth Edition (DSM-IV) to DSM-5, ASD (F43.0) and PTSD (F43.10) no longer are regarded as anxiety disorders; they are now listed as a separate group called trauma- and stressor-related disorders: an overanxious patient is afraid of what might happen, whereas the patient with PTSD reexperiences and fears what has happened. The patient with PTSD is stuck in a heightened perception of threat and uses avoidant behaviors that maintain the symptoms.

ASD is the most common psychiatric disorder seen in survivors of major burns, in addition to PTSD, and it has a prevalence as high as 19% after burns.[48,64,65] ASD symptoms appear immediately following the trauma, last for at least 3 days, and usually resolve within a month after the trauma.[16]

In contrast to PTSD, dissociative symptoms can be present. Whereas these symptoms previously (i.e., in DSM-IV) had been given a central role for the diagnosis, it is now understood that some individuals develop ASD without dissociative symptoms.[16,66]

In children, repetitive reenactment of the traumatic event in play can be a symptom of intrusion and/or dissociation.

The presence of avoidant symptoms during the acute phase of recovery has been shown to predict chronic posttraumatic disorder in burn patients.[67,68] It is of great importance to recognize symptoms of ASD and PTSD at an early stage because the former has been shown to be a predictor for PTSD, and, once PTSD is established, it usually will persist.[48,69]

PTSD is, in addition to depression and general anxiety disorder (GAD), one of the most common psychiatric disorders seen in survivors of major burns with prevalence rates ranging between 7% and 45%.[2,48,49,65,70,71] In DSM-5 behavioral symptoms of PTSD encompass four instead of the previous three clusters: (B) intrusion, (C) avoidance, (D) negative cognition and mood—this is the new cluster—and (E) arousal (which in DSM-IV was the D cluster).[16] Aggressive, reckless, or self-destructive behaviors are now recognized as aspects of arousal. The DSM-5 definition of PTSD no longer differentiates between acute and chronic PTSD. Instead, two new subtypes of PTSD are identified in DSM-5: PTSD in children younger than 6 years (PTSD preschool subtype) and PTSD with prominent dissociative symptoms (PTSD Dissociative subtype) (for a review of the changes, see reference 66).

About one-third of burn survivors develop PTSD within 2 years of their injury,[72] and this was true for even small burns.[73] Individuals should be interviewed about sleep patterns and startle response because nightmares and altered sleep patterns are usually the symptoms first noted. In fact, in adults, it has been shown that one of the most important piece of information when screening for PTSD is nightmares.[74] Another potential marker for ASD and PTSD is heart rate at admission to the burn unit, although it appears to be mediated by gender.[75] A significant number of burn survivors will experience PTSD symptoms, including intrusive memories of the injury, during their acute recovery.[76,77] Children may express intrusive symptoms by reenactment of the traumatic event, and nightmares may not be directly related to the event.[16]

The presence of avoidant PTSD symptoms during the acute phase of recovery is reported to predict chronic PTSD in burn patients.[67–69,72,78]

Long-Term Postburn Disorders

Pain and previous psychiatric illness are the main factors that have been suggested as reasons for psychiatric problems beyond the time of discharge from the burn care center.[49] Pain and depression seem to be linked in such a way that they can cause each other.[79] Also, acute pain at the time of discharge from the hospital seems to produce long-term suicidal ideation.[80,81] There is a reciprocal relationship between pain with depression and anxiety.[81]

Another predictor of psychiatric problems is the presence of psychiatric or personality disorders preburn.[2] Cognitive processes may play an important role because, for example, burn-related attentional bias has been shown to be strongly associated with PTSD 1 year post injury.[82] Skull burns are associated with cognitive as well as affective disorders post burn,[83] but there does not seem to be a relationship to facial burns or even very large burns.

It has been observed that depressive symptoms were linked to physical limitations at 5 years after injury.[84] The appearance and location of the burn scar may be predictive for PTSD symptoms of avoidance and emotional numbing[85] or depression, especially in women.[86] In contrast, other studies found that neither the severity nor the visibility of burn scars influence long-term adjustment, but rather social introversion, which predicted the development of pathological shame.[87,88] Many patients with PTSD have comorbid depression;[89] both are sequelae of trauma and share a lot of symptoms, but they develop independently of each other.[90] In the trauma literature,[91] as well as in the burns literature,[92] subgroups of patients developing PTSD symptoms in different patterns over time can be identified (e.g., resilient with no or low symptoms, recovery, delayed, and chronic). The chronic group carries more of the above-mentioned medical, social, and psychological risk factors and should, together with those who have delayed onset of symptoms, receive the most attention from the burn rehabilitation team.

General Anxiety Disorder

Many patients continue beyond acute hospitalization to have periods during which they appear extremely anxious and express fear. These periods often recur in association with return to a hospital for reconstructive surgeries. General anxiety disorder (GAD, F41.1) is characterized by excessive worry for more days than not for at least 3 months and difficulty in controlling the anxiety. Typical symptoms are restlessness or the feeling of being on edge, muscle tension, and changes in behavior due to anxiety and worry, such as avoidance of potentially negative events, procrastination, or seeking reassurance.[16]

In the literature, the prevalence of anxiety disorders in adults during the year after burn—usually GAD or agoraphobia without panic—is less than 20%, and those with very small burns had even less anxiety.[7,93] Avoidant coping style was significantly correlated with the level of anxiety at 3 months.[6] In a study of young adults burned as children and with much larger burns than those examined in other studies, all the anxiety disorders were found, and they were twice as common as in matched controls: 12.9% of the subjects had a specific phobia and 6.9% had generalized anxiety.[94]

Not infrequently, anxiety spills over to other situations and/or becomes focused on specific objects; thus, phobias develop that are characterized by excessive persistent fear in response to specific stimuli. In a burned patient, difficulty controlling anxiety, restlessness, and behavioral changes are diagnostic of anxiety disorders since some other symptoms can be related to burn injuries specifically.

Although adults may express anxiety through "panic" symptoms such as sweating, palpitations, trembling, or nausea, children may express anxiety by crying, tantrums, freezing, or clinging. A differential diagnosis of these anxiety disorders distinct from PTSD is difficult and requires a careful interview.

Major Depressive Disorder

Although feeling depressed is a reaction most observers would expect of burned patients, only a relatively small number of patients with burns have been observed to have symptoms of severe depression (F32.x and F33.x).[2,49,64,95,96] In most studies preinjury depression or lower levels of well-being were stronger predictors than burn size for subsequent depression. All the same, those individuals who experience symptoms of depression during hospitalization will continue to do so after discharge so that early recognition and treatment may improve their situation considerably.[95] Depression is also a rare long-term sequela of burns in children: fewer than 50% of the children had ever suffered symptoms of major depression, and, in a sample of adolescent survivors, only 6% met criteria for a major depressive disorder.[96,97]

Symptoms of a major depressive episode according to DSM-5 are as follows: (1) depressed mood, (2) diminished interest or pleasure in activities ("anhedonia"), (3) significant weight or appetite changes, (4) insomnia or hypersomnia, (5) psychomotor agitation or retardation, (6) fatigue, (7) feelings of worthlessness or guilt, (8) diminished ability to think or concentrate, and (9) recurrent thoughts about death.[16] Children and adolescents may display irritable mood instead of depressed mood and a failure to gain weight instead of weight or appetite changes.

This is an extremely difficult diagnosis to make during the acute burn period since many of the criteria are linked to physical symptoms. A number of approaches have been used to determine the incidence among adult survivors of major burns using self-report measures such as the Beck Depression Inventory. A review of the literature on depression in burn survivors found a prevalence of major depression at 1 year post discharge of between 4% and 7%. At more than 1 year post discharge the prevalence ranged between 9% and 23% (for a comprehensive review, refer to Thombs et al.[98]

Even beyond the acute phase, the diagnosis is often complicated by grief. The critical symptoms of major depressive disorder are the first two listed—depressed mood and anhedonia—whereas grief is mainly characterized by feelings of emptiness and loss.[16]

Persistent Depressive Disorder

A smaller percentage of burned patients, around 4%, will develop a milder but more protracted type of depression called persistent depressive disorder, or dysthymia (F34.1).[98,99] In some cases the persistent depressive disorder may be preceded and/or interspersed by major depression. The main differences between major depression and persistent depressive disorder are that diagnostic criteria for the latter do not include the symptoms anhedonia, psychomotor agitation/retardation, and recurrent thoughts about death. The time frame also differs: persistent depressive disorder must be present for at least 2 years in adults or at least 1 year in children and adolescents in order to be diagnosed. Patients often report chronic anger, appetite changes, sleep difficulties, fatigue, low self-esteem, poor concentration, difficulty making decisions, and feelings of hopelessness. The same combination of medication and psychotherapy is recommended for patients with persistent depressive disorder as for major depression.

Substance-Related and Addictive Disorders

There are few studies that indicate the prevalence of substance abuse or alcohol abuse in adults. Recent studies indicate that substance abuse may be one of the most prevalent psychiatric disorders. A Finnish study found that 26% of the surveyed patients had alcohol abuse or dependence, and 6.5% had drug abuse or dependence during a 6-month follow-up after trauma.[49] Another study reported that 25% of former patients had an at-risk drinking pattern 2–7 years after burn injury, and it was predicted by an avoidant coping pattern that involved using alcohol, tobacco, or other drugs to handle problems.[100] Certainly prior abuse is a major risk factor for abuse after burns. Maes et al.[93] reported an incidence of 6% for new-onset psychoactive substance use disorders after trauma. In a study in young adults who were burned as children the prevalence of the use of alcohol and substances was 7.9% for alcohol and 35.7% for other substances; however this rate later fell to 3% for alcohol and 9.9% for other substances.[94] These young adult prevalence rates are lower than the reference population in the United States for alcohol but were higher for substance abuse/dependence, which may reflect the socioeconomic background of the subjects studied.

Comorbidity and Problems Beyond Psychiatric Illness

PTSD and depression are both linked to poor long-term outcomes in adults.[39,70] PTSD and pain together predicted poor functional and increased disability after major burns. PTSD symptoms led to greater physical and psychosocial disability, poorer social functioning, and less vitality.[39] Pain is linked to poor concurrent physical functioning, and depression can predict decreased physical health 2 months post discharge.[80,101]

Adjustment in Children After Burns

A significant number of the children and adolescents who survive major thermal injury develop a variety of significant behavioral and emotional problems at some point in their lives, but good adjustment is achieved by the majority of individuals.[102–106] In studies in adolescent and young adult survivors of pediatric burns, about half

of the individuals met criteria for one or more psychiatric disorders,[94,97] and adult survivors of childhood burns have a significantly higher relative rate of both psychiatric and physical illnesses.[107] About one-fifth of children with burns are reported to have more problems with conduct and peers than does the norm population,[106] and 35% of preschool children with burns were diagnosed with at least one psychological disorder.[108] A recent study also showed that 13.2% of infants and toddlers with burns met the proposed alternative criteria for PTSD.[109] Severity of symptoms and adjustment were associated with family relations and maternal PTSD. Compared to a group of survivors of flood trauma and a community sample, burned children had significantly more phobic disorders, overanxious disorders, enuresis, encopresis, major depression, PTSD, and substance/ethanol abuse.[96,110] Sleep disorders and psychotic disorders were also slightly more common among the burned children.

Parents usually report more problems than do the children themselves or their teachers.[102,111,112] This observation could be explained by increased problems in these children following severe burns that would not be easily observed by persons who do not live with them or that parents became overly sensitive to any indication of difficulty for their children following burns.

Another area of long-term psychiatric outcome following pediatric burns that has received little attention is the development of personality disorders. In the same sample of young adults mentioned earlier,[94] personality disorders were common and significantly associated with comorbid Axis I diagnoses.[113]

Diagnosis (Screening Instruments, SCID)

Two techniques are used to determine the prevalence of psychiatric disorders in burn survivors. The one most commonly used has been the self-report questionnaire, such as the Beck Depression Inventory, Impact of Event Scale-Revised,[114] Davidson Trauma Scale, Brief Symptom Inventory, McGill Pain Questionnaire, and Quality of Life surveys such as the Short Form 36 (SF-36) or the EQ-5D, which has been validated with burn survivors.[115]

For a more complete diagnostic survey, the gold standard is the Structured Clinical Interview for DSM-5 Disorders (SCID-5) interview.

The American Burn Association had a consensus conference in February 2013 to establish a recommendation for uniform psychiatric screening and diagnostic tools for the burn survivor. Wiechman et al. published a list of recommended tools a few months later.[116] The group focused on depression and PTSD symptoms.

Criteria for the screening instruments were that they be validated, easy to use, and free. For depression in adults, the Patient Health Questionnaire (PHQ-2 and 9), Beck Depression Inventory, Brief Symptom Inventory, and SCID were recommended; for childhood depression, the Child Depression Inventory was recommended. For PTSD symptoms in adults, the PTSD Symptom Checklist and in children the UCLA PTSD Index were recommended.

Treatment

DELIRIUM AND AGITATION

Due to the problems associated with phenothiazines, benzodiazepines have been used to a greater extent in recent years for the combative, delirious patient.[117–119] The two most commonly used benzodiazepines are diazepam and lorazepam. Lorazepam (0.03 mg/kg) orally or intravenously can usually be given every 4–8 hours; for a very combative patient it can be given hourly. A third benzodiazepine that is frequently used is midazolam at 0.05 mg/kg IV, typically used in conjunction with morphine for procedures such as tubbing and staple removal. Midazolam is also used for sedation as a continuous infusion for intubated patients. When using the benzodiazepine class of medications, a clinician must balance the desired effects of relaxation with oversedation. Visual and auditory hallucinations may occur if the dose of benzodiazepine is too high. In cases of excessive anxiety in the presence of adequate pain control, lorazepam can be added to a patient's treatment. Nighttime doses usually enhance sleep. Diazepam may be used in place of lorazepam if simultaneous muscle relaxation is desired.[120] Diazepam has an extremely long half-life, 40 hours, and therefore should be used sparingly. To avoid excessive sedation by benzodiazepines, a patient should not be awakened for the next dose.

ASD AND PTSD

Therapy is the same for ASD and PTSD and usually includes a combination of psychotherapy and pharmacotherapy. For a comprehensive description of common aspects of psychotherapy for PTSD, see Schnyder et al.[121] Trauma-focused cognitive behavioral therapy (TFCBT) can relieve PTSD symptoms and typically includes imagined and in vivo exposure, where prolonged exposure is one of the most effective treatment protocols today. Exposure involves in-depth recalling and verbalizing of the event, physically revisiting the site of the accident either in person or, as most recently studied, by means of virtual reality. Another treatment component is cognitive restructuring and skills training, sometimes by role play and cognitive tasks. Training in anxiety management using stabilizing and relaxation techniques is also important for recovery from PTSD. Another evidence-based psychological treatment is eye-movement desensitization and reprocessing (EMDR) where in-depth processing of the memory is achieved by having the patient track a bilateral stimulus with his or her eyes at the same time as the memory is retrieved. In a Cochrane review, TFCBT and EMDR were found more effective in the treatment of PTSD in the long term than were other psychotherapies or waitlist conditions.[122]

Pharmacotherapy developed over the past two decades with the use of selective serotonin reuptake inhibitors (SSRIs), such as sertraline and fluoxetine, as first-line drugs. Other useful medications are tricyclic antidepressants (TCAs); antipsychotics, such as risperidone and quetiapine fumarate; and $\alpha 2$ adrenergic agonists, such as clonidine. SSRI antidepressants, such as fluoxetine, or a TCA like imipramine should be considered for ASD.[123] Both SSRIs and TCAs are helpful in reducing nightmares and improving

sleep patterns. Treatment with an SSRI or TCA should be continued for at least 9 months to a year following the improvement of symptoms because of the risk of relapse.

One of the major issues with the use of TCA is that cardiac arrhythmias, associated with a prolonged PR interval, can be life-threatening.[124] When medication is discontinued, it should be reduced over time to avoid uncomfortable—although not medically threatening—discontinuation symptoms. The relatively long half-life of fluoxetine usually protects patients from any discontinuation symptoms but requires extended vigilance for any drug–drug interactions.

Typically the SSRIs are given in the morning rather than the evening because they may interfere with sleep onset. Side effects of SSRIs include gastrointestinal upset, increased agitation, headaches, sexual symptoms, and sweating. A rare but potentially life-threatening side effect is serotonergic syndrome,[125] characterized by at least three of the following symptoms: delirium, agitation, sweating, fever, hyperreflexia, myoclonus, tremor, incoordination, diarrhea, and shivering. Severe cases can result in hyperpyrexia, shock, or death. The risk of serotonergic syndrome increases when patients are on multiple medications that potentiate central nervous system serotonin, such as an SSRI and a monoamine oxidase inhibitor. There is a reported case of serotonin syndrome in a pediatric burn patient who was receiving fluoxetine and linezolid, a broad-spectrum antibiotic with monoamine oxidase inhibition.[126] Sexual side effects are the most likely reason that a teen or an adult would refuse to take an SSRI.

In an emergency room setting, propranolol has been tried with some success for those with minor injuries. It has been reported to be very helpful in the treatment of PTSD and ASD and to prevent their occurrence following a variety of different types of trauma. Longer-term studies with larger injuries have not shown propranolol to be helpful for the prevention or treatment of ASD or PTSD.[127,128] Benzodiazepines will control some immediate symptoms but are not useful long term.

Concerns that midazolam administration might interfere with this process and actually enhance PTSD could not be substantiated.[129]

OTHER ANXIETY DISORDERS

Most burn patients, certainly those who qualify for the diagnosis of generalized or overanxious disorder, will benefit from lorazepam therapy in addition to psychotherapy. If anxiety is associated with other symptoms of posttraumatic stress, such as hypervigilance or poor sleep, an SSRI[123] or the older TCAs[130] should be considered. The SSRIs have the advantage of being safer drugs for outpatient treatment since an overdose is unlikely to cause the significant cardiac problems that have been attributed to the TCAs.[131]

MAJOR DEPRESSION

Major depression, with or without grief reaction, should be treated by a team approach. The patient should be involved in scheduled daily activities. Psychotherapy should begin to identify and address appropriate issues. Medication with SSRIs or TCAs, as described for acute and posttraumatic stress, is often helpful. Once the symptoms have responded to medication, treatment should continue for 9 months to a year in order to avoid relapse on discontinuation.

Many times the depression is comorbid with PTSD. Therefore medications that affect both are preferred. Fluoxetine and the other SSRIs are the first-line medications for treatment of patients with depressive symptoms.[124,132]

SLEEP DISTURBANCES

After discharge, many burn survivors have significant sleep problems. As in the hospital setting this may be secondary to PTSD symptoms, depression, itch, or pain. Pain in the hospital before discharge will predict insomnia.[45] When sleep disturbance with nightmares is associated with posttraumatic anxiety, as described earlier, antidepressant medications are the drugs of choice. Imipramine and doxepin are both sedating antidepressants that are effective treatments for sleep problems in burn patients. Trazodone and nefazodone are alternative medications for insomnia and do not appear to alter sleep architecture as much as other antidepressants. Mirtazapine is another antidepressant that has been used for insomnia, although little is known about its effects on sleep architecture. Pain and itch are other problems that can interfere with sleep and should be addressed with appropriate analgesic or antipruritic medications.[133] If a patient continues to have significant sleep problems, sleep can be induced with diphenhydramine. Diphenhydramine doses of 1.5 mg/kg are often used throughout the day for itching and may be used alone for sleep at night or as an adjunct to other sleep medications. Usually, doses of 25 or 50 mg in the evening are adequate. Recently quetiapine fumarate (Seroquel) PO has been found to be safe and useful in this setting.

SPECIAL ASPECTS IN PEDIATRIC TREATMENT

As with adults, pediatric patients suffering with psychiatric symptoms can benefit from psychotherapy, with appropriate indicated treatment for their specific problems. A number of specific therapies have been adapted for treatment of anxiety, PTSD, and depression in children and adolescents. In addition, specific treatments for pediatric burn survivors have been developed, such as social skills training addressing disfigurement.[134] In school-aged children there is preliminary support for a brief, early psychological intervention in reducing later internalizing problems.[135]

Early opiate management of burn-related pain is important for decreasing the risk of long-term PTSD in children.[136]

Pediatric burn patients appear to have a much higher rate of adverse reactions to haloperidol, and alternative management of agitation should be considered.[137] Chlorpromazine and thioridazine may be used in place of haloperidol in the dosage range of 25–100 mg per dose. Chlorpromazine and thioridazine have strong sedative effects and interfere with learning but are less likely than haloperidol to produce associated dystonia, pseudo-parkinsonism, and akathisia. If more than 2 mg of haloperidol per day is used, attention must be given to simultaneous administration of 1

or 2 mg/d of benztropine or 2–5 mg/d of trihexyphenidyl in divided doses. Benztropine or trihexyphenidyl are used to avoid dystonia, pseudo-parkinsonism, and akathisia.[117] Occasionally, dystonia takes the form of an oculogyric crisis, which resembles an acute neurological catastrophe[138] and can be a true medical emergency if respiration is impaired. These reactions are usually alleviated by 50 mg IV diphenhydramine.

The treatment of anxiety and depression in children with SSRIs and TCAs requires closer attention to dosage and potential side effects. The usual starting dose of fluoxetine is 5 mg for children weighing less than 40 kg, 10 mg for children between 40 and 60 kg, and the adult dose for any children weighing more than 60 kg. The usual starting dose of imipramine is 25 mg/d unless the patient weighs less than 25 kg. The beginning dose is 12.5 mg for those under 25 kg. The dose can be increased rapidly over the next few days to a dose of 1 mg/kg. If the symptoms are still uncontrolled, the dose may be increased stepwise to 3 mg/kg, but only with frequent checking of the plasma level and electrocardiographic changes with each increment of dose. A steady state is usually not reached until a given dose is maintained for 3–5 days. The preferable time of administration is in the evening to aid with sleep. Major side effects of the TCAs are anticholinergic (dry mouth and dry nasal passages, constipation, urinary hesitance, and occasional esophageal reflux).[117] Autonomic complications such as orthostatic hypotension, palpitations, and hypertension have been reported in adolescents using this medication.[139] Cardiac arrhythmias associated with a prolonged PR interval can be life-threatening.[124,132] Sudden death has been reported for teenagers and children receiving desipramine and other TCAs.[140] Amitriptyline or doxepin may be used in place of imipramine. The dosages are similar; however both these medications may cause more sedation than imipramine.[117]

Following clinical reports of increased suicidal ideation in pediatric patients treated with certain antidepressant medications and a review of clinical trial data, the U.S. Food and Drug Administration instructed all manufacturers to include a "black box" warning with all antidepressant medications.[141] Pediatric patients and their caretakers must be aware of these risks, and clinicians should closely monitor children and adolescents on these medications for possibly increased suicidal ideation and behavior.[142]

NONPHARMACOLOGICAL PREVENTION OF PTSD

Currently there is no evidence-based nonpharmacological method for prevention of PTSD. The dominating approach is psychological first aid that is largely based on consensus agreement and has replaced the much criticized psychological debriefing as the standard intervention for trauma victims.[143] However there are preliminary indications that TFCBT can be effective in preventing PTSD in groups of trauma victims with early signs of high symptomatology.[144] Other complementary and alternative treatment modalities such as meditation, mindfulness, and acupuncture may also be effective, but to date the evidence is not as strong as for the aforementioned modalities.[145,146]

Resilience, Posttraumatic Growth

Although it has become generally accepted knowledge that trauma and injury can lead to psychological and psychiatric problems, the fact that a considerable proportion of individuals do not develop problems after trauma and injury has found much less attention, and, to date, there is only an extremely small number of studies in burn patients.

Resilience and posttraumatic growth (PTG) are two separate constructs. Resilience is a trait that exists before exposure to trauma or adverse events that PTG.[147,148] Resilient individuals have an ability to "bounce back" and regain balance in all aspects of life, as well as having endurance in the face of adverse events.[147–151] Resilience is the most common response pattern seen after burns: approximately 40% of adult patients respond in this way.[92] Three categories of protective factors, which also are predictive of resilience, have been identified:[150] individual characteristics, relationships, and social network.

In contrast, PTG is the development of new behaviors and attitudes that were not present before the event. It is a positive psychological development, the result of struggles in the face of hardship or traumatic events.[147,152] The Posttraumatic Growth Inventory[152] identifies five different aspects of PTG: new possibilities, relating to others, personal strength, spiritual change, and appreciation of life. PTG appears to be somewhat related to the personality traits of optimism and extraversion. Female gender and social support are the strongest predictors of PTG, and higher levels of education and higher socioeconomic status also are predictive.[145,147]

Resilience and PTG can both occur concurrently with distress and lower quality of life; in fact PTG may not occur without some level of distress, but distress diminishes over time in individuals who experience PTG. Longitudinal studies show that PTG levels out at about 6 months after trauma.[147]

INTERVENTIONS TO FOSTER PTG

While alleviating distress does not foster PTG, growth can protect from further distress. The patient's own experiences and psychological development appear to play a central role in PTG. The caregiver's role should be to support and improve coping, strengthen self-image, and enhance social support; caregivers "must be comfortable in allowing the patient to struggle with the event."[147,153] Common aspects of PTG in burn patients appear to be the use of active and flexible coping, social support, enhanced self-image, and the successful search for meaning.[148,154,155]

Conclusion

Preinjury psychiatric morbidity can have a major effect on outcome after a burn. Furthermore, psychiatric symptoms occur commonly as part of the complex systemic response to burn injuries. Psychological and pharmacologic treatment is important in the successful recovery of a burned person and may reduce the risk of long-term psychiatric sequelae of the injury. It is important to note that

psychological adaptation is a lengthy process occurring over months or years. During the postburn years, it is imperative that the burn team assesses the mental and affective states of patients while assessing their physical recovery. In most cases, patients with sleep disorders, depression, or withdrawal from previous activities will not seek psychiatric attention and treatment, although these problems can be ameliorated by treatment. It therefore becomes a responsibility of the expert in burn care and the entire burn team to be aware of frequently occurring problems, to ask the right questions to assess a patient's status, and to assist a patient in receiving psychological and psychiatric assistance.

66 Psychosocial Recovery and Reintegration of Patients With Burn Injuries

LAURA ROSENBERG, MARTA ROSENBERG, RUTH B. RIMMER, and JAMES A. FAUERBACH

Introduction

Burn survivors may deal with diverse psychosocial issues in the recovery from a major burn injury. Common concerns include adapting to physical limitations and permanent changes; dealing with grief and loss; experiencing traumatic stress, anxiety, pain, sleep disturbance, depression, and body image concerns; and other adjustment issues. Approximately 30% of survivors experience long-term psychosocial difficulties.[1,2] Psychological healing occurs across time commensurate with physical healing in a relatively predictable and consistent pattern.[3] Awareness of this process permits survivors and their family members to anticipate the development of psychosocial issues, view concerns as normal reactions to the trauma instead of symptoms of psychological impairment, and facilitates coping with these issues. The goal of the recovery process is to attain optimal psychological, emotional, and social functioning (Figs. 66.1 and 66.2). Therefore, availability of psychosocial support is important for the recovery of the burn survivor and the adjustment of the family.

This chapter provides an overview of psychosocial issues that burn survivors and their families may experience during the phases of the recovery. There is also a review of important psychosocial constructs that can affect recovery such as assisting with grief and loss; cultural sensitivity; psychological distress; acute and posttrauma distress; resilience and recovery; body image concerns, stigmatization and social integration; social belongingness; long-term quality of life; and interventions beyond acute care. The medical management of pain and anxiety are presented in chapter 4 in this book.

Integrating Psychological Treatment With Physical Treatment

Comprehensive burn treatment requires a coordinated interdisciplinary team approach for physical and psychosocial recovery to occur concurrently. Mental health professionals on a burn team provide direct patient care and work indirectly through consultation with other caregivers to address survivors' psychosocial concerns and to assist family members with their adjustment. Integrating the family into the treatment plan from the beginning facilitates successful outcomes.

PREINJURY ADJUSTMENT

Shortly after being admitted to the burn unit, a clinical interview is done to gather information regarding variables that may influence the patient's recovery and treatment. Information about the burn injury, previous stressful events, risk factors, preburn physical and psychological health, coping skills, family and social support, and the family's strengths and weaknesses are important factors to take into account when developing treatment plans.[4,5] Gathering information about factors that contributed to the circumstances of the burn is emphasized in instances of suspected maltreatment and neglect.[6] Because patients will be dependent to some extent on family during recovery, it is essential to identify risk factors in the family system. Risk factors that may predispose individuals to burn injury and that may affect postburn recovery include physical illness, substance abuse, psychiatric illness, behavioral problems, poverty, inadequate social support, and heightened family disruption.[5,7–9] Part of the clinical interview involves initiation of a therapeutic alliance with those who are most likely to be involved in assisting a patient's recovery.

ADMISSION CRISIS

When people with burns are admitted to the intensive care unit (ICU), they may be frightened, confused, experience shock and disbelief, have pain and anxiety, and fear dying. While the physiological emergency is treated medically, the psychological crisis must also be addressed. The goals at this time are to establish therapeutic rapport with the patient, decrease anxiety, and assess strengths and needs of the patient. The first two tasks are addressed immediately by orienting the patient, focusing on immediate priorities, and assuring the patient that the burn team is composed of knowledgeable experts who will provide excellent care. The patient's heightened anxiety can be expected to interfere with his or her comprehension, so it is usually necessary to repeat statements of reassurance. To prevent a patient from becoming emotionally overwhelmed, it may be necessary initially to avoid or limit talking about trauma-related content. Children in this early stage of recovery may exhibit signs of cognitive and emotional regression, and it is important to respond to them on that level. Techniques such as deep breathing, relaxation with

focused imagery, and hypnotherapy may decrease patients' anxiety.

Family members are often traumatized and may experience difficulty eating, sleeping, or concentrating, and feel a loss of control and a generalized sense of incompetence and helplessness. Providing psychosocial support and education about recovery may facilitate the coping of the family. They may need frequent repetition of information and direction in providing comfort to the patient. The psychotherapeutic goals to be accomplished with the family include establishing a therapeutic relationship and diminishing anxiety. This can be facilitated by assisting with orientation to the hospital, providing information about normal reactions to trauma, and validating that their distress is normal and temporary, which helps communicate empathy and understanding. Learning about the injury and its treatment helps restore the family's sense of competence and provides opportunities for them to experience the reality of their roles in helping the patient. The manner in which an individual and a family will ultimately adjust to the long-term sequelae of a burn is often determined in the early stages of recovery.

CRITICAL CARE PHASE

This phase involves intensive medical and surgical care until the majority of open wounds are covered, and it is an important phase psychologically. Organic factors resulting from the injury and treatment can contribute to psychological symptoms of disorientation, confusion, sleep disturbance, transient psychosis, and delirium. Helpful interventions include frequent orientation to person, place, time; placing comforting objects in patient's view to see and touch; and making the environment as soothing as possible. Visits from family and friends can provide familiarity, reassurance, and comfort the patient. A schedule that approximates a regular wake–sleep cycle helps patients begin to feel normal.

Reassurance from staff about normal aspects of recovery, the treatment plan, and how staff plans to help improve function can decrease anxiety and provide a sense of hope. When a patient is alert the psychotherapist can facilitate grief work to help the patient adjust to the effects of the burn. Patients with altered mental states may be able to hear although not respond, and discretion should be used regarding what is said near them. Psychological interventions are aimed at diminishing anxiety and increasing comfort instead of correcting the person's perception of reality.[10]

Pain and anxiety management are crucial in this stage of recovery. Providing good pain control enhances psychological recovery. Routine and scheduled assessments of background and procedural pain[11–13] and anxiety[11,13] validates a patient's concerns but also set an expectancy of relief. The use of standardized scales provides the message that experiencing a range of pain is normal. When staff assess comfort routinely, patients are less likely to feel anxious about their pain management. Clinicians, researchers, and burn survivors have noted that patient recall of satisfaction with acute pain management in the hospital has indicated the need to improve this salient aspect of burn care. Perhaps this may be accomplished by combining a standard pain medication regimen with individualized adjustments based on behavioral observation and patient-reported pain.[14] Similarly, survivors have voiced dissatisfaction with various aspects of care and aftercare, including pain management and the means by which they observed and coped with their injuries.[15] These are ongoing areas of focus and psychosocial intervention.

Psychological interventions for pain and anxiety should be used in conjunction with pharmacological management. Anticipatory anxiety may influence a person's perception of pain. Cognitive and behavioral interventions that enhance a patient's mastery or control can decrease pain and anxiety. Patients often tolerate procedures better when the reasons for each procedure are explained. They may feel more comfortable participating in their own care and gain some mastery over pain when they are allowed to remove their own dressings or participate in wound debridement. The presence of a supportive person during procedures can

be effective in decreasing pain. Instructing a family member on how to comfort his or her loved one is important during these procedures.

Other effective interventions in decreasing pain and distress associated with burn treatment include deep breathing, progressive relaxation, visual imagery, biofeedback, hypnosis, virtual reality, mindfulness exercises, and relaxed jaw.[16] Hypnosis induces a relaxed and focused state of awareness that can be extremely helpful in facilitating comfort for patients. Hypnotic inductions and suggestions must be modified to facilitate a patient's use of imagery. Some individuals will respond well to suggestions of imagining a "favorite place." Older children may respond well to storytelling, with suggestions for comfort and mastery interwoven into the story.[17] Survivors may benefit from interventions that redirect their attention away from the painful procedure. Studies found immersive virtual reality, in which individuals' attention was immersed in a computer-generated world, was effective in reducing pain during wound care[18–20] and in the tub room.[21] This intervention may also be helpful during physical therapy.[22,23] Mott and colleagues reported augmented reality, where a character viewed on a screen, was effective in decreasing pain ratings of children with burns during prolonged wound care.[24] Music therapy is an excellent adjunct to analgesia during burn care with children.[25–27] Fratianne and colleagues mentioned that music therapy significantly decreased the perception of pain in children during wound care;[28] whereas a sensory-focused intervention was more effective with adult burn survivors.[29] Child life interventions such as medical play that gives children control by having them role play and manipulate medical equipment, preoperative preparation about procedures or surgeries, and procedural support can facilitate coping in children and adolescents and decrease anxiety during burn care. The child's age and development need to be considered when selecting the intervention.[30]

Although over time family members may become more at ease with hospital routines, they will continue to have difficulty coping, feel anxious, and need updates about their patient's present and future status,[31] and they may develop new concerns as they are given new roles and responsibilities. Being away from support systems can be difficult. It is helpful to provide information about what to expect in the immediate future, to facilitate patient interaction, and provide honest information while allowing family members to protect themselves from overwhelming despair. Staff can find ways to allow family members to nurture their loved one and can assist them in becoming comfortable in caring for their patient's needs. Taking the time to treat the family is a very important part of treating the patient. This facilitates the family's resumption of feelings of competence and control, promotes hope, and encourages them to join with the burn team in the healing and rehabilitation of the patient. Psychotherapeutic work with the family should also identify and plan for management of family issues that may impede a patient's recovery and rehabilitation.

IN-HOSPITAL RECUPERATION PHASE

This phase involves burn survivors becoming physically and emotionally stronger as they face new challenges. Patients begin to comprehend the extent of their injury and may experience difficulty adapting to physical limitations and changes in their physical appearance. They may feel apprehensive about the future, continue to grieve losses, experience a loss of control and autonomy due to being dependent on others, and feel ambivalent about resuming self-care. The team can help motivate the survivor to participate in his or her treatment and assume responsibility for recovery. Individuals who desire optimal recovery need to comply with the medical team's instructions, many of which require significant physical discomfort. Pain continues to be a concern as patients become increasingly active in rehabilitative exercises. Pain and anxiety management are important to regain optimal physical functioning, and the interventions mentioned previously can facilitate pain and anxiety management.

Emotional lability and cognitive and behavioral regression may occur with younger children. Children often have difficulty expressing verbally their thoughts and feelings and may exhibit behavioral outbursts. Parents may be relieved to find that such behaviors are normal, and they often require guidance with implementation of treatment plans that target and positively reinforce desirable behaviors. Emotional reactions such as frustration, anger, and feelings of hopelessness can be difficult for family members to cope with. Hopelessness can occur when patients feel a lack of control and eventually give up trying, which can lead to depression. Research found that depressive symptoms may decrease during the initial hospitalization,[32] and depression during hospitalization is associated with physical functioning the first year post burn.[33] Psychotherapeutic work may involve helping the patient experience control, combat feelings of hopelessness and helplessness, facilitate healthy expression of emotions, achieve success, and feel rewarded while progressing through difficult procedures. Early in this phase, as the patient begins to ask about the future, the psychotherapist can describe the predictable pattern of emotional vicissitudes indicating that they are normal and can be endured and managed. Staff can demonstrate positive regard and acceptance of the patient while also helping the patient exercise control over destructive behaviors. Responses to questions should be honest but hopeful regarding the expectations of treatment and recovery. Interventions aimed at facilitating grief work, coping with body image concerns, management of anxiety and depression, and social skills training to facilitate social interactions are helpful.

Much psychotherapeutic work during this phase is accomplished with patient and family together. Families must learn to assist the patient's adjustment to the new situation, and the family system must accommodate as well. Research suggests it is important to strengthen the family unit, facilitate family closeness, and support attempts to organize their lives to incorporate additional duties involved in providing continued care for the patient.[34,35] Families will have to adapt to changes in their relationships and in the home environment that are necessary for the patient's recovery and rehabilitation after discharge.

REINTEGRATION PHASE

Preparing for a patient's discharge to outpatient status and eventually home begins upon admission to the burn unit.

A major objective is to facilitate a person's reintegration to life at home with the family and back to his or her community. Community reintegration is the process of becoming involved in the community, school, work, and leisure activities.[36] Returning home signifies social interactions with the immediate family as well as the extended family, friends, and strangers. Individuals must prepare for those encounters. They often feel anxious, fear social rejection, worry about being accepted, and are concerned about receiving social support.[37] Returning to a cohesive and supportive family environment[35,38] and loyal friends[39] can make this transition much smoother.

Psychotherapeutic activities involve education and preparation of patient and family about difficulties that may be encountered at discharge. Coping skills that can help should be discussed and practiced. Survivors and families often deny that they will have problems; however, psychotherapists can help prepare patients by offering suggestions to address problems that others have experienced. Issues such as recurrence of posttraumatic stress symptoms, anxiety and pain management, sleep disturbance, irritability, or fear of resuming sexual activities should be discussed prior to discharge.

There are now a spectrum of programs available to the survivor and some for the family. These professional programs help individuals and families through all the phases of recovery from major burn injuries. The Model System Knowledge Translation Center has a large number of print and downloadable forms containing useful information on a wide-range of burn-specific topics available in English and Spanish.

The Phoenix Society for Burn Survivors Inc. is "a nonprofit organization dedicated to empowering anyone affected by a burn injury."[40] This organization has several videos providing information and instruction on new skills, such as social skills, training survivors how to conduct supportive therapy, image enhancement, and school reentry.[40]

Cognitive-behavioral therapists have developed several techniques for treating negative body image and social anxiety related to a physical difference. Likely the most important is teaching a specific set of social skills.[41–43] Social skills programs are available to facilitate positive reintegration into society, improve social comfort, and increase confidence in social interactions. Social skills include having a short precise answer to explain "what happened," guiding the topic of conversation, using confident body language and eye contact, and assertively confronting confused and rude behavior. After mastering these skills through in-therapy practice, the survivor is encouraged to practice the skills by engaging in social activities. This practice helps break the social avoidance–depression cycle that may maintain the burn survivor's negative body image.

The program Be Your Best, by Barbara Kammerer Quayle and The Phoenix Society for Burn Survivors Inc., was developed to help burn survivors with community reintegration.[44] The UBelong Social Skills program includes skills to increase social comfort and confidence. Acquiring such skills can make encountering new people and situations and handling stares and unwelcome comments easier. They can help survivors and their loved ones navigate such encounters with added confidence.[44,45] Additionally Changing Faces, by James Partridge, a program dedicated to assisting persons with facial disfigurement, and recommends a brief social skills training program called 3-2-1-GO![46,47] Each of these programs provides strategies to prepare patients and their loved ones to answer questions related to the burn and to deal with staring and stigmatization. The patient may benefit from rehearsal using these skills on brief outings outside the hospital. If difficulties are encountered, the patient can consult with the burn team for direction and support to develop an alternate plan. Support groups for inpatients, outpatients, and their families can be extremely helpful in the process of anticipating difficulties at discharge and rehearsing solutions while also providing emotional support.

Reintegration of the patient into the family is also an area where the burn team can provide assistance. Patients are usually pleased to go home, but upon arrival, may find that their role in the family has changed significantly. The spouse–partner or parent–child relationship may now be one of survivor–caregiver, and the patient may feel helpless or burdensome. Staff can offer advice to families on ways to make the transition home go more smoothly. Tips such as spending time listening to the patient and trying to better understand his or her burn and hospital experience, limiting visitors so the patient can rest, working through feelings of guilt or blame, asking for help from friends and family, and utilizing relaxation techniques for pain management can aid both the patient and family in an easier return home.[48]

The burn team may also prepare the community to which a patient will return. Instructing those unfamiliar with burns in what to say or do to ease a survivor's reentry may assist with reintegration.[49–51] Variables that may affect burn survivors' ability to return to work once they are discharged from the hospital include size and severity of burn,[52,53] duration of hospitalization,[53,54] location of burn,[52,53] physical impairment,[53–56] pain,[55,56] prior employment history,[52,53,56] lack of vocational training,[57] work environment impediments,[54] and psychosocial difficulties.[53–57] Variables found to assist with return to work were psychosocial support, positive thinking, and vocational training.[56,57] Quinn and colleagues found that 66% of burn survivors returned to work within the first 2 years post burn.[53] In a study of young adults who sustained burns during childhood, Meyer and colleagues found 65% of the sample were employed either full- or part-time.[58] Individuals who do worked reported improved quality of life.[59,60]

Factors that affect adults returning to work can also influence school reentry for children. Staley and colleagues reported that children with small burns returned to school within the first week or month post burn, and most performed well academically.[61] However pediatric burn survivors often require assistance to return to school so they can learn, develop, and form peer relationships. Many burn centers in the United States have developed school reentry programs. These programs are designed to educate staff and students about aspects of burns, provide generic information about treatment and recovery, emphasize the child's abilities and needs, clarify ways in which the child may require assistance, address the importance of normalizing school activities, and providing peer support and acceptance. Working with the family and the school, a burn professional develops a plan to integrate the child back into

school. Usually, part of the process includes the burn professional visiting the child's classroom, explaining the nature of burns and rehabilitation, engendering compassion and support for the survivor, and answering questions. Burn professionals running school reentry programs have received a good deal of positive feedback from schools and families, but the long-term efficacy of school reentry programs has not been empirically demonstrated.[51,62] A few studies found interventions such as on-site school visits[62] and educational videos/DVDs[62,63] are beneficial. The Journey Back, by The Phoenix Society for Burn Survivors, is a comprehensive program providing generic materials designed to help pediatric burn survivors, families, and school communities with the re-entry process.[64] Another program, developed by Shriners Hospitals for Children–Cincinnati, is the Remember Me Program, which keeps the pediatric burn patient in touch with his or her classmates during the lengthy burn-related hospitalization. A teddy bear is placed in the child's seat while he is absent, and communication with and from classmates is encouraged.[65]

REHABILITATION PHASE, POSTDISCHARGE

When survivors transition to the outpatient setting and home, they continue to have physical and psychosocial needs. Rehabilitation may require several months to years, wounds may be vulnerable to breakdown, and individuals may need to use special splints and pressure garments' and continue to exercise. Grief work often continues as survivors cope with losses and delayed grief reactions can occur. Symptoms of posttraumatic stress may recur upon leaving the protective hospital environment. Body image concerns may become more acute as survivors confront stigmatizing reactions from others. Family's social and emotional resources may become taxed as the family transitions into becoming the patient's primary caregivers.

The ratings of significant others on a standardized behavioral scale suggested that young adult survivors of childhood burns who were an average of 14 years post burn were doing well. However on standardized psychiatric interviews, a high percentage of survivors reported experiencing psychiatric disorders specifically related to social situations,[66] and personality disorders[67] warranting diagnoses. Similar results were found in a study of adolescents who were an average 10 years post burn.[68] In these studies survivors[44,48] were rated by a physical therapist to have no physical limitations that prevented caring for themselves and participating in ordinary activities, their anxieties were severe enough to limit their achievement to full capacity.[68] Even if most burn survivors eventually function satisfactorily by external criteria, clinically, they may be suffering significant distress that is not easily observable. A psychosocial goal is to understand the sources of survivors' distress and to develop interventions that enable survivors to become full participants in society. It would be extremely valuable to patients leaving the hospital, as well as to their social network, employers, and care providers, if there were a set of predictors that could reliably estimate when and to what degree functional improvement could be expected over time. Fauerbach and colleagues evaluated functional impairment of survivors from discharge and across 2 years and found psychological impairment was predicted by prior alcohol abuse, psychological distress, and psychological function both before the burn and at discharge.[69] These data can inform providers and adult patients about factors that could be modified to effect more desirable outcomes.

Assisting With Grief Following Trauma

Traumatic events are frightening experiences that create uncertainty, anxiety, and a sense of threat for victims and their families.[70,71] An individual who experiences a burn injury may face multiple changes and losses, including separation from one's support network and home environment, uncertainty regarding the length of hospitalization and process, changes with physical appearance, and in certain circumstances, death of loved ones. On the burn unit, these issues often become the focus of psychosocial intervention. Successful grief therapy requires that mental health professionals have an understanding of the traumatic event and knowledge of the individual's past experiences with loss and coping styles and cultural and religious beliefs.[70] Mental health professionals can assist re-establishing a sense of equilibrium following trauma by facilitating the grieving process.

The terms "bereavement," "grief," and "complicated grief" merit clarification. *Bereavement* refers to coping with the death of a loved one, whereas *grief* is a broader term referring to coping with loss in general.[72] Grief reactions are individually unique and age dependent.[71,73] *Complicated grief* occurs in adults when the grieving process is compromised by trauma. Prigerson and Jacobs described complicated bereavement as difficulty comprehending and accepting the death of a loved one, persistent and intense longing for the deceased, intrusive thoughts about the deceased, and avoidance of painful memories.[74] Children can also experience childhood traumatic grief when there is traumatic loss or bereavement.[71,75,76] This construct evolved from the literature in child development and trauma and occurs when trauma symptoms interfere with the child's ability to grieve normally. The child may engage in avoidance behaviors that interfere with the normal grieving process.[71,75,76] Traumatic grief can co-occur with psychiatric disorders such as depression and posttraumatic stress disorder (PTSD).[71,75,77] The prevalence of burn survivors and family members who experience traumatic grief is unknown. Clinical experience suggests that many burn survivors progress through the grieving process without complications and are resilient when faced with loss. Brown and Goodman found that children who retained a positive memory and ongoing presence of their loved one were able to grieve normally.[71]

On the burn unit, mental health professionals may need to inform the burn survivor about multiple losses and life changes, which may include changes in appearance, loss of body parts, the death of others such as family and friends, loss of a pet, or loss of a home. In some circumstances it requires informing, supporting, and preparing the family for bereavement of the burn trauma victim. This is a delicate process that requires appropriate timing and psychosocial planning. Important factors to consider when planning the disclosure process with patients and families include the patient's medical stability and ability to participate in

conversations; the readiness of the patient and family to hear the news; identification of what they know about the trauma and the factors related to the traumatic event; their wishes regarding disclosure; and knowledge of their cultural, religious and spiritual needs.[78] Bronson and Price discussed important principles to keep in mind when working with grieving children after burn trauma. They suggest a process that includes supportive and compassionate truth-telling, acceptance, respectfulness of individual differences and feelings, and giving the individual an opportunity to say good-bye.[79] If death occurs on the burn unit, staff can psychologically support the family by obtaining desired spiritual assistance, assisting them with paperwork for the burial process, allowing them quiet private time with the deceased, and providing distraught family with memory items if they wish to have them.

Cultural Sensitivity

Burn survivors come from diverse cultures, and burn care teams must be sensitive to how cultural issues can affect survivors and families in all the phases of the recovery process. "Culture" refers to the socially transmitted expectations, beliefs, traditions, and behavioral patterns of a given community at a point in time.[80] Factors influencing culture include country of origin, geographical location within the country, ethnicity, and socioeconomic background. Staff must also be aware of their own biases, values, and assumptions that stem from their cultures.[81,82]

Acculturation is the process by which individuals from one culture embrace patterns, customs, beliefs, values, and the language of the dominant culture.[83,84] Patients and their families on first arriving at a burn care facility must rapidly adapt to the culture of the hospital environment. Even if the hospital is within their own community, they experience some level of culture shock and acculturation. This process is even more complicated for those who are transported for care to communities far removed from their homes and perhaps in another country. For some patients, this traumatic situation is the first time they have traveled to another country and the first time they have had to deal with differences in language, currency, living accommodations, and foods. Individuals' concepts of time and space, appropriate hospitality, importance of greetings, how nonverbal gestures are interpreted, and ways of expressing gratitude may differ greatly among cultures. Ideas of what caused the burn injury and what is necessary for healing to occur also are determined by cultural values.[85,86]

Coping with such a multitude of unfamiliar experiences in a traumatic situation is an extraordinary challenge that can inhibit a patient's or family's ability to participate in the recovery process. The burn team must be aware of cultural differences and make culturally appropriate accommodations to a patient's treatment plan. Cultural traditions can be incorporated into treatment plans to enhance participation toward recovery. For example, if a Latino family believes that the burn incident was a result of an "evil eye," they may request a cleansing ritual.[83] It is impossible for providers to know the beliefs and expectations of every culture; however, cultural sensitivity and a willingness to learn are necessary for good patient–provider communication and improve outcome. Staff can acknowledge their lack of familiarity and ask the patient/family whether there is anything the team can do to help meet their cultural, spiritual, and religious needs. The question conveys respect for cultural differences and a desire to help through the acculturation process.

Knowledge and sensitivity of cultural practices is also important when focusing on safety and prevention education with patients and families. Epidemiological research has focused on identification of sociodemographic risk factors and cultural practices that have contributed to burn injuries in developed and developing countries and found differences among these countries.[87–91] The highest incidence of severe burns occurs in low- and middle-income countries,[92] with children being at highest risk.[87] In developing countries, factors such as poverty, crowding, food preparation practices, unstable cooking methods, and inconsistent supervision practices place young children at high risk for scald burns.[88,93,94] Identification of modifiable risk factors and cultural practices can facilitate education about prevention for burn survivors and their families. A recent study of children 5 and younger from Mexico who received medical care in a U.S. hospital found the primary causes of burns were flame and scald injuries. Flame burns were caused by explosions of flammable substances and house fires, and scalds were attributed to falling in large containers of hot liquids placed on the ground and spills.[91]

Postburn Psychological Distress and Long-Term Outcome

There are many disturbing aspects of a major burn injury including memories and emotions from the burn injury event and its circumstances, the initial sight of the wound, and pain both at rest and during unavoidable wound care and rehabilitation. Further challenges accrue as healing progresses, such as changes in appearance and function as skin contracts and scars progress through the maturation phases. There are additional disturbances from expected or actual reactions of family, friends, associates, and strangers as these members of the social sphere view the wounds, the scars throughout maturation phases, rehabilitation splints and garments, and the like. Each of these stressors, when exceeding individual and group resilience factors, imposes a burden on the person (distress within mind–body self) and between the person and his or her social network (reciprocal distress between/within the patient and those affected individuals within the embedded social network).

Among the most common manifestations of psychosocial distress for burn survivors following an injury are sleep disturbance,[95,96] depression,[97,98] body image dissatisfaction,[99] and acute and posttraumatic distress.[96,100] Not unexpectedly, the average level of psychological distress among those with major burns was significantly higher than that of a normative sample.[34]

ACUTE AND POSTTRAUMA DISTRESS

Acute stress disorder (ASD) and Post-traumatic stress disorder (PTSD) following exposure to trauma may occur. According to the *Diagnostic and Statistical Manual of Mental*

Disorders (DSM-5), individuals with trauma disorders experience intrusion symptoms, negative mood, dissociative symptoms, avoidance behaviors, and increased arousal.[101] The prevalence rate of ASD among adult burn survivors has varied between 10% and 23%,[100,102,103] whereas the rate among pediatric survivors has been between 8% and 31%.[11,104,105] It is estimated that 15–45% of adult burn survivors meet the criteria for PTSD in the first year post burn,[103] and almost 50% meet the criteria for at least one of the PTSD symptoms clusters.[99,106] The current and lifetime incidences of PTSD in pediatric burn survivors are 7% and 30% respectively;[107] and in young adults who sustained childhood burns, they were 9% and 21% respectively.[66]

Posttrauma distress has been found to be associated with greater lengths of acute hospitalization,[106] enhanced sense of distress, and impaired adjustment to injury.[108] In the population of patients surviving severe burns, certain aspects of pretrauma adjustment (history of mood disorder) and coping style[109] can influence the risk of developing PTSD following trauma exposure.[5] Individual factors (avoidance of reminders) and aspects of the injury (injury severity, facial injury) have been associated with poorer outcome.[110] Those with high levels of trait neuroticism appear to be at greater risk of PTSD symptomatology following burn injury, whereas high levels of extraversion appear protective against PTSD.[52,111]

It might be assumed that PTSD is related to greater initial injury; however, PTSD among burn survivors has not been found to be related to severity of injury.[112] On the other hand, high levels of acute posttrauma stress symptomatology have been shown to be positively related to perception of more intense pain among hospitalized burn patients.[113,114] High emotional distress and ASD symptoms during hospitalization are risk factors for PTSD in adults 2 years post burn.[103,115] However, in a long-term follow-up study of children who experienced ASD symptoms during their initial hospitalization and a non-ASD matched comparison group, there was no significant difference in the prevalence of lifetime PTSD between the groups. Eight percent of the children in the ASD group and 5% in the non-ASD group met diagnostic criteria for PTSD. Children were an average of 5 years post burn.[116]

Chronicity of Postburn Psychological Distress: From In-Hospital Through Long-Term Follow-Up

Prospective longitudinal research has shown that the level of distress one reports experiencing during acute hospitalization tends to persist across at least 2 years of follow-up. Analyses of 2-year longitudinal data quite consistently identified 3–4 groups of survivors whose level of distress (posttrauma distress, body image dissatisfaction/social discomfort, generalized distress) formed trajectories characterized as chronically severe, moderately severe hovering around cutoff for clinical disorder, a subclinical group, and a group essentially without symptoms.[103,117,118] The stability of these trajectories is illustrated in that, across the 2-year follow-up, only 5–10% of participants reported a reliable and clinically significant change in distress that moved them from one trajectory to another.[103] Of the 5–10% of participants who changed from one trajectory to another, about half reported less distress (improved) and half reported increased distress (worsened). The stability in distress trajectories among survivors of major burns is largely unique relative to other trauma-exposed samples. These other populations tend to show recovery trajectories of early recovery (~6 months), mid-term recovery (~12 months), and a chronic trajectory, and some studies found a delayed-onset trajectory with early low symptom severity followed by increasing symptoms beginning about 6 months out.[119] Thus, some research to date has identified varied forms of psychological distress, their prevalence, the stability of distress level over long-term follow-up, and the enduring impact of early psychological distress on longitudinal psychological and social adjustment. These replicated findings highlight the need for identifying early survivors with high levels of distress to attempt to circumvent the suffering, impairment, and disability that may ensue.

The goal of rehabilitation is to enable full social-environmental integration, including access to social opportunities and physical space (absence of physical barriers). The National Institute of Disability and Independent Living Rehabilitation Research (NIDLRR) formerly the National Institute of Disability Rehabilitation Research (NIDRR) presents a paradigm for conceptualizing and conducting rehabilitation research that places environmental factors on an equal footing with person factors.[120] Burn-related research has begun to progress beyond identifying forms of distress and quantifying their prevalence, largely on the basis of targeted federal funding by the NIDLRR through its multicenter Burn Model System database and both multicenter and site-specific projects.[121] There are at least three key questions to address as research focus shifts to developing new psychological, behavioral, and social treatments: What are the mechanisms by which early distress levels are maintained across long-term follow-up? Is the best approach to prevent distress by (a) reducing risk factors, (b) enhancing resilience factors, or (c) reducing risk and enhancing resilience? Also, can high levels of distress, once developed, be effectively reduced and maintained at low levels? Finally, can the factors that initiate and maintain low distress levels be influenced by medical, psychological, or social factors in a way that can provide relief to those experiencing distress?

Theory-Guided Research as the Next Step in Enhancing Psychological and Social Adjustment

Unfortunately there has not been enough burn-specific research in which a priori aims were explicitly stated addressing the questions just listed. It is proposed that, in order to promote such research, a common theory and language should be adopted in the field. Specifically, learning-based theories grounded in biology and neuroscience[122] are the best formulated theories, and treatments developed with these theories have acquired the strongest evidence

base in other trauma-related fields.[123] Thus it is suggested that burn researchers utilize theories and associated design/methods to more effectively guide treatment development in burns and to conceptualize the related research aims. Our general approach to assessment is a behavioral approach based on learning principles (e.g. conditioning, cognitive restructuring, and social learning theories) where adjustment is the target of intervention. Assessment and treatment are integrally related, and both occur simultaneously throughout the recovery and rehabilitation process. In this section, posttrauma distress is examined, but similar explication will be necessary for each problem area being addressed, such as body image dissatisfaction, social stigmatization, and social rejection.

Formulating Psychological Distress Following Burn Injury: Using Posttrauma Distress as an Illustration

Classical conditioning can be used to describe the process involved in the development of trauma symptoms. The traumatic event can be conceptualized as the unconditioned stimulus (UCS) that causes an unconditioned response (UCR) such as fight–flight, freeze, and distress. Reexperiencing the trauma is the conditioned stimulus (CS) and elicits a conditioned response (CR) such as flight–fight, freeze, and distress. Failure to extinguish the CR when a CS is presented may lead to maladaptive behavior. In addition, there are preinjury variables that may contribute to a person's difficulty coping, including early life experiences, previous traumas, learned behaviors, genetic predisposition, and personality characteristics.

Maintenance occurs when approaching cues, reminders, and triggers (CS) cause increased distress (feelings of horror/helplessness) (CR) and, if perceived intolerable, can lead to escape, avoidance, and withdrawal behaviors. The avoidance response is reinforced by lessening the distress and more likely to continue as the habit strengthens with each exposure and avoidance pairing. Three key motives have been observed in adult burn survivors, and these have been conceptualized as: *Approach* (move toward threat; Fight), *Avoidance* (move away from threat; Flight), and *Approach-Avoidance* conflict or ambivalence (alternately moving toward then away from threat; Freeze). The behaviors associated with these motives are the classic survival responses.[115] For example, re-experiencing symptoms of ASD/PTSD can be understood as CS that elicit basic survival motivations and behaviors (CR) that were elicited by the life-threatening event itself (UCS).

We propose use of cognitive-behavioral interventions designed to lessen the trauma-related distress target symptoms of re-experiencing (memories, flashbacks, nightmares), avoidance behaviors (flight from cues/contexts), and hyperarousal (anticipation or expectation of further threat/harm). It is proposed that an important component of the cognitive and emotional processing of traumatic events is to provide or renew the sense that memories, even horrific ones, can no longer harm us directly, are the means by which we can learn from the past, and can help us to be more prepared for the future. The ability to plan for the future will reduce the likelihood of recurrence and provide one the means for helping others to acquire this knowledge without having to go through a similar episode.

Social learning occurs by watching another person behave in novel ways as they respond to social situations of importance to the observer. When observing a person whom we hold in high esteem as that person achieves a desired outcome (reduced distress), the observer is more likely to acquire and practice that behavior. Social learning can help one to learn new methods of healthy coping. Seeing someone skillfully use social skills to defuse a negative comment can be helpful. Such learning enhances one's comfort and confidence in intentionally overcoming the distress associated with trauma memories and social stigmatization.

RESILIENCE AND RECOVERY

Resilience is the capability to adjust well when dealing with difficult situations. While some individuals adapt well, others experience difficulty.[119] When exposed to a traumatic event or significant stressors, coping is affected by the individual's characteristics and social structures. Social support in the form of emotional, material, and cognitive support is important in the adjustment process. These facets of social support can be facilitated and maintained by different systems, including family, community, state, national, and international systems.[119]

BODY IMAGE, STIGMATIZATION, AND SOCIAL INTEGRATION

Body image is one's self-evaluation of one's physical appearance.[124] Negative body image or body dissatisfaction is the belief that one is unattractive. Body image is highly correlated with self-esteem, particularly among adolescents and young adults. Negative body image is a component of or is highly associated with a number of psychiatric disorders including depression, social anxiety, eating disorders, and drug abuse.[124] Due to the fact that burn survivors may be permanently scarred by their injuries, it is commonly hypothesized that burn survivors are at high risk of developing a negative body image.[125–128] Body image is a consequence of the interaction between a person and his or her social environment.[124,129] In order to understand the challenge of adapting one's body image to having burn scars, it is necessary to be familiar with the appearance norms of the burn survivor's culture. These sociocultural norms establish criteria for the importance of appearance, how one should appear, and the room for deviation allowed from the norms.[124,127,129,130]

SOCIAL BELONGINGNESS AS CORE SURVIVAL NEED

Belongingness is understood as one of the core needs driving human social behavior. Individuals are particularly sensitive to being excluded, especially when this is on the basis of one's appearance and function that cannot be readily changed.[131] The *pivotal sociometer theory* posits that self-esteem is a marker for the degree of belonging one is

experiencing.[131] As belonging improves (inclusion in an activity), self-esteem increases. When belonging declines (excluded from an activity), self-esteem diminishes. A recent meta-analysis confirmed expectations that, following social exclusion, negative mood increases and both positive mood and self-esteem decline.[132] Exclusion-related social pain stimulates neural structures that also affect mood and self-esteem and thus motivate adaptive coping to these threats to social belonging.[132]

An elegant series of experiments found that the group of participants who were made to feel excluded, relative to those who were not made to feel excluded afterward attended more to positive memories and interpreted ambiguous stimuli more positively.[133] Of note, this automatic emotion regulation process was observed among individuals with high self-esteem and low depression but not among those with low self-esteem or high depression.[133] In addition, a study was conducted among participants whose self-esteem was strongly based on appearance and who were subjected to social exclusion. Those with high self-esteem sought to reconnect to those who had excluded them, whereas those with low self-esteem avoided social contact.[134] Taken together, these findings suggests that high self-esteem along with low depression is a good marker for resilience, whereas low self-esteem in the presence of high depression is a good marker for vulnerability. These means of estimating vulnerability (low self-esteem, high depression) and resilience (high self-esteem, low depression) may serve as a means of discerning in the acute phase those burn survivors at high versus low risk for having difficulty reintegrating into social roles and public settings.

Perceived discrimination, similar in nature and impact to social exclusion, has also been linked to poor health outcomes.[135] A systematic review found strong evidence that discrimination increases the stress response and concluded that it is associated with increased engagement in health risk behavior and decreased participation in protective health behaviors.[136] Discrimination is a form of exclusion that is omnipresent culturally and globally, is distressing, and negatively impacts health and adjustment.[135]

APPEARANCE, SOCIAL STIGMATIZATION, AND SOCIAL EXCLUSION

Appearance norms are communicated to the individual through both mass media and interpersonal behavior. Via mass media (magazines, television, and the Internet), people are exposed to hundreds of images daily of "beautiful people" technologically enhanced through processes such as airbrushing, soft-focus camera shots, and manipulated digital images. The message, implicit or explicit, of cosmetic product advertisements is that you are an inadequate person unless you are very attractive, and that a particular product will enhance your appearance. There is also interpersonal pressure to conform to appearance norms. One review of the literature on appearance concluded that people tend to both make positive assumptions about "good-looking" people and treat them more favorably than less attractive people.[137] On the other hand people who deviate from the beauty standard are more likely to experience stigmatization and discrimination behavior.[138] For example, children are most frequently teased about their appearance in comparison to all other aspects of their person or behavior.

The most troubling challenge for many people re-entering society following major burns is their own appraisal of scars and related changes in appearance and function and their expectations of what others will think and do. Social stigmatization is a process in which people are socially rejected (put out) and ostracized (kept out) based on a negative stereotype.[139] People with visible differences have long been stigmatized in the mass media. In many movies and video games, the villain is a person with a physical difference, often burn scars. Stigmatizing interpersonal behaviors experienced by burn survivors include an absence of friendliness and courtesy, staring, pointing, startled and disgusted reactions, ignoring, avoidance, confused behavior, teasing, bullying, and discrimination.[126,127,138,140] There is evidence that people with visible differences are more likely than people without visible differences to experience stigmatizing interpersonal behavior. For example, when interacting with an actor who had makeup applied that looked like a real disfigurement, participants were less likely to offer assistance or sit or stand close, and they limited their interactions. Job interviewers rated actors without such disfigurements as more fit for the position than those with a mock visible difference.[141–143]

This emphasis on an attractive appearance is an onerous barrier to inclusion and social participation for those with a visible difference. In addition, acquired disfigurement can be difficult to incorporate into preinjury body image.[144] Body image, a facet of self-esteem, is formed at the nexus at which individual differences intersect with social group norms.[145] Consequently, injury-related disfigurement creates distress over both an altered body image and social exclusion based on appearance. Burn injuries cause an immediate change in appearance, and to complicate matters, uncertainty about final appearance outcome persists as healing is followed by months or years of scar maturation during which appearance typically becomes worse before improving.[146] This change in appearance thus represents an amalgam of threats to safety, body image/self-esteem, and social belonging.

What are the psychosocial consequences for burn survivors living in a highly beauty-conscious society? Few studies have investigated the frequency of body image dissatisfaction and perceived stigmatization and their correlates among burn survivors.

Studies that have compared the body image of burn survivors to a nonburn comparison group have found no normative differences.[147,148] In one study comparing a group of long-term pediatric burn survivors to an age-matched nonburn comparison group on a body image measure, there was no difference between the males in the two groups. Among the females, on average, the burn group had higher body image scores than the comparison group.[148] This surprising finding needs to be interpreted with caution given that it has not been replicated. Much more remains to be done in order to discern whether, with whom, and at what point in recovery burn survivors are most affected by altered appearance. Furthermore, there remains much to do in order to firmly establish what person, injury, and social factors may protect against body image dissatisfaction or promote recovery from it.

FACTORS AFFECTING BODY IMAGE DISSATISFACTION AND SOCIAL DISCOMFORT

Physical appearance is an almost universal criterion for group membership.[149] The greater the degree to which one fits in with the group culture, including normative appearance, the greater likelihood one has of being included. This is problematic in that burn scars often change appearance in a manner that unnecessarily disrupts inclusion and may lower the belonging and self-esteem of some burn survivors. Recent studies among burn survivors investigated the theory that social exclusion of individuals with differences in appearance is motivated by the fear of disease or injury[149] or emotions.[150] It seems plausible to consider that there may be two stages of observer's reactions to altered appearance. The first is likely genetically determined and is the fear of external signs on the body that might connote disease. This reaction is automatic and largely beyond conscious choice. The second reaction is more likely to involve a higher order of cognition that is acquired through social norms, parental training, and peer conformity. This higher level of cognitive processing and emotion regulation involves conscious appraisal of appearance alterations and takes into consideration social norms for appropriate behavior.

In regards to risk factors for negative body image, severity of burn scarring has proved to have a modest relationship with body image among both adult and child burn survivors. Across studies, the correlation between burn severity and body image has ranged from 0.00 to 0.40.[99,148,151,152] One study suggested that the relationship between perceived scar severity and body image is moderated by importance of appearance.[153] For those burn survivors who placed little value on physical appearance, self-rated scar severity had no relationship with body image. For those burn survivors who highly valued physical appearance, scar severity was highly predictive of body image dissatisfaction. All studies investigating the relationship between scar severity and body image have been limited by the lack of a reliable, standardized measure of scar severity. Many studies to date have used proxy variables to measure scar severity, such as total body surface area (TBSA), TBSA-full thickness (TBSA-FT), and location or number of burn-related surgeries.

Within the literature there has been a theoretical debate regarding the relationship between burn scar location and body image. The "visible hypothesis" posits that socially visible scars, such as scars on the face, will be highly related to body image dissatisfaction because burn survivors with visible scars will experience more frequent stigmatizing reactions from others. The "hidden scar" hypothesis posits that because the person has fewer opportunities to learn how to deal with the reactions of others, he or she will live in fear of the scar being revealed and thus have a negative body image. There is little empirical evidence for either hypothesis. In the studies that have tested these formulations, the correlation between facial scarring and body image ranged from 0.00 to 0.20.[151] Gender has also been investigated as a possible risk factor. In comparison to men, women burn survivors tend to have lower body image satisfaction; however the gender difference in burn survivors has not been as great or as consistent across studies as it is in the general population. Across studies the strongest correlates of body image among burn survivors has been social and emotional variables such as social support, perceived social stigmatization, importance of appearance, and depression (*r's* ranging from 0.30 to 0.60).[99,148,151,152,154]

In regards to stigmatization a few studies have focused on pediatric burn survivors. Among pediatric burn survivors, there is some evidence that appearance-related stigmatization is a common concern. In a survey of 250 pediatric burn survivors, 60% of participants reported being bullied within the last 6 months. Twenty-five percent of the sample indicated that bullying was a "big problem."[155] However, to date, there is not enough evidence to conclude that burn survivors experience stigmatizing interpersonal behavior more frequently than the general population. First, appearance-related teasing appears to be very common in the general population. In a survey of adolescents in Britain, 52% of the sample had experienced distress related to appearance-related teasing, and 10% reported at least one incidence of avoiding going to school fearing appearance-related teasing.[128] No studies have been completed directly comparing the experience of burn survivors with stigmatizing behaviors to a comparison group. Two studies comparing the frequency with which children with craniofacial differences experienced teasing and other victimization behavior to a comparison group found no differences between groups.[156,157]

To date there is no empirical evidence that burn survivors as a group experience higher levels of negative body image or more stigmatizing behavior than nonburn comparison groups. However relatively few studies have been completed, and these findings need to be replicated before they are accepted as fact. Over the past decade, a number of new standardized measures and structured interviews have been validated to measure body image, perceived stigmatization, and social comfort among people with visible differences.[153,158–160] Hopefully these instruments will facilitate future body image research among burn survivors. Clinical experience suggests that approximately 20–30% of burn survivors struggle with body image and social integration issues. For these burn survivors, the emotional pain that results from body image dissatisfaction and social discomfort can be very intense.

DISTRESS OF FAMILIES OF BURN SURVIVORS

Long-term impact on families of burn survivors has not been well studied, but clinical experience and scant empirical data indicate the sequelae to be significant. Family members may continue to experience symptoms of post-traumatic stress after a patient has returned home.[31] Parents of survivors of massive injuries appear extraordinarily stressed even several years after their children's recoveries.[4,161] A series of studies found that parents of pediatric burn patients reported significant depressive symptoms at 2 years post injury, and they attributed their distress to their children.[4,162] Although parental distress appears to improve with time for most, parents of the most troubled burned children continued across time to be troubled themselves.[162] Parents also express concern for their other children, whom some felt had been slighted of attention and time while the child with a burn injury required a lot of the family's attention. Even free medical and surgical care did

not eliminate the burden of direct and indirect costs of burn injury, and many families experience financial difficulties attendant to the injury and treatment of their child.[4]

LONG-TERM OUTCOME: QUALITY OF LIFE

After survival is assured, quality of life is arguably the most important outcome to individuals who are seriously ill or injured. Health-related quality of life has been defined as a multifactorial construct that involves an individual's degree of satisfaction and level of health and functioning in several core domains including: physical-behavioral (ability to perform self-care behaviors) and psychological well-being (subjective sense of contentment and the absence of emotional distress), social and role functioning (ability to fulfill family, work, and community responsibilities), and personal perception of health (satisfaction with one's health status).[163] Research has found that participation in a comprehensive wellness and exercise program helps improve physical and psychosocial well-being for burn survivors.[164–168]

Quality of life has been investigated using general health questionnaires or measures that focus on specific behaviors. Recent research has begun to focus on the overall quality of life.[169–171] As with self-report behavioral scales, most long-term (>2 years) burn survivors appear to have eventually developed satisfactory adjustment and are within normal range on domain subscales of the SF-36, a widely used measure that assesses general health quality of life.[163,169,171] Using a measure that examined specific behaviors, young adults who sustained burns as children rated their overall quality of life lower than the normative group.[170]

Many burn survivors question if they can have meaningful relationships and have questions about intimacy and sexual activity. Meyer and colleagues examined the sexual attitudes and behaviors of adult burn survivors and found that, overall, they felt positive about their sexual experiences; however gender differences were evident, with the women reporting an easier time finding partners.[172] Bianchi found that there was no relationship between burn severity and sexual esteem for male survivors.[173]

The past couple of decades of our burn-related research has consistently shown that early psychological distress (i.e., in-hospital) can have an enduring impact on physical, psychological, and social health and function.[34,100,174] For example, psychological distress while in the hospital was found to be associated with significantly greater impairment of physical and psychological function and slower rates of recovery over the course of the first year following a major burn injury, even when preburn physical and psychological health and function were statistically controlled.[174] In a second longitudinal study following burn survivors over the first year of recovery, psychological distress was highly correlated with poor quality of life throughout the study.[175] In addition, body image dissatisfaction upon leaving the hospital is associated with prolonged periods of poorer mental health-related quality of life among adult patients following disfiguring burns, and this was independent of general distress, injury severity, and preinjury psychosocial adjustment.[99] Furthermore, posttrauma distress during the late inpatient phase is predictive of significant problems with adjustment during subsequent phases of recovery.[108,176] These and other quality-of-life outcome studies clearly establish the enduring impact of early distress on early, mid-term, and long-term psychosocial adjustment. In conclusion, the quality-of-life research points to the importance of early detection and treatment of psychosocial problems among burn survivors.

INTERVENTIONS FOR BURN SURVIVORS BEYOND ACUTE CARE

Moving beyond general social support, psychologists and psychiatrists specializing in burn recovery have been working to develop theoretically based, empirically testable interventions that can be tailored to the individual needs of both pediatric and adult patients. As stated earlier, the psychosocial sequelae of a burn are quite varied. In order to create effective individual treatment plans there need to be effective treatment protocols for treating specific common problems. Within recent years detailed psychotherapy treatment programs have been described to treat PTSD[177] and ASD[178] and to teach social skills training for coping with disfigurement.[42,43] However much more research is needed to empirically demonstrate the efficacy of these interventions among burn survivors and other groups with physical differences.[179]

Cognitive therapy for the treatment of body image and social integration concerns of people with visible differences is an example of a tailored psychotherapy.[42,43,180,181] Although much has been learned about the risk and protective factors for body image issues and social adjustment, there are few empirically validated treatments.[154] The therapy is based on a detailed conceptualization of how a survivor's social environment, thoughts, behaviors, and emotions interact to maintain the survivor's distress. Given the sociocultural premium placed on appearance, it is understandable that some burn survivors adapt personal values that prioritize physical appearance. Consequently these individuals may ruminate about the discrepancy between their appearance and the ideal (their lost appearance). Self-conscious about appearance, these individuals may act in ways that confirm their belief that their appearance is socially unacceptable. For example, they may minimize or avoid social interactions with others. This social avoidance may be interpreted by others as curt or rejecting behavior by the burn survivor. Thus brief awkward social encounters turn into self-confirming experiences that validate survivors' beliefs that their burn scars make them socially inadequate persons.

Many burn survivors lack access to mental health care in general and access to mental health providers with expertise in treating burn survivors in particular. Most burn survivors who suffer psychological symptoms of distress following discharge from a burn center and who desire treatment must rely on mental health professionals in the community. However, it may be difficult for them to find helpful resources. In a study of young adults who sustained burns during childhood, none were receiving professional help for their difficulties as adults.[66] Burn survivors do not always qualify for financial assistance because their "disabilities" are declared insufficient to require such aid. Even when they can afford such treatment, they may be unable

to find a mental health professional to work with them who is knowledgeable about burn care.

Given the limited access to effective psychotherapy, perhaps more effective strategies for improving psychosocial outcomes for burn survivors are those interventions that create more accepting and tolerant social environments. Programs or organizations with the mission of engendering social acceptance for burn survivors and other people with physical differences include school reentry programs, burn camps, the Phoenix Society for Burn Survivors in the United States,[40] and Changing Faces based in the United Kingdom.[46,47] Burn camps provide an opportunity for pediatric burn survivors to interact and socialize with other burn survivors and participate in recreational activities in a supportive environment. These camps may increase self-esteem and also help to build confidence and diminish anxiety.[182,183] Some camps were designed to provide mental health and rehabilitation services to children once they have left the hospital, whereas other camps are for recreational purposes only.[184] A recent study revealed that increased years of attendance at burn camp was positively correlated with lower rates of somatic, separation, and total anxiety symptoms.[185] Adolescents in another study credited the burn camp experience with helping them with identity formation and reflection, improved social interactions, and increased initiative and cooperation with others. Results suggested that burn camp participation not only helped burn-injured youth deal with their burns, but also assisted them in the development of social and basic life skills.[186] Increased posttraumatic growth has also been a documented outcome of long-term tenure at burn camp, as well as attendance at young adult retreats that serve burn-injured youth ages 16–21.[187] These programs provide assistance with the transition to adulthood and provide burn survivor support beyond the burn camp setting.

The Phoenix Society for Burn Survivors in conjunction with multiple burn centers coordinates the Soar Program, which provides peer support for hospitalized patients and their families. "In addition, they host the annual World Burn Congress, a conference that brings together burn survivors, their families, firefighters, and burn care professionals to address the aftercare and reintegration issues of burn survivors."[40] The Phoenix Society for Burn Survivors and the American Burn Association also have a joint Aftercare and Reintegration Committee. This group is devoted to improving psychological health and social reintegration following burns.

As mentioned previously, Changing Faces is another charity based in the United Kingdom and is dedicated to creating "a culture of inclusion for people with disfigurement."[47] In addition to providing counseling and supporting research, it organizes sustained political campaigns in support of the civil and human rights of people with visible differences. For example the group has organized the ongoing "face equality" campaign with the goal of challenging "media, advertisers, and the film industry to adopt more factual and unbiased portrayals of people with disfigurements, actively avoiding language and imagery that creates prejudice." In addition, the campaign has asked politicians and policy-makers to "ensure that facial prejudice and discrimination are effectively outlawed by improving anti-discrimination law and promoting best practice."[47]

Summary

Most burn survivors do eventually adapt well and resume lives of productive activity with satisfactory self-esteem and social interactions. Empirical data indicate that the first year or so postburn is fraught with discomfort and distress, but much of the difficulty is transient. The process of psychological adaptation often continues for several years. Symptoms of disturbance that linger among burn survivors are likely to be such that only intimate friends and family members will observe them, so it is valuable for persons with expertise in burn care adaptation to periodically assess survivors and provide an opportunity for intervention.

That most burn survivors do amazingly well should never be interpreted as indicative of ease in adaptation. We must never diminish the pain and suffering they endure from physical and psychological wounds. As psychotherapists to a large number of burn survivors, we know very well the struggles survivors can experience. They have moments of true despair and hopelessness, moments of rage, and moments of joy. Fortunate psychotherapists can know them through all extremes: looking for glimmers of hope, validating anger, celebrating victories, and gaining deep respect for resilience of human beings.

Acknowldgments

We would like to acknowledge Patricia E. Blakeney, PhD, and John W. Lawrence, PhD, who contributed to the previous psychosocial chapter(s) for this book.
