Preface

Over the past three decades, vast improvements in survival from severe burns have been accompanied by a progressively greater understanding of the complex processes underlying this type of trauma. Basic science, and translational and clinical discoveries have provided new opportunities to advance burn care along its entire spectrum from management of burn shock, inhalation injury, sepsis, and hypermetabolism to scar reconstruction and rehabilitation. These and other key aspects of care, which are the focus of this book, share the goal of providing burn survivors more complete recovery from burns so that they can return to their communities as fully functioning members. All aspects of the physiological, psychological, and emotional care of acutely burned patients evolving through recovery, rehabilitation, and reintegration back into society and daily life are reexamined in this new, fifth edition.

The objective of the fifth edition of this book remains the same—to serve as a sophisticated instruction manual for a variety of health care professionals less experienced in burns. It is intended to be a resource not only for surgeons, anesthesiologists, and residents, but also for nurses and allied health professionals. Although this edition of the book covers many of the same fundamental concepts and techniques as the previous edition, the chapters have been extensively updated with new data and references to reflect advances in care and knowledge that have arisen over the past 5 years. In some cases, the chapters have been completely rewritten. The new edition also contains new chapters dealing with the care of unique populations, as well as newer topics in reconstruction and scarring. As before, demonstrative color illustrations are provided throughout the book. Moreover, many chapters are accompanied by online PowerPoint presentations to aid group discussion, as well as video clips to enhance understanding of complex concepts and techniques.

This new edition would not be possible without the many respected colleagues and friends who have volunteered their time and worked tirelessly to produce the various chapters. Grateful acknowledgment is also given to Elsevier publishing staff, who have maintained a high standard in the development and preparation of this fifth edition. Special thanks are offered to Dr. Derek Culnan, who graciously assisted in reviewing and updating material throughout the book, as well as to Genevieve Bitz and Dr. Kasie Cole for editorial assistance. Finally, I wish to thank my wife, Rose, for her invaluable support.

In Memorium of Ted Huang, MD

Derek Culnan, MD, Genevieve Bitz, Karel D. Capek, MD, David Herndon, MD

Last year, returning with his wife from a medical mission trip to Taiwan, Dr. Ted Huang died. On that day, we lost a colleague; a friend; and a surgeon of unquestioned skill, passion, and knowledge as well as a teacher unstinting in his advice and zeal to help others. Following a career as a leader in the fields of gender reassignment and cosmetic surgery, Dr. Huang retired to spend the next 20 years working to revolutionize the practice of surgical reconstruction of pediatric burns. He left behind a legacy in research and surgery in the papers he authored and the surgeons he mentored that few can achieve. He was the principal author of the previous four editions of the reconstructive section of this book. Stepping into the OR filled him with joy, for he was a man who truly loved and lived his career. When a surgical fellow once asked if he could assist, Dr. Huang responded, "I've been operating on burn scars since before you were born. If I need your help, then the patient and I both have a big problem. But, if you want, you can come have fun with me." We are better for having known him, and our principal regret is that we never figured out the recipe for his legendary bread, which, as with everything, he doled out generously to family, friends, patients, and colleagues. As he would undoubtedly have said, that's how the cookie crumbles. This book is a testimonial to his humanity and skill, from those he collaborated with and those he mentored. Thank you, Dr. Huang, for everything.

With greatest honor and humility we dedicate this book to you.

List of Contributors

Rajeev B Ahuja MS MCh DNB FICS FACS FAMS
Senior Consultant in Plastic Surgery
Department of Plastic Surgery
Sir Ganga Ram Hospital Marg;
Ex-Head, Department of Burns and Plastic Surgery
Lok Nayak Hospital and Associated Maulana Azad Medical College

1 A Brief History of Acute Burn Care Management

LUDWIK K. BRANSKI, DAVID N. HERNDON, and ROBERT E. BARROW

The recognition of burns and their treatment is evident in cave paintings that are more than 3500 years old. Documentation in the Egyptian Smith papyrus of 1500 BC advocated the use of a salve of resin and honey for treating burns.[1] In 600 BC, the Chinese used tinctures and extracts from tea leaves. Nearly 200 years later, Hippocrates described the use of rendered pig fat and resin-impregnated bulky dressings, which was alternated with warm vinegar soaks augmented with tanning solutions made from oak bark. Celsus, in the 1st century AD, mentioned the use of wine and myrrh as a lotion for burns, most probably for their bacteriostatic properties.[1] Vinegar and exposure of the open wound to air was used by Galen (130–210 AD) as a means of treating burns, while the Arabian physician Rhases recommended cold water for alleviating the pain associated with burns. Ambroise Paré (1510–1590 AD), who effectively treated burns with onions, was probably the first to describe a procedure for early burn wound excision. In 1607, Guilhelmus Fabricius Hildanus, a German surgeon, published *De Combustionibus*, in which he discussed the pathophysiology of burns and made unique contributions to the treatment of contractures. In 1797, Edward Kentish published an essay describing pressure dressings as a means to relieve burn pain and blisters. Around this same time, Marjolin identified squamous cell carcinomas that developed in chronic open burn wounds. In the early 19th century, Guillaume Dupuytren (Fig. 1.1) reviewed the care of 50 burn patients treated with occlusive dressings and developed a classification of burn depth that remains in use today.[2] He was perhaps the first to recognize gastric and duodenal ulceration as a complication of severe burns, a problem that was discussed in more detail by Curling of London in 1842.[3] In 1843, the first hospital for the treatment of large burns used a cottage on the grounds of the Edinburgh Royal Infirmary.

Truman G. Blocker Jr. (Fig. 1.2) may have been the first to demonstrate the value of the multidisciplinary team approach to disaster burns when, on April 16, 1947, two freighters loaded with ammonium nitrate fertilizer exploded at a dock in Texas City, killing 560 people and injuring more than 3000. At that time, Blocker mobilized the University of Texas Medical Branch in Galveston, Texas, to treat the arriving truckloads of casualties. This "Texas City Disaster" is still known as the deadliest industrial accident in American history. Over the next 9 years, Truman and Virginia Blocker followed more than 800 of these burn patients and published a number of papers and government reports on their findings.[4–6] The Blockers became renowned for their work in advancing burn care, with both receiving the Harvey Allen Distinguished Service Award from the American Burn Association (ABA). Truman Blocker Jr. was also recognized for his pioneering research in treating burns "by cleansing, exposing the burn wounds to air, and feeding them as much as they could tolerate."[7] In 1962, his dedication to treating burned children convinced the Shriners of North America to build their first Burn Institute for Children in Galveston, Texas.[7]

Between 1942 and 1952, shock, sepsis, and multiorgan failure caused a 50% mortality rate in children with burns covering 50% of their total body surface area (TBSA).[8] Recently burn care in children has improved survival such that a burn covering more than 95% TBSA can be survived in more than 50% of cases.[9] In the 1970s, Andrew M. Munster (Fig. 1.3) became interested in measuring quality of life after excisional surgery and other improvements led to a dramatic decrease in mortality. First published in 1982, his Burn Specific Health Scale became the foundation for most modern studies in burns outcome.[10] The scale has since been updated and extended to children.[11]

Further improvements in burn care presented in this brief historical review include excision and coverage of the burn wound, control of infection, fluid resuscitation, nutritional support, treatment of major inhalation injuries, and support of the hypermetabolic response.

Early Excision

In the early 1940s, it was recognized that one of the most effective therapies for reducing mortality from a major thermal injury was the removal of burn eschar and immediate wound closure.[12] This approach had previously not been practical in large burns owing to the associated high rate of infection and blood loss. Between 1954 and 1959, Douglas Jackson and colleagues at the Birmingham Accident Hospital advanced this technique in a series of pilot and controlled trials starting with immediate fascial excision and grafting of small burn areas and eventually covering up to 65% of the TBSA with autograft and homograft skin.[13] In this breakthrough publication, Jackson concluded that "with adequate safeguards, excision and grafting of 20% to 30% body surface area can be carried out on the day of injury without increased risk to the patient." This technique, however, was far from being accepted by the majority of burn surgeons, and delayed serial excision remained the prevalent approach to large burns. It was Zora Janzekovic (Fig. 1.4), working alone in Yugoslavia in the 1960s, who developed the concept of removing deep second-degree burns by tangential excision with a simple uncalibrated knife. She treated 2615 patients with deep second-degree burns by tangential excision of eschar between the third and fifth days after burn and covered the

Fig. 1.1 Guillaume Dupuytren.

Fig. 1.2 Truman G. Blocker Jr.

Fig. 1.3 Andrew M. Munster.

Fig. 1.4 Zora Janzekovic.

excised wound with skin autograft.[14] Using this technique, burned patients were able to return to work within 2 weeks or so from the time of injury. For her achievements, in 1974, she received the ABA Everett Idris Evans Memorial Medal and, in 2011, the ABA lifetime achievement award.

In the early 1970s, William Monafo (Fig. 1.5) was one of the first Americans to advocate the use of tangential excision and grafting of larger burns.[15] John Burke (Fig. 1.6), while at Massachusetts General Hospital in Boston, reported unprecedented survival in children with burns of more than 80% TBSA.[16] His use of a combination of tangential excision for the smaller burns (Janzekovic's technique) and excision to the level of fascia for the larger burns resulted in a decrease in both hospital time and mortality. Lauren Engrav et al.,[17] in a randomized prospective study, compared tangential excision to nonoperative treatment of burns. This study showed that, compared to nonoperative treatment, early excision and grafting of deep second-degree burns reduced hospitalization time and hypertrophic scarring. In 1988, Ron G. Tompkins et al.,[18] in a statistical review of the Boston Shriners Hospital patient population from 1968 to 1986, reported a dramatic decrease in mortality in severely burned children that he attributed mainly to the advent of early excision and grafting of massive burns in use since the 1970s. In a randomized prospective trial of 85 patients with third-degree burns covering 30% or more of their TBSA, Herndon et al.[19] reported a decrease in mortality in those treated with early excision of the entire wound compared to conservative treatment. Other studies have reported that prompt excision

Fig. 1.5 William Monafo.

Fig. 1.6 John Burke.

of the burn eschar improves long-term outcome and cosmesis, thereby reducing the amount of reconstructive procedures required.

Skin Grafting

Progress in skin grafting techniques has paralleled the developments in wound excision. In 1869, J. P. Reverdin, a Swiss medical student, successfully reproduced skin grafts.[20] In the 1870s, George David Pollock popularized the method in England.[21] The method gained widespread attention throughout Europe, but because the results were extremely variable it quickly fell into disrepute. J. S. Davis resurrected this technique in 1914 and reported the use of "small deep skin grafts," which were later known as "pinch grafts."[22] Split-thickness skin grafts became more popular during the 1930s, due in part to improved and reliable instrumentation. The "Humby knife," developed in 1936, was the first reliable dermatome, but its use was cumbersome. E. C. Padgett developed an adjustable dermatome that had cosmetic advantages and allowed the procurement of a consistent split-thickness skin graft.[23,24] Padgett also developed a system for categorizing skin grafts into four types based on thickness.[25] In1964 J. C. Tanner Jr. and colleagues revolutionized wound grafting with the development of the meshed skin graft;[26] however for prompt excision and immediate wound closure to be practical in burns covering more than 50% of the TBSA, alternative materials and approaches to wound closure were necessary. To meet these demands, a system of cryopreservation and long-term storage of human skin for periods extending up to several months was developed.[27] Although controversy surrounds the degree of viability of the cells within the preserved skin, this method has allowed greater flexibility in the clinical use of autologous skin and allogenic skin harvested from cadavers. J. Wesley Alexander (Fig. 1.7) developed a simple method for widely expanding autograft skin and then covering it with cadaver skin.[28] This so-called "sandwich technique" has been the mainstay of treatment of massively burned individuals.

Fig. 1.7 J. Wesley Alexander.

In 1981, John Burke and Ioannis Yannas developed an artificial skin that consists of a silastic epidermis and a porous collagen–chondroitin dermis and is marketed today as Integra. Burke was also the first to use this artificial skin on very large burns that covered more than 80% of the TBSA.[29] David Heimbach led one of the early multicenter randomized clinical trials using Integra.[30] Its use in the

coverage of extensive burns has remained limited partly due to the persistently high cost of the material and the need for a two-stage approach. Integra has since become popular for smaller immediate burn coverage and burn reconstruction. In 1989, J. F. Hansbrough and S. T. Boyce first reported the use of cultured autologous keratinocytes and fibroblasts on top of a collagen membrane (composite skin graft; CSS).[31] A larger trial by Boyce[32] revealed that the use of CSS in extensive burns reduces the requirement for harvesting of donor skin compared to conventional skin autografts and that the quality of grafted skin did not differ between CSS and skin autograft after 1 year. The search for an engineered skin substitute to replace all of the functions of intact human skin is ongoing; composite cultured skin analogs, perhaps combined with mesenchymal stem cells, may offer the best opportunity for better outcomes.[33,34]

Topical Control of Infection

Infection control is an important major advancement in burn care that has reduced mortality. One of the first topical antimicrobials, sodium hypochlorite (NaClO), discovered in the 18th century, was widely used as a disinfectant throughout the 19th century, but its use was frequently associated with irritation and topical reactions.[35] In 1915, Henry D. Dakin standardized hypochlorite solutions and described the concentration of 0.5% NaClO as most effective.[36] His discovery came at a time when scores of severely wounded soldiers were dying of wound infections on the battlefields of World War I. With the help of a Rockefeller Institute grant, Dakin teamed up with the then already famous French surgeon and Nobel Prize winner Alexis Carrel to create a system of mechanical cleansing, surgical débridement, and topical application of hypochlorite solution, which was meticulously protocolized and used successfully in wounds and burns.[37] Subsequently concentrations of sodium hypochlorite were investigated for antibacterial activity and tissue toxicity in vitro and in vivo, and it was found that a concentration of 0.025% NaClO was most efficacious because it had sufficient bactericidal properties but fewer detrimental effects on wound healing.[38]

Mafenide acetate (Sulfamylon), a drug used by the Germans for treatment of open wounds in World War II, was adapted for treating burns at the Institute of Surgical Research in San Antonio, Texas, by microbiologist Robert Lindberg and surgeon John Moncrief.[39] This antibiotic would penetrate third-degree eschar and was extremely effective against a wide spectrum of pathogens. Simultaneously, in New York, Charles Fox developed silver sulfadiazine cream (Silvadene), which was almost as efficacious as mafenide acetate.[40] Although mafenide acetate penetrates the burn eschar quickly, it is a carbonic anhydrase inhibitor that can cause systemic acidosis and compensatory hyperventilation and may lead to pulmonary edema. Because of its success in controlling infection in burns combined with minimal side effects, silver sulfadiazine has become the mainstay of topical antimicrobial therapy.

Carl Moyer and William Monafo initially used 0.5% silver nitrate soaks as a potent topical antibacterial agent for burns, a treatment that was described in their landmark publication[41] and remains the treatment of choice in many burn centers today. With the introduction of efficacious silver-containing topical antimicrobials, burn wound sepsis rapidly decreased. Early excision and coverage further reduced the morbidity and mortality from burn wound sepsis. Nystatin in combination with silver sulfadiazine has been used to control *Candida* at Shriners Burns Hospital for Children in Galveston, Texas.[42] Mafenide acetate, however, remains useful in treating invasive wound infections.[43]

Nutritional Support

P. A. Shaffer and W. Coleman advocated high caloric feeding for burn patients as early as 1909,[44] and D. W. Wilmore supported supranormal feeding with a caloric intake as high as 8000 kcal/day.[45] P. William Curreri (Fig. 1.8) retrospectively looked at a number of burned patients to quantify the amount of calories required to maintain body weight over a period of time. In a study of nine adults with 40% TBSA burns, he found that maintenance feeding at 25 kcal/kg plus an additional 40 kcal/% TBSA burned per day would maintain their body weight during acute hospitalization.[46] A. B. Sutherland proposed that children should receive 60 kcal/kg body weight plus 35 kcal/% TBSA burned per day to maintain their body weight.[47] D. N. Herndon et al. subsequently showed that supplemental parenteral nutrition increased both immune deficiency and mortality and recommended continuous enteral feeding, when tolerated, as a standard treatment for burns.[48]

The composition of nutritional sources for burned patients has been debated in the past. In 1959, F. D. Moore advocated that the negative nitrogen balance and weight loss in burns and trauma should be met with an adequate intake of nitrogen and calories.[49] This was supported by many others, including T. Blocker Jr.,[50] C. Artz, [51] and later by Sutherland.[47]

Fig. 1.8 P. William Curreri.

Fluid Resuscitation

The foundation of current fluid and electrolyte management began with the studies of Frank P. Underhill, who, as Professor of Pharmacology and Toxicology at Yale, studied 20 individuals burned in a 1921 fire at the Rialto Theatre.[52] Underhill found that the composition of blister fluid was similar to that of plasma and could be replicated by a salt solution containing protein. He suggested that burn patient mortality was due to loss of fluid and not, as previously thought, from toxins. In 1944, C. C. Lund and N. C. Browder estimated burn surface areas and developed diagrams by which physicians could easily draw the burned areas and derive a quantifiable percent describing the surface area burned.[53] This led to fluid replacement strategies based on surface area burned. G. A. Knaysi et al. proposed a simple "rule-of-nines" for evaluating the percentage of body surface area burned.[54] In the late 1940s, O. Cope and F. D. Moore (Figs. 1.9 and 1.10) were able to quantify the amount of fluid required per area burned for adequate resuscitation from the amount needed in young adults who were trapped inside the burning Coconut Grove Nightclub in Boston in 1942. They postulated that the space between cells was a major recipient of plasma loss, causing swelling in both injured and uninjured tissues in proportion to the burn size.[55] Moore concluded that additional fluid, over that collected from the bed sheets and measured as evaporative water loss, was needed in the first 8 hours after burn to replace "third space" losses. He then developed a formula for replacement of fluid based on the percent of the body surface area burned.[56] M. G. Kyle and A. B. Wallace showed that the heads of children were relatively larger and the legs relatively shorter than in adults, and they modified the fluid replacement formulas for use in children.[57] I. E. Evans and his colleagues made recommendations relating fluid requirements to body weight and surface area burned.[58] From their recommendations, intravenous infusion of normal saline plus colloid (1.0 mL per kg/% burn) along with 2000 mL dextrose 5% solution to cover insensible water losses was administered over the first 24 hours after burn. One year later, E. Reiss presented the Brooke formula, which modified the Evans formula by substituting lactated Ringer's for normal saline and reducing the amount of colloid given.[59] Charles R. Baxter (Fig. 1.11) and G. Tom Shires (Fig. 1.12) developed a formula without colloid, which is now referred to as the Parkland formula.[60] This is perhaps the most widely used formula today and recommends 4 mL of lactated Ringer's solution per kg/% TBSA burned during the first 24 hours after burn. All these formulas advocate giving half of the fluid in the first 8 hours

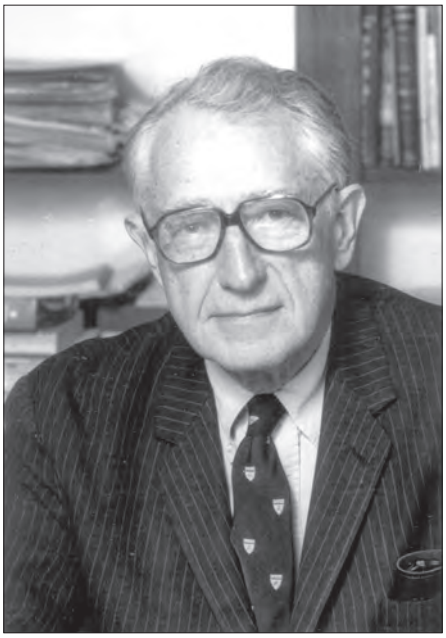

Fig. 1.10 Francis D. Moore.

Fig. 1.9 Oliver Cope.

Fig. 1.11 Charles R. Baxter.

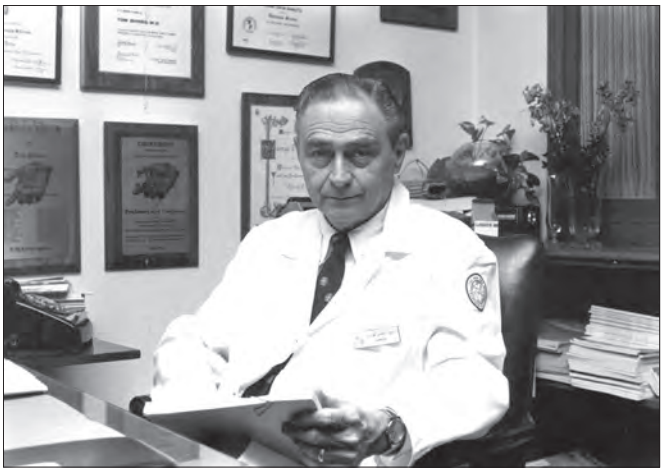

Fig. 1.12 G. Tom Shires.

after burn and the other half in the subsequent 16 hours. Baxter and Shires discovered that after a cutaneous burn, not only is fluid deposited in the interstitial space, but marked intracellular edema also develops. The excessive disruption of the sodium–potassium pump activity results in the inability of cells to remove excess fluid. They also showed that protein, given in the first 24 hours after injury, was not necessary and postulated that, if used, it would leak out of the vessels and exacerbate edema. This was later substantiated in studies of burn patients with toxic inhalation injuries.[61] After a severe thermal injury fluid accumulates in the wound, and, unless there is adequate and early fluid replacement, hypovolemic shock will develop. A prolonged systemic inflammatory response to severe burns can lead to multiorgan dysfunction, sepsis, and even mortality. It has been suggested that, for maximum benefit, fluid resuscitation should begin as early as 2 hours after burn.[9,62] Fluid requirements in children are greater with a concomitant inhalation injury, delayed fluid resuscitation, and larger burns.

Inhalation Injury

During the 1950s and 1960s, burn wound sepsis, nutrition, kidney dysfunction, wound coverage, and shock were the main foci of burn care specialists. Over the past 50 years, these problems have been clinically treated with increasing success; hence a greater interest in a concomitant inhalation injury evolved. A simple classification of inhalation injury separates problems occurring in the first 24 hours after injury, which include upper airway obstruction and edema, from those that manifest after 24 hours. These include pulmonary edema and tracheobronchitis, which can progress to pneumonia, mucosal edema, and airway occlusion due to the formation of airway plugs from mucosal sloughing.[63,64] The extent of damage from the larynx to tracheobronchial tree depends on the solubility of the toxic substance and the duration of exposure. Nearly 45% of inhalation injuries are limited to the upper passages above the vocal cords, and 50% have an injury to the major airways. Less than 5% have a direct

Fig. 1.13 Basil A. Pruitt.

parenchymal injury that results in early acute respiratory death.[64]

With the development of objective diagnostic methods, the incidence of an inhalation injury in burned patients can now be identified and its complications identified. Xenon-133 scanning was first used in 1972 in the diagnosis of inhalation injury.[65,66] When this radioisotope method is used in conjunction with a medical history, the identification of an inhalation injury is quite reliable. The fiberoptic bronchoscope is another diagnostic tool that, under topical anesthesia, can be used for the early diagnosis of an inhalation injury.[67] It is also capable of pulmonary lavage to remove airway plugs and deposited particulate matter.

K. Z. Shirani, Basil A. Pruitt (Fig. 1.13), and A. D. Mason reported that smoke inhalation injury and pneumonia, in addition to age and burn size, greatly increased burn mortality.[68] The realization that the physician should not underresuscitate burn patients with an inhalation injury was emphasized by P. D. Navar et al.[69] and D. N. Herndon et al.[70] A major inhalation injury requires 2 mL per kg/% TBSA burn more fluid in the first 24 hours after burn to maintain adequate urine output and organ perfusion. Multicenter studies looking at patients with acute respiratory distress syndrome (ARDS) have advocated respiratory support at low peak pressures to reduce the incidence of barotrauma. The high-frequency oscillating ventilator, advocated by C. J. Fitzpatrick[71] and J. Cortiella et al.,[72] has added the benefit of pressure ventilation at low tidal volumes plus rapid inspiratory minute volume, which provides a vibration to encourage inspissated sputum to travel up the airways. The use of heparin, *N*-acetylcysteine, nitric oxide inhalation, and bronchodilator aerosols have also been used with some apparent benefit, at least in pediatric populations.[73] Inhalation injury remains one of the most prominent causes of death in thermally injured patients. In children, the lethal burn area for a 10% mortality without a concomitant

inhalation injury is 73% TBSA; however with an inhalation injury, the lethal burn size for a 10% mortality rate is 50% TBSA.[74]

Hypermetabolic Response to Trauma

Major decreases in mortality have also resulted from a better understanding of how to support the hypermetabolic response to severe burns. This response is characterized by an increase in the metabolic rate and peripheral catabolism. The catabolic response was described by H. Sneve as exhaustion and emaciation, and he recommended a nourishing diet and exercise.[75] O. Cope et al.[76] quantified the metabolic rate in patients with moderate burns, and Francis D. Moore advocated the maintenance of cell mass by continuous feeding to prevent catabolism after trauma and injury.[77] Over the past 30 years, the hypermetabolic response to burn has been shown to increase metabolism, negative nitrogen balance, glucose intolerance, and insulin resistance. In 1974, Douglas Wilmore and colleagues defined catecholamines as the primary mediator of this hypermetabolic response and suggested that catecholamines were five- to sixfold elevated after major burns, thereby causing an increase in peripheral lipolysis and catabolism of peripheral protein.[78] In 1984, P. Q. Bessey demonstrated that the stress response required not only catecholamines but also cortisol and glucagon.[79] Wilmore et al. examined the effect of ambient temperature on the hypermetabolic response to burns and reported that burn patients desired an environmental temperature of 33°C and were striving for a core temperature of 38.5°C.[80] Warming the environment from 28°C to 33°C substantially decreased the hypermetabolic response, but did not abolish it. He suggested that the wound itself served as the afferent arm of the hypermetabolic response, and its consuming greed for glucose and other nutrients was at the expense of the rest of the body.[81] Wilmore also believed that heat was produced by biochemical inefficiency, which was later defined by Robert Wolfe as futile substrate cycling.[82] Wolfe et al. also demonstrated that burned patients were glucose intolerant and insulin resistant, with an increase in glucose transport to the periphery but a decrease in glucose uptake into the cells.[83] D. W. Hart et al. further showed that the metabolic response rose with increasing burn size, reaching a plateau at a 40% TBSA burn.[84]

In the past three decades, pharmacologic modulators, such as the β-receptor antagonist propranolol, the anabolic agent human recombinant growth hormone, the synthetic anabolic testosterone analog oxandrolone, insulin, and the glucose uptake modulator metformin, have all shown some beneficial effects in reducing the hypermetabolic response in burn patients.

Conclusion

The evolution of burn treatments has been extremely productive over the past 50 years. The mortality of severely burned patients has decreased significantly thanks to improvements in early resuscitation, infection control, nutrition, attenuation of the hypermetabolic response, and new and improved surgical approaches. In burned children, a 98% TBSA burn now has a 50% survival rate.[74] It is hoped that the next few years will witness the development of an artificial skin that combines the concepts of J. F. Burke [29] with the tissue culture technology described by E. Bell.[85] Inhalation injury, however, remains one of the major determinants of mortality in those with severe burns. Further improvements in the treatment of inhalation injuries are expected through the development of arterial venous carbon dioxide removal and extracorporeal membrane oxygenation devices.[86] Research continues to strive for a better understanding of the pathophysiology of burn scar contractures and hypertrophic scarring.[87] Although decreases in burn mortality can be expected, continued advances to rehabilitate patients and return them to productive life are an important step forward in burn care management.

2 Teamwork for Total Burn Care: Burn Centers and Multidisciplinary Burn Teams

JANOS CAMBIASO-DANIEL, OSCAR E. SUMAN, MARY JACO, DEBRA A. BENJAMIN, and DAVID N. HERNDON

Introduction

Severe burn injuries evoke strong emotional responses in most people including health professionals who are confronted by the specter of pain, deformity, and potential death. Intense pain and repeated episodes of sepsis, followed by either death or survival encumbered by pronounced disfigurement and disability, have been the expected sequelae to serious burns for most of mankind's history.[1] However, these dire consequences have been ameliorated so that, although burn injury is still intensely painful and tragic, the probability of death has been significantly diminished. During the decade prior to 1951, young adults (15–43 years of age) with total body surface area (TBSA) burns of 45% or greater had a 49% mortality rate (Table 2.1).[2] Forty years later, statistics from the pediatric and adult burn units in Galveston, Texas, show that a 49% mortality rate is associated with TBSA burns of 70% or greater in the same age group. Over the past decade, these mortality figures have improved even more dramatically, so that almost all infants and children can be expected to survive when resuscitated adequately and quickly.[3] Although improved survival has been the primary focus of burn treatment advancement for many decades, today the major goal—since survival rates have highly increased—is rehabilitation of burn survivors to maximize quality of life and reduce morbidity.

Such improvement in forestalling death is a direct result of the maturation of burn care science. Scientifically sound analyses of patient data have led to the development of formulas for fluid resuscitation[4–6] and nutritional support.[7,8] Clinical research has demonstrated the utility of topical antimicrobials in delaying onset of sepsis, thereby contributing to decreased mortality of burn patients. Prospective randomized clinical trials have shown that early surgical therapy is efficacious in improving survival for many burned patients by decreasing blood loss and diminishing the occurrence of sepsis.[9–14] Basic science and clinical research have helped decrease mortality by characterizing the pathophysiological changes related to inhalation injury and suggesting treatment methods that have decreased the incidence of pulmonary edema and pneumonia.[15–18] Scientific investigations of the hypermetabolic response to major burn injury have led to improved management of this life-threatening phenomenon, not only enhancing survival, but also promising an improved quality of life.[19–32]

Optimal treatment of severely burned patients requires significant healthcare resources and has led to the development of highly specialized burn centers over the past decades. Centralizing services to regional burn centers has made implementation of multidisciplinary acute critical care and long-term rehabilitation possible. It has also enhanced opportunities for study and research over the past several decades. This has led to great advances both in our knowledge and in clinical outcomes, with further advancements being expected.

Implementation of a wide range of medical discoveries and innovations has improved patient outcomes following severe burns over the past half century. Key areas of advancements in recent decades include fluid resuscitation protocols; early burn wound excision and closure with grafts or skin substitutes, nutritional support regimens, topical antimicrobials and treatment of sepsis, thermally neutral ambient temperatures, and pharmacological modulation of hypermetabolic and catabolic responses. These factors have helped to decrease morbidity and mortality following severe burns by improving wound healing, reducing inflammation and energy demands, and attenuating hypermetabolism and muscle catabolism.

Melding scientific research with clinical care has been promoted in recent burn care history largely because of the aggregation of burn patients into single-purpose units staffed by dedicated healthcare personnel. Dedicated burn units were first established in Great Britain to facilitate nursing care. The first U.S. burn center was established at the Medical College of Virginia in 1946. The same year, the U.S. Army Surgical Research Unit (later renamed the U.S. Army Institute of Surgical Research) was established. Directors of both centers and later, the founders of the burn centers at University of Texas Medical Branch in 1947 and Shriners Hospitals for Children–Galveston in 1963 emphasized the importance of collaboration between clinical care and basic scientific disciplines to improve the patient's outcome.[1]

The organizational design of these centers engendered a self-perpetuating feedback loop of clinical and basic scientific inquiry. In this system, scientists receive first-hand information about clinical problems, while clinicians receive provocative ideas about patient responses to injury from experts in other disciplines. Advances in burn care attest to the value of a dedicated burn unit organized around a collegial group of basic scientists, clinical researchers, and

Table 2.1 Percent total body surface area (TBSA) burn producing an expected mortality of 50% in 1952, 1993, and 2006

Age (years)	1953† (% TBSA)	1993* (% TBSA)	2006° (% TBSA)
0–14	49	98	99

clinical caregivers, all asking questions of each other, sharing observations and information, and seeking solutions to improve patient welfare.

Findings from the group at the Army Surgical Research Institute point to the necessity of involving many disciplines in the treatment of patients with major burn injuries and emphasize the utility of a team concept.[1] For this reason the International Society of Burn Injuries and its journal, *Burns*, as well as the American Burn Association and its publication, *Journal of Burn Care and Research*, have publicized the notion of successful multidisciplinary work by burn teams to widespread audiences.

Members of a Burn Team

The management of severe burn injuries benefits from concentrated integration of health services and professionals, with care being significantly enhanced by a true multidisciplinary approach. The complex nature of burn injuries necessitates a diverse range of skills for optimal care. A single specialist cannot be expected to possess all skills, knowledge, and energy required for the comprehensive care of severely injured patients. For this reason, reliance is placed on a group of specialists to provide integrated care through innovative organization and collaboration.

In addition to including burn-specific providers, the burn team consists of epidemiologists, molecular biologists, microbiologists, physiologists, biochemists, pharmacists, pathologists, endocrinologists, and numerous other scientific as well as medical specialists. Because burn injury is a complex systemic injury, the search for improved treatments leads to inquiry from many approaches. Each scientific finding stimulates new questions and the potential involvement of additional specialists.

At times, the burn team can be thought of as including the environmental service workers responsible for cleaning the unit, the volunteers who may assist in a variety of ways to provide comfort for patients and families, the hospital administrator, and many others who support the day-to-day operations of a burn center and significantly impact the well-being of patients and staff. However, the traditional burn team consists of a multidisciplinary group of direct-care providers. Although burn surgeons, plastic surgeons, nurses, nutritionists, and physical and occupational therapists form the skeletal core; most burn units also include anesthesiologists, respiratory therapists, pharmacists, spiritual therapists, and music therapists. The increasing number of survivors has consequently also added psychologists, psychiatrists, and, more recently, exercise physiologists to the burn team. In pediatric units, child life specialists and school teachers are also significant members of the team of caregivers.

Patient satisfaction can be formally measured through questionnaires to provide positive feedback to caregivers and highlight potential areas of improvement. Allowing patients to feel as if they are part of decisions about their care, listening and responding to concerns, providing encouragement, and displaying empathy are all important for maintaining satisfaction in patients and their families. These approaches also reduce fear, apprehension, and misunderstandings.

Healing relies on a complex array of factors. These include individual factors such as motivation, pre-existing health status, obesity, malnutrition, comorbidities, family support, and social support. They also include wider societal factors such as reintegration, individual perception, and coping strategies as well as factors specific to the mechanism of injury such as trauma, bereavement, grief, and loss.

Patients and their families are infrequently mentioned as members of the team but are obviously important in influencing the outcome of treatment. Persons with major burn injuries contribute actively to their own recovery, and each brings individual needs and agendas into the hospital setting that may influence the way treatment is provided by the professional care team.[33] The patient's family members often become active participants. This is even more important in the case of children, but is also true in the case of adult patients. Family members become conduits of information from the professional staff to the patient. At times, they act as spokespersons for the patient, and, at other times, they become advocates for the staff in encouraging the patient to cooperate with dreaded procedures.

With so many diverse personalities and specialists potentially involved, purporting to know what or who constitutes a burn team may seem absurd. Nevertheless, references to "burn teams" are plentiful, and there is agreement on the specialists and care providers whose expertise is required for the optimal care of patients with significant burn injuries (Fig. 2.1).

BURN SURGEONS

Ultimate responsibility and overall control for the care of a patient lies with the admitting burn surgeon, the key figure of the burn team. The burn surgeon is either a general surgeon or plastic surgeon with expertise in providing emergency and critical care, as well as in performing skin grafting and amputations. The burn surgeon provides leadership and guidance for the rest of the team, which may include several surgeons. The surgeon's leadership is particularly important during the early phase of patient care when moment-to-moment decisions must be made based on the surgeon's knowledge of physiologic responses to injury, current scientific evidence, and appropriate medical/surgical treatments. The surgeon must not only possess

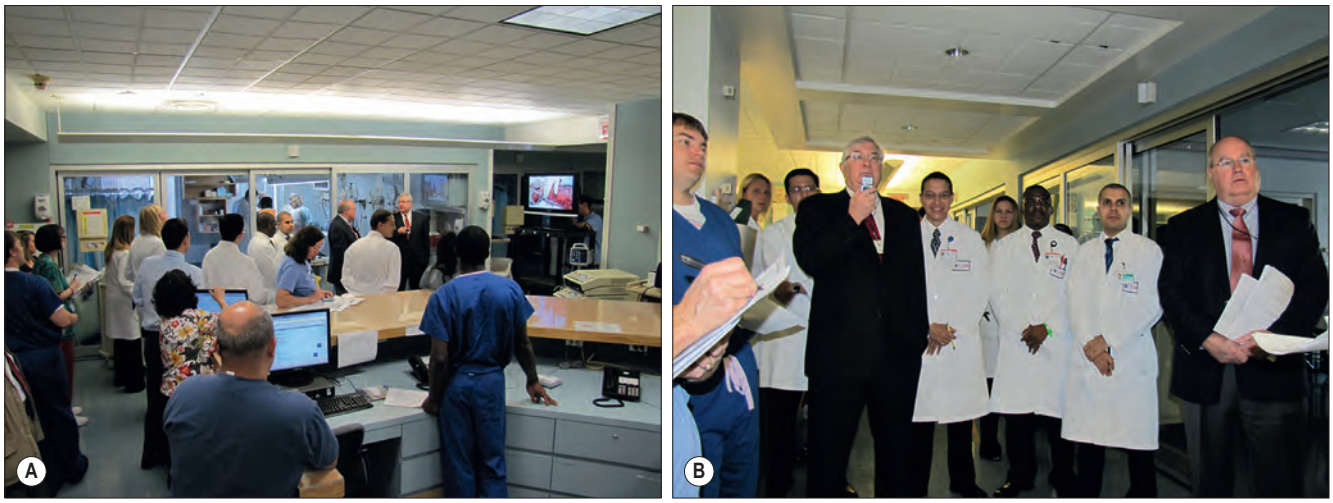

Fig. 2.1 (**A, B**) Experts from diverse disciplines gather together with common goals and tasks and overlapping values to achieve their objectives.

knowledge and skills in medicine, but also be able to clearly exchange information with a diverse staff of experts in other disciplines and lead the team. The surgeon alone cannot provide comprehensive care but must be wise enough to know when and how to seek counsel as well as how to clearly and firmly give directions to direct activities surrounding patient care. The senior surgeon of the team is accorded the most authority and control of any member of the team and thus bears the responsibility and receives accolades for the success of the team as a whole.[33]

PLASTIC SURGEONS

Next to burn surgeons, who are particularly involved in the immediate and acute phase of surgical treatment, are the plastic surgeons, who are typically involved instead in long-term surgical treatment. The plastic surgeons aim to deliver care that yields the best functional and aesthetic results for the burn survivor. The burn surgeon should always work in close collaboration with the plastic surgeon. Most burn surgeons are plastic surgeons, but in instances where this is not the case, the presence of plastic surgeons in the team is essential. Ideally, this collaboration should start during the initial phase of surgical treatment. The plastic surgeon's duty is primarily to care for the patient in terms of functional improvement through surgeries that aim to lessen scarring and decrease the functional limitations created by scarring. This surgical treatment often requires numerous operations that may take place for years after the burn injury.

ANESTHESIOLOGISTS

An anesthesiologist who is an expert in the altered physiologic parameters of burned patients is critical to the survival of the patient who usually undergoes multiple acute surgical procedures. Anesthesiologists on the burn team must be familiar with the phases of burn recovery and the physiologic changes to be anticipated as burn wounds heal.[1] Anesthesiologists play significant roles in facilitating comfort for burned patients, not only in the operating room, but also during the painful ordeals of dressing changes, staple removal, and physical exercise.

NURSES

Nurses represent the largest single disciplinary segment of the burn team, providing continuous coordinated care to the patient. The nursing staff is responsible for technical management of the 24-hour physical treatment of the patient. They control the therapeutic milieu that allows the patient to recover. They also provide emotional support to the patient and patient's family.[34] Nursing staff are often the first to identify changes in a patient's condition and initiate therapeutic interventions. Because recovery from a major burn is rather slow, burn nurses must merge the qualities of sophisticated intensive care nursing with the challenging aspects of psychiatric nursing. Nursing case management can play an important role in burn treatment, extending the coordination of care beyond hospitalization through the lengthy period of outpatient rehabilitation.

PHYSICAL AND OCCUPATIONAL THERAPISTS

Occupational and physical therapists begin planning therapeutic interventions at the patient's admission to maximize functional recovery. Burned patients require special positioning and splinting, early mobilization, strengthening exercises, endurance activities, and pressure garments to promote healing while controlling scar formation. These therapists must be very creative in designing and applying the appropriate appliances. Knowledge of the timing of application is necessary. In addition, rehabilitation therapists must become expert behavioral managers since their necessary treatments are usually painful to the recovering patient who will resist in a variety of ways. While the patient is angry, protesting loudly, or pleading for mercy, the rehabilitation therapist must persist with aggressive treatment to combat quickly forming and very strong scar contractures. The same therapist, however, is typically rewarded

with adoration and gratitude from an enabled burn survivor.

RESPIRATORY THERAPISTS

Inhalation injury, prolonged bed rest, fluid shifts, and the threat of pneumonia, all concomitant with burn injury, render respiratory therapists essential to the patient's welfare. Respiratory therapists evaluate pulmonary mechanics, perform therapy to facilitate breathing, and closely monitor the status of the patient's respiratory functioning and improvements during the recovery.

EXERCISE PHYSIOLOGIST

The exercise physiologist has recently been recognized as a key member of the comprehensive burn rehabilitation team. Traditionally, exercise physiologists study acute and chronic adaptations to a wide range of exercise conditions. At our institution, the exercise physiologist performs clinical duties and conducts clinical research.

Clinical duties include monitoring and assessing cardiovascular and pulmonary exercise function, as well as muscle function. Additional clinical duties include writing exercise prescriptions for cardiopulmonary and musculoskeletal rehabilitation. Clinical research conducted by the exercise physiologist mainly focuses on the effect of exercise on burn sequelae and the mechanisms by which exercise can reduce or reverse burn-induced catabolic and hypermetabolic conditions and improve a patient's quality of life.

There is no licensing body or requirements for exercise physiologists to practice their profession. However, many organizations, such as the American College of Sports Medicine and the Clinical Exercise Physiology Association, offer national certifications. These certifications include the exercise test technologist, exercise specialist, health/fitness director, and clinical exercise specialist. We recommend that if the exercise physiologist is primarily involved in clinical duties, he or she should have a minimum of a master's degree and be nationally certified by a well-known and respected organization. If clinical or basic research will be part of his or her duties, then we recommend a doctorate degree as well as a national certification.

NUTRITIONISTS

A nutritionist or dietitian monitors daily caloric intake and weight maintenance. These specialists also recommend dietary interventions to provide optimal nutritional support to combat the hypermetabolic and catabolic responses to burn injury. Caloric intake as well as intake of appropriate vitamins, minerals, and trace elements must be managed to promote wound healing and facilitate recovery. Nutritionists and exercise physiologists may work together in implementing methods to increase daily physical activity (caloric expenditure) to counteract any sequelae due to a sedentary lifestyle.

PSYCHOSOCIAL EXPERTS

Psychiatrists, psychologists, and social workers with expertise in human behavior and psychotherapeutic interventions provide continuous sensitivity in caring for the emotional and mental well-being of patients and their families. These professionals must be knowledgeable about the process of burn recovery as well as human behavior to make optimal interventions. They serve as confidants and supports for patients, families of patients, and, on occasion, other burn team members.[35] They often assist colleagues from other disciplines in developing behavioral interventions for problematic patients, allowing the colleague and patient to achieve therapeutic success.[36] During initial hospitalization, these experts manage the patient's mental status, pain tolerance, and anxiety level to provide comfort to the patient and facilitate physical recovery. As the patient progresses toward rehabilitation, the role of the mental health team becomes more prominent in supporting optimal psychological, social, and physical rehabilitation.

SPIRITUAL THERAPISTS

Not all patients and relatives are religious, but for those who are religious, the presence of a spiritual therapist can be extremely important and can help to overcome or deal with the difficult times the burn survivors are experiencing. The power and efficacy of prayer and religious-spiritual involvement during illness and recovery have been often discussed and have been demonstrated to be very important for many patients.[37] For these reasons, hospitals and especially burn centers should have a spiritual therapist in the team to assist not only the burn survivors but also their relatives.[38]

MUSIC THERAPISTS

Music therapy is the use of music interventions to accomplish individualized goals within a therapeutic relationship between the patient and the figure of the music therapist. The principal goals and interventions can be designed to promote wellness, manage stress, alleviate pain, express feelings, enhance memory, improve communication, and promote physical rehabilitation.[39] As reported, music therapy can improve a patient's range of motion and help during the hospitalization and rehabilitation periods.[40] The music therapist has an important role to play for burn patients and should be considered an essential member of the burn team.

STUDENTS, RESIDENTS, AND FELLOWS

Medical students, graduate students, postdoctoral fellows, and residents are vital members of the burn care team. Burn care professionals often do not have the time or energy to perform activities outside of work hours or set responsibilities. However, these young students, fellows, and residents frequently have the time, energy, and desire to take on additional work, whether in the form of clinical work or research. The close working relationship between these individuals and the rest of the burn care team yields numerous benefits, including the conception of new clinical and translational questions that, when answered, directly improve patient care.

Dynamics and Functioning of the Burn Team

Gathering a group of experts from diverse disciplines does not form a team.[41] In fact, the diversity of the disciplines, along with individual differences in gender, ethnicity, values, professional experience, and professional status, render such teamwork a process fraught with opportunities for disagreements, jealousies, and confusion.[42] The process of working together to accomplish the primary goal (i.e., returning burn survivors to a normal, functional life) is further complicated by the fact that the patient and the patient's family must collaborate with these professionals. It is not unusual for the patient to attempt to diminish his or her immediate discomfort by pitting one team member against another or "splitting" the team. Much as young children will try to manipulate parents by first going to one and then the other, patients will complain about one staff member to another or assert to one staff member that another staff member allows less demanding rehabilitation exercises or some special privilege.[43] Time must be devoted to a process of trust building among the team members. It is also imperative that the team communicate openly and frequently or the group will lose effectiveness.

Communicating and discussing a daily, weekly, and long-term management plan among team members allows for clarification and organization of early plans to flag issues early on with regard to further surgery, rehabilitation, discharge planning, nutritional goals, patient understanding, and patient compliance. Such issues are all simultaneously addressed in a holistic approach.

The group becomes a team when they share common goals and tasks as well as when they have overlapping values that will be served by accomplishing their goals.[44,45] The team becomes an efficient work group through a process of establishing mechanisms of collaboration and cooperation that facilitate focusing on explicit tasks rather than on covert distractions of personal need and interpersonal conflict.[44,46] Work groups develop best under conditions that allow each individual to feel acknowledged as valuable to the team.[47]

Multidisciplinary burn care involves taking into account all aspects of patient care when treatment decisions are made as well as considering subsequent effects and consequences of decisions. With good communication and coordination among all team members, the team can optimize outcome for a patient in every aspect of their care (Fig. 2.1).

Research into the area of multidisciplinary teams has highlighted the wide application of such teams in healthcare settings as well as some of the shortcomings affecting their efficacy.[41] Clearly defining the various components of these teams will allow improved analysis. Some of the factors that are useful for assessing how well a team is functioning are listed in Box 2.1.

A burn team has defined and shared goals with clear tasks. For a group of burn experts to become an efficient team, skillful leadership that facilitates the development of shared values among team members and ensures the validation of team members as they accomplish tasks is necessary. The burn team consists of many experts from diverse professional backgrounds; each profession has its own culture, problem-solving approach, and language.[48] For the team to benefit fully from the expertise of its members, every expert voice must be heard and acknowledged. Team members must be willing to learn from each other, eventually developing their own culture and language that all can understand. Attitudes of superiority and prejudice are most disruptive to the performance of the team.

Disagreement and conflict will be present, but these can be expressed and resolved in a respectful manner. Research suggests that intelligent management of emotions is linked with successful team performance in problem-solving and conflict resolution.[49] When handled well, conflicts and disagreements can increase understanding and provide new perspectives, in turn enhancing working relationships and leading to improved patient care.[50]

The acknowledged formal leader of the team is the senior surgeon, who may find the arduous job of medical and social leadership difficult and perplexing (Fig. 2.1). Empirical studies indicate, with remarkable consistency, that the functions required for successful leadership can be grouped into two somewhat incompatible clusters: (1) directing the group toward tasks and goal attainment and (2) facilitating interactions among group members and enhancing their feelings of worth.[44,47,50]

At times, task-oriented behavior by the leader may clash with the needs of the group for emotional support. During those times, the group may inadvertently impede the successful performance of both the leader and the team by seeking alternate means of establishing feelings of self-worth. When the social/emotional needs of the group are not met, the group begins to spend more time attempting to satisfy individual needs and less time pursuing task-related activities.

Studies of group behavior demonstrate that high-performance teams are characterized by synergy between task accomplishment and individual need fulfillment.[44,51] Since one formal leader cannot always attend to task and interpersonal nuances, groups informally or formally allocate leadership activities to multiple persons.[44,46,47] According to the literature in organizational behavior, the most

Box 2.1 Factors for analyzing multidisciplinary team effectiveness and function

Size of team
Composition (professions represented)
Specific responsibilities
Leadership style (individual or co-leadership/voluntary or assigned/stable or rotating/authoritarian or nonauthoritarian)
Scope of work (consultation or intervention or both/idea generating/decision-making)
Organizational support
Communication and interactional patterns within the team (e.g., frequency/intensity/type)
Contact with the patient, family, or care system (e.g., frequency/intensity/type)
Point in treatment process when team is involved (e.g., intake through to discharge, one phase only, only if case not progressing)

(From Al-Mousawi et al., Burn Teams and Burn Centers,[52] adapted from Schofield & Amodeo[41])

effective leader is one who engages the talents of others and empowers them to utilize their abilities to further the work of the group.[44,46] Failure to empower the informal leaders limits their ability to contribute fully.

For the identified leader of the burn team (i.e., the senior surgeon) to create a successful, efficient burn team, the leader must be prepared to share leadership with one or more "informal" leaders in such a way that all leadership functions are fulfilled.[44,46,47] The prominence and identity of any one of the informal leaders will change according to the situation. The successful formal leader will encourage and support the leadership roles of other members of the team, developing a climate in which the team members are more likely to cooperate and collaborate toward achievement beyond individual capacity.

For many physicians, the concept of sharing leadership and power initially appears threatening, for it is the physician, after all, who must ultimately write the orders and be responsible for the patient's medical needs. However, sharing power does not mean giving up control. The physician shares leadership by seeking information and advice from other team members and empowers them by validating the importance of their expertise in the decision-making process. However, the physician maintains control and responsibility over the patient's care and medical treatment.

Summary

Centralized care provided in designated burn units has promoted a team approach to both scientific investigation and clinical care that has demonstrably improved the welfare of burn patients. Multidisciplinary efforts are imperative to continue improving and understanding the rehabilitation and emotional, psychological, and physiologic recovery of burn patients. Tremendous scientific and technological advances have led to dramatic increases in the survival of burn victims.

Wider issues to be considered by leaders in the field include burn prevention, access to care in rural regions and developing countries, and promotion of investment and funding for burn care. Centralization of care at burn centers as well as enhanced care have provided tremendous opportunities for research and education.

We hope that, in the future, scientists and clinicians will follow the same model of collaboration to pursue solutions to the perplexing problems that burn survivors must encounter. Physical discomforts such as itching still interfere with patient rehabilitation. New techniques for controlling hypertrophic scars and surgical reconstruction could do much to diminish disfigurement.[52] The use of treatments to attenuate hypermetabolism, use of anabolic agents,[19,27] and supervised strength and endurance training[22,23] are all currently being investigated as means of enhancing the well-being of survivors of massive burn injuries. Further development of psychological expertise within burn care and increased public awareness of the competence of burn survivors may ease the survivor's transition from an incapacitated patient to a functional member of society. We hope that, in the future, burn care will continue to devote the same energy and resources that have produced such tremendous advances in saving lives and optimizing the quality of life for survivors.

3 Epidemiological, Demographic and Outcome Characteristics of Burns

STEVEN E. WOLF, LEOPOLDO C. CANCIO, and BASIL A. PRUITT

Introduction

In 2014, approximately 200,000 deaths occurred in the United States from all injuries, and 31 million sustained nonfatal injuries. In a population of 318,857,056 persons, this represents a per capita death rate from injury of 0.063% (or approximately 6 per 10,000), and a nonfatal injury rate of 9.73% (or approximately 1 in 10). Therefore injury is common but related death is uncommon. For injuries from fire and burns specifically, 3,194 deaths occurred (1/100,000 population), which represented 1.6% of all injury fatalities but only 1.3% of injuries. In all, 408,945 nonfatal burns occurred in the United States in 2014, giving a rate of 0.129% of persons in the United States sustaining a burn, or about 1 per 1000.

We constructed trend lines in addition to the preceding data in the rate of reported injuries and death since 2005. These data were found on the WISQAR database produced by the U.S. Centers for Disease Control and Prevention (CDC).[1] We found that total injuries were relatively unchanged in this period from 2005 to 2009, then saw a large spike (a 10% increase) from 2010 to 2012. This spike has since receded (Fig. 3.1). When seen on a per capita basis, a 7.5% increase in the rate of reported injury occurred in the 2010–2012 period; therefore the spike in reported injuries was not from an increase in population; this is an interesting societal trend. Of further interest is the increase in injury fatalities which began at the same time and is mostly associated with an increased injury mortality rate (a 12.3% increase from 0.57% to 0.64%). This continues to rise despite a subsequent decline in total and per capita injuries. Whether this is from an increase in injury severity or age distribution cannot be answered in these data. A potential reason is a perceived increase in the use of palliative withdrawal of care, suggesting that those who might live with known treatments are unnecessarily adding to the mortality rate.

The incidence of total burns saw a similar spike in the 2010–2012 period, but this was not reflected in the per capita statistics, likely because of blunting by the relatively low incidence of burns (Fig. 3.2). Interestingly burn fatalities continue to decrease overall with a flattening trajectory in 2013–2014. The per capita numbers also showed a decline that has leveled at 0.001% (1 in 100,000). What is not seen is an increase in burn fatality rate that is evident in the all-injury fatality rate.

Burns occur unequally among the age groups in the WISQAR data, and the interim changes from 2005 to 2014 are interesting. The total number of burns have generally decreased in those aged 0–45, whereas the total number of burns in those older than 45 have increased dramatically, 31% from 2005 to 2014 in those aged 46–65, and 12% in those aged over 65 (Table 3.1).

The spike seen in total injuries between 2010 and 2012 is parallel with burns in those aged 0–4 but has settled back to a 6% decline in this age group from that in 2005. For those aged 5–18, we see a similar steady decline in the number of burns, and also in those aged 19–45. However the numbers of burns in those aged 46–65 and in those older than 65 years have seen a steady and dramatic increase. When indexed to population, this is almost completely accounted for by the increase in population in these age groups. Therefore no increase in per capita rate has occurred, and the increased numbers are from an increase in the population of those aged over 45 years.

When considering plans in health care utilization to respond to changes in the incidence of burns, strategies should be for the *total* number of burns likely to be encountered. For regional plans, per capita estimations should be used as specific regions grow and contract. In this light, the past 10 years have seen a significant decrease in the total number of burns in those aged 45 years and younger. Populations in the United States are generally stable for these age groups in the past 10 years, thus the decline in total numbers of burns must be attributed to cultural changes and prevention efforts, both legislative and educational. Therefore future resource utilization for the care of burns in this age group in the United States will likely continue to diminish unless some change occurs in the population. However those older than 45 years continue to increase in many areas, and thus considerations might be made to plan for further growth in burns in older persons.

We then analyzed the epidemiologic data from the National Burn Repository (NBR) available from the American Burn Association for the years 2006–2015.[2] In this, we examined recent trends in burn incidence and qualities in the United States. The NBR contains data from 96 of the128 self-designated burn centers in the United States as well as 7 burn centers in Canada, Sweden, and Switzerland. Of these 96 centers, 65 were verified as a burn center using American Burn Association criteria. The data we include here come only from the reporting US centers.

The distribution of burns among age groups in the NBR data has more granularity than does the WISQAR data. Burn distribution has a major grouping in those younger than 10 years of age. Those aged 11–20 have a smaller incidence, which then increases in those aged 21–60;

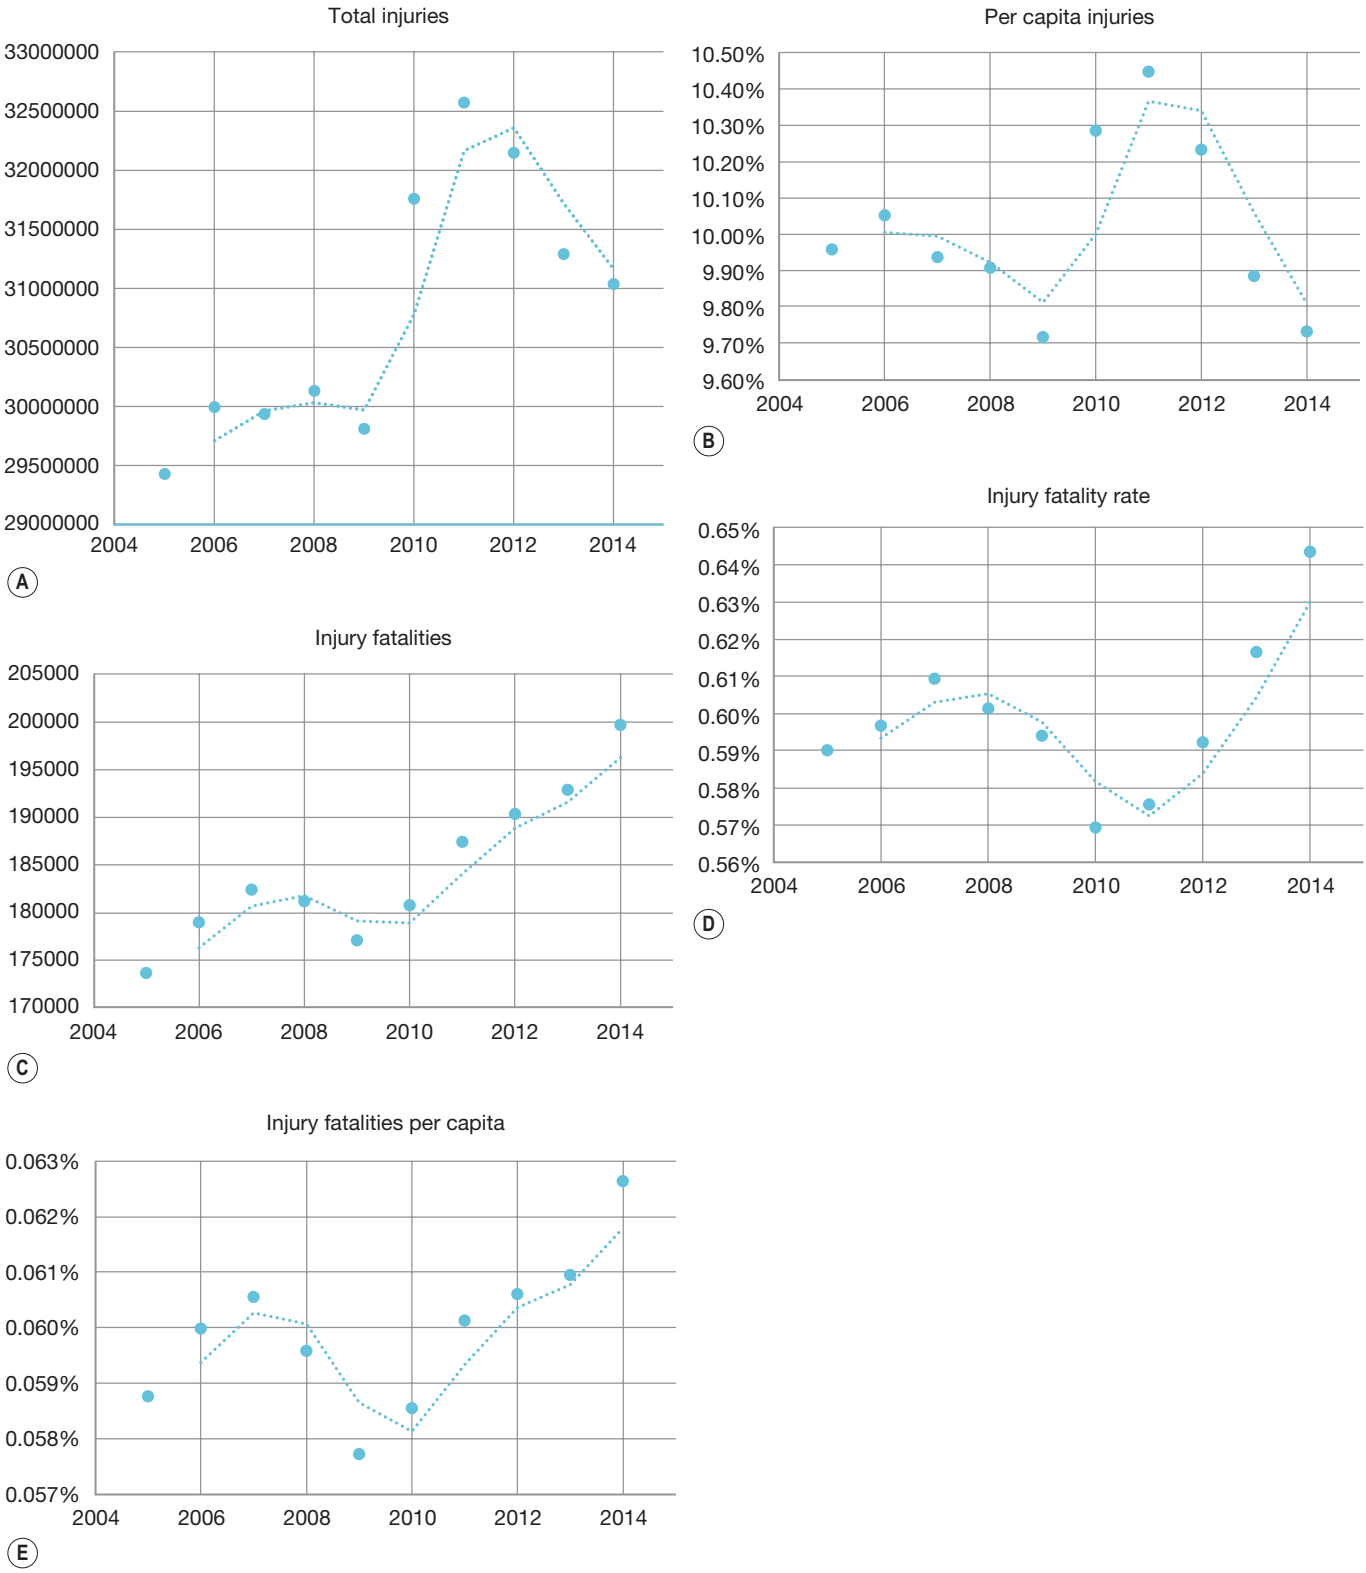

Fig. 3.1 Injury statistics taken from the WISQARS database maintained by the U.S. Centers for Disease Control and Prevention. Panel A describes the total number of reported injuries from the period 2005–2014. The y-axis is the total number of injuries. The trendline is the moving average of the adjoining two values. Panel B describes the per capita incidence of reported injuries in %, calculated by dividing the number of injuries by population for that year. Panel C describes the total number of fatalities ascribed to injury for the years 2005–2014. Panel D is the injury fatality rate by year calculated by dividing the number of fatalities by the number of reported injuries. Panel E is the injury fatalities per capita, calculated by dividing the number of fatalities by the population for that year.

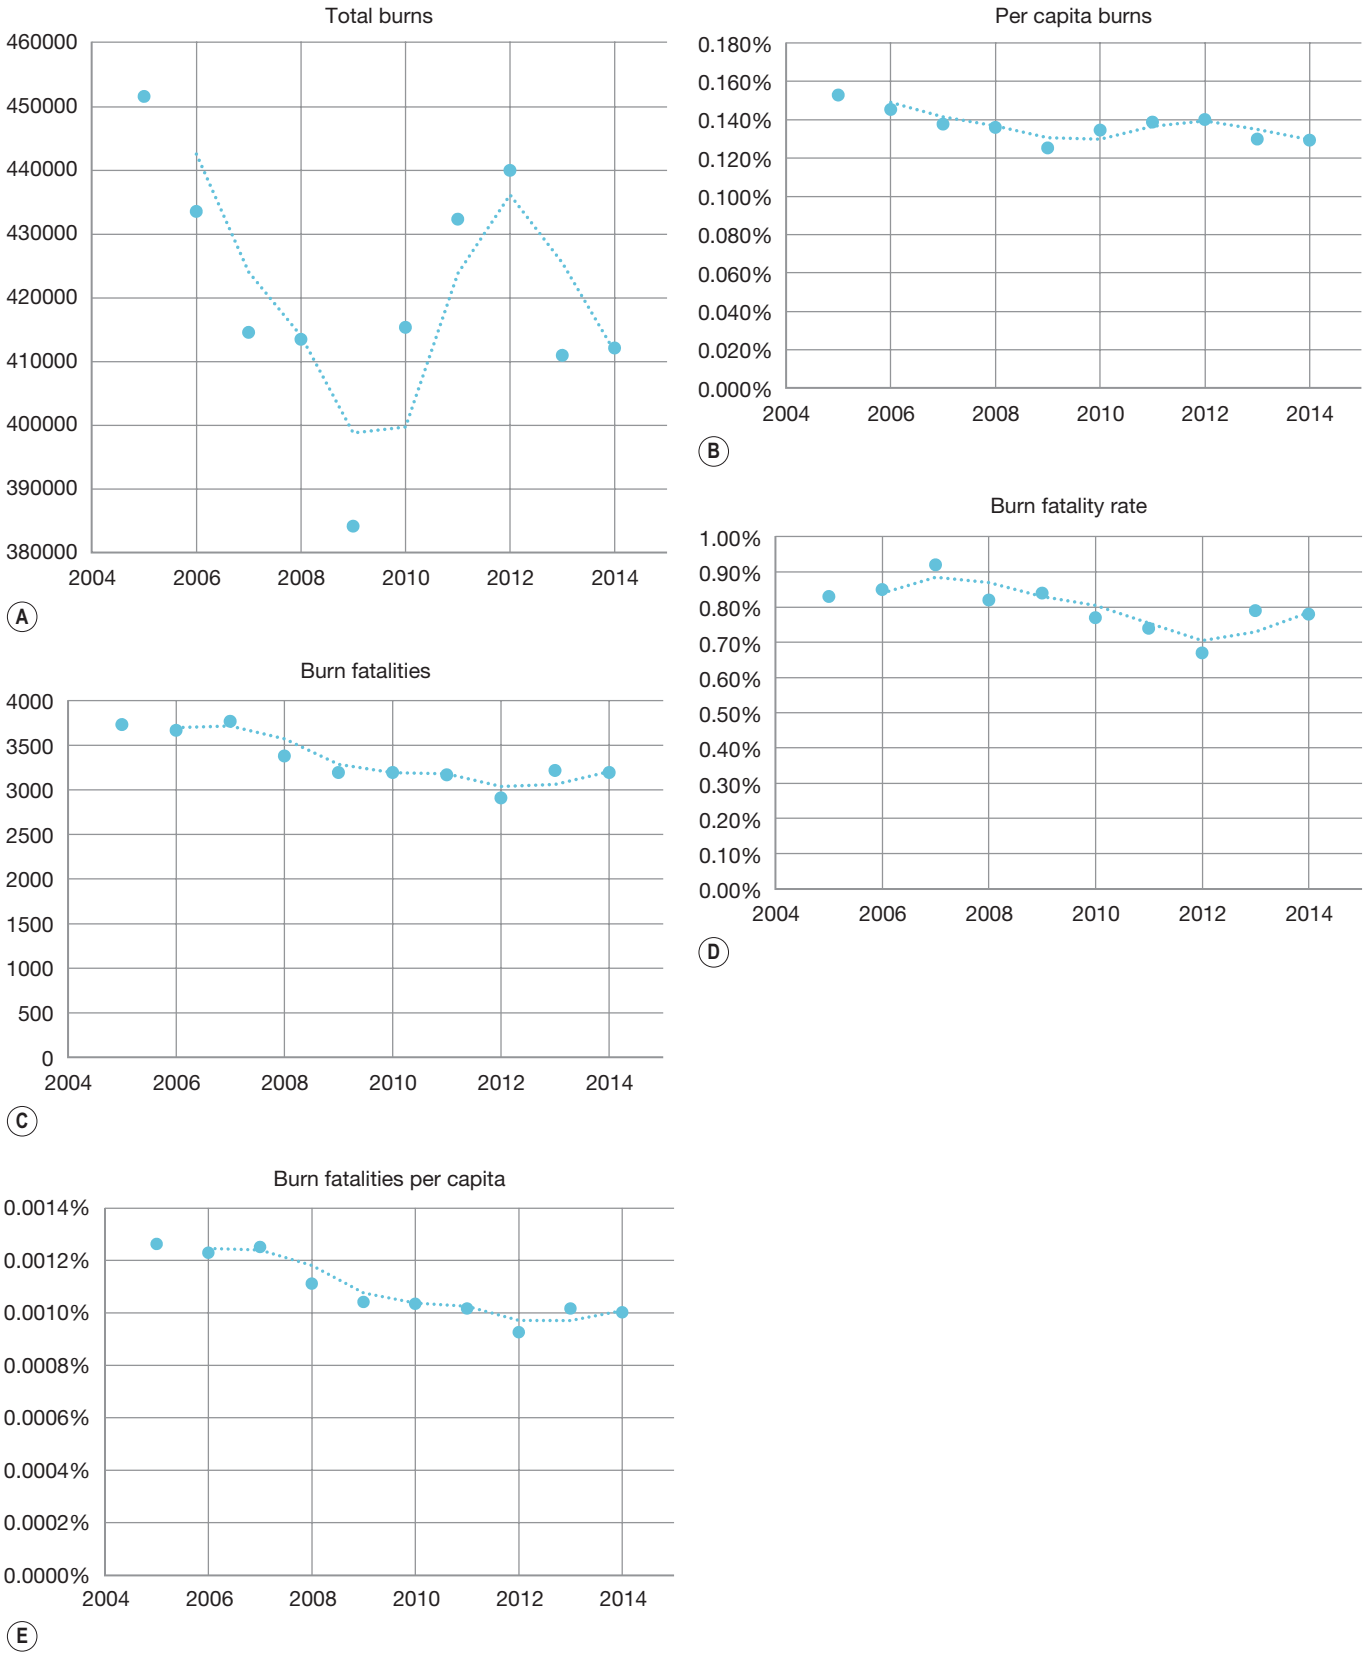

Fig. 3.2 Burn injury statistics taken from the WISQARS database maintained by the U.S. Centers for Disease Control and Prevention. Panel A describes the total number of injuries from the period 2005–2014. The y-axis is the number of injuries, with the included trendline the moving average of the two adjoining values. Panel B describes the per capita incidence with a trendline similarly calculated. Panel C is the number of fatalities with Panel D as the corresponding fatality rate. Finally, Panel E is the per capita burn fatalities.

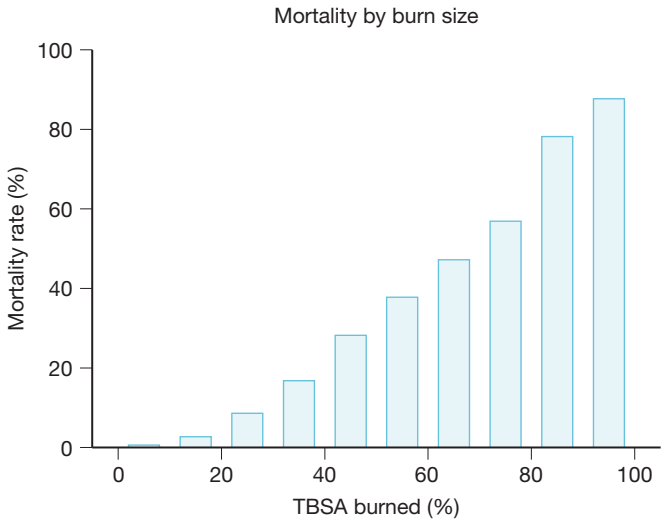

Fig. 3.4 Reported mortality by burn size.

thereafter the total numbers decline (Fig. 3.3) for a bimodal distribution when grouped in this way. Among these, 67% were in men, which is similar to previous reports of burns by gender. In terms of ethnicity, 58% of burns in the United States were in European-Americans, 21% in African-Americans, 13% in Hispanic-Americans, 5% in other ethnicities, and 3% in Asian-Americans.

Most burns were below 10% total body surface (TBSA), which included 78% of the burned population. Another 14% measured 11–20% TBSA, and the remaining 8% were greater than 20% TBSA. These numbers are all from designated burn centers, and it is likely that many additional burns below 10% TBSA were treated in nonburn centers. With this in mind, it is likely that almost all burns over 10% were treated at burn centers, thus the distribution in the NBR data is likely to be biased to larger burns from the true incidence in the United States.

Most burns were the result of injuries due to fire and flame at 41% of the total. Scalds accounted for another 33%, followed by contact with hot objects at 9%, and then chemical and electrical burns at 3% each. Overall mortality for those with burns was 3.1% during this period, which declined by almost 25% from 4.0% in 2006. Mortality was generally higher in women, except in 2015. Deaths did increase significantly with burn size (as expected), which was almost linear with increasing burned area (regression formula $y = x - 13.7$, $r^2 = 0.97$) (Fig. 3.4). This is a change from previous mortality rates, which was mostly a first-order distribution. According to this formula, probability of mortality for a burn (without considering age) can be estimated at %TBSA burned minus 14.

We did a probit analysis on the overall mortality data which revealed an LD50 for a 55% TBSA burn among all age groups. Thus a 55% TBSA burn would be expected to have a mortality rate of 50%; this is an improvement from previous reports.[3] When the Baux score (age plus TBSA burned) was examined for mortality, a 50% mortality was reported at about 105 and a 90% mortality was reported at 130.

Demography

Geographic and housing tract location significantly influences the rate of house fires and the subsequent death rates from associated burns. Age of the home, economic status, number of vacant houses, and immigration status affect the house fire rate.[4–5] House fire death rates are higher in

Table 3.2 Causes of Burn Injuries.

	Fires (%)	Injuries (%)	Deaths (%)	Odds Ratio of Death
Cooking Equipment	46	44	19	0.4
Heating Equipment	16	12	19	1.2
Electrical Equipment	9	9	16	1.8
Intentional	8	7	14	1.8
Smoking	5	10	22	4.4

the Eastern part of the United States, particularly the Southeast, compared to the West.[6] Cooking is the leading cause of house fires in the United States: 46% of house fires and 44% of fire-related injuries are by this cause.[7] Another leading cause of house fires is from heating equipment at 16% of instances. Other causes include electrical system fires (9%), intentional fires (8%), and fires from cigarette smoking (5%). Interestingly the cause of fire with the highest mortality is that from cigarette smoking, comprising 22% of residential fire-related deaths (Table 3.2). The ratio of deaths compared to other causes is also much higher in this group, at 4.4.

Gratifyingly the number of residential fires has dramatically decreased since 2004, falling 22%; similarly related fire death rates have fallen by the same amount. Injuries, however, have only gone down by 7%, suggesting that in those fires that do occur, more injuries are occurring.[8] Interestingly fire death rates are reduced by 50% with working fire alarms.[9] When the rate of fire deaths is considered by state, we find these are highest in Alabama, Alaska, Arkansas, District of Columbia, Mississippi, Oklahoma, Tennessee, and West Virginia. The lowest rates are Arizona, California, Colorado, Florida, Massachusetts, Nevada, New Jersey, Texas, and Utah.

The economic consequences of residential fires are also great. The highest fire-related losses in recent history were in 2008, with $16.7 billion in property damage and other direct costs. This has significantly fallen since then, with a reported $11.5 billion in losses in 2013.[8] The healthcare costs of burns are also prodigious. Each year in the United States, 40,000–60,000 people undergo in-hospital care for burns. The average charges for hospital care of a burned patient range from $47,557.00 to $1,203,410.00 (average $92,377), with much higher costs incurred by patients with extensive burns. The length of hospital stay ranges from one day to hundreds of days (mean 9.7), and, for patients 80 years and older is more than twice as long as that for children under 5.[2]

High-Risk Populations

CHILDREN

The number of pediatric burn patients admitted to hospitals is influenced by cultural differences, resource availability, and medical practice. Consequently the number of pediatric burn patients admitted to a hospital for treatment varies by geographic area from a low rate of 1.4/100,000 population in North America to a high of 10.8/100,000 population in Africa.[1,10] It has been estimated that 113,108 children aged 18 and younger were treated for burns in the United States in 2014. Of those injuries, approximately 60% were scald burns in those under 5 years of age; contact burns, 20%; fire/flame, 15%; and 5%, other.[2] For those aged 5–18, scalds accounted for approximately 33% of injuries; fire/flame, 45%; contact, 10%; and other, 12%, demonstrating a shift from scalds to fire and flame with increasing age. In 2013, 334 children died from fires or burns, and 44% of these were 4 years of age and younger.[9]

Scald burns are the most common cause of burns in the particularly young. The occurrence of tap water scalds can be prevented by adjusting the temperature settings on hot water heaters or by installing special faucet valves so that water does not leave the tap at temperatures above 120°F (48.8°C).[9,11] All code-making bodies at the national and regional levels have established standards for new or reconstructed dwellings requiring antiscald technology and a maximum water temperature of 120°F.

Home exercise treadmills represent a recently identified source of burns in pediatric patients. The injuries are a consequence of contact with a moving treadmill and almost always involve the upper extremity (97%), often the volar surface of the hand.[12] Approximately 50% undergo surgical intervention in the form of skin grafting, and some develop hypertrophic scars.[13]

ELDERLY

The elderly represent an increasing population segment, as previously described, and they have an increased prevalence in the burned population due to increased numbers as well as increased risk of being burned. Furthermore mortality from burns increases with age. The WISQAR data demonstrate that about 6% of all burns occur in those older than 65 years, although other reports from single centers approach 16% of all admissions for burns,[14] and mortality in this age group is significantly higher than that of all other ages, at 4.7% of all over 65 years of age who are burned compared to between 0.4% and 1.4% in all other age groups.

Interestingly the rates of burn by gender are almost even in the elderly who are burned, 51% in men and 49% in women. In an older paper, it was noted that 67% of injuries in the elderly are caused by flame or explosion, 20% by scalds, 6% by electricity, 2% by chemicals, and 6% by other causes. Forty-one percent of the injuries occurred in the bedroom and/or living room, 28% out of doors or in the workplace, 18% in the kitchen, 8% in the bathroom, and 5% in the garage or basement. Seventy-seven percent of the patients had one or more preexisting medical conditions.[15] Examination of predictors of mortality revealed that the usual signals such as increasing age, burn size, and inhalation injury continue to remain the most useful in this age group, but each of these had much more impact on mortality than in other age groups, as reflected by the much higher mortality rate.[14] Several authors reported lower mortality rates in the elderly than expected from standard prediction models, such as those from Bull, ASBI, and Ryan,[16] indicating that we are improving in this age group as well.

A recently identified factor in burns in the elderly are those in relation to dementia. Harvey and others identified a 1.6 odds ratio of burns between the aged with and without dementia. In addition, the burns were more likely to be larger, were more likely associated with ignition of clothing or scalds, and hospital length of stay was twice as long.[17]

DISABLED

The disabled are a group of patients considered to be burn-prone and are often injured in the home in incidents associated with scalds. From a report in 1993, the effects of disability and preexisting disease in those patients are evident in the duration of hospital stay (27.6 days on average) and the death rate (22.2%) associated with the modest average extent of burn (10% TBSA).[18] Another report on burns in generally elderly patients with dementia (who were also disabled) emphasized prevention measures to reduce the incidence of burns when such patients are performing the activities of daily living.[19]

MILITARY PERSONNEL

In wartime, military personnel are at high risk for burns both related to combat and nonintentional causes. The incidence of burns is associated with the types of weapons employed and combat units engaged and has ranged from 2.3% to as high as 85% in a number of conflicts over the past 8 decades. The detonation of a nuclear weapon at Hiroshima in 1945 instantaneously generated an estimated 57,700 burned patients and destroyed many treatment facilities, which thereby compromised their care.[20] In the Vietnam conflict, as a consequence of the total air superiority achieved by the U.S. Air Force and the lack of armored fighting vehicle activity, those with burns constituted only 4.6% of all patients admitted to Army medical treatment facilities from 1963 to 1975.[21] Approximately 60% of the 13,047 burned patients were nonbattle injuries. Furthermore in the Panama police action in late 1989, the low incidence of burns (only 6 or 2.3% of the total 259 casualties had burns) has been attributed to the fact that the action involved only infantry and airborne forces using small-arms weaponry.

Burns during conflicts have not always been this low, as exemplified by the Israeli conflicts of 1973 and 1982, and the British Army of the Rhine experience in World War II. Both of these conflicts were dense, with personnel in armored fighting vehicles who had a relatively high incidence of burns.[22,23] Burns have also been common injuries in war at sea, such as in the Falkland Islands campaign of 1982: 34% of all casualties from the British Navy ships were burns.[24,25] The increased incidence of burns, 10.5% and 8.6% in the Israeli conflicts of 1973 and 1982, respectively, as compared to the 4.6% incidence in the 1967 Israeli conflict, was considered to reflect what has been termed "battlefield saturation" with tanks and antitank weaponry.[22,26] Decreasing incidence of burns in armored vehicle combat has been attributed to enforced use of flame-retardant garments and the effectiveness of an automatic fire extinguishing system within tanks.[26] Those factors have also been credited with reducing the extent of the burns that did occur. For example, in the 1973 Israeli conflict 29% of burned patients had injuries of more than 40% TBSA, and only 21% had burns of less than 10% TBSA. After institution of garment and fire-extinguisher policies, in the 1982 Israeli conflict those same categories of burns represented 18% and 51%, respectively, of all burn injuries.

Modern weaponry may have eliminated the differential incidence of burns between armored fighting vehicle personnel and those in other combat elements. One of every seven casualties had burns in the British and Argentinean forces in the 1982 Falkland Islands conflict in which there was little if any involvement of armored fighting vehicles.[24,25] Conversely only 36 (7.8%) burns were sustained in the total 458 casualties in the U.S. Forces during Operation Desert Shield/Desert Storm in 1990–1991, in which there was extensive involvement of armored fighting vehicles.

In the most recent armed conflicts, Operations Iraqi Freedom and Enduring Freedom, the U.S. Army Burn Center (U.S. Army Institute of Surgical Research [ISR]) in San Antonio, Texas, provided care for all military patients who sustained burns. Trained burn surgeons from the ISR provided care at the Burn Center in San Antonio; at a general hospital in Landstuhl, Germany, while in transit from the theater of operations to the continental United States; as well as at the Level III hospital in-theater (Balad, Iraq). During this conflict, approximately 900 combat casualties were admitted to the burn center, among whom 34 expired (3.9%).[27] Interestingly another 11 expired within 10 years of injury from either a drug overdose (5), another combat injury (3), or a motor vehicle crash (3).[28] Therefore about 10% of deaths occurred from self-induced overdose, which should be investigated further and mitigated. On average, definitive care was administered in the United States within 96 hours of injury, which was accomplished through active use of the Global Patient Movement Regulating Center and the Burn Flight Team. This team consists of Army personnel who work with existing Air Force crews to support and rapidly transport severely burned patients from theater. In this conflict, more than 250 critically ill patients were transported successfully, with only one mortality during the flight.[29]

The U.S. Army Burn Center maintains readiness by caring for civilians in south Texas, and this activity continued during the conflict. When examined, these two populations who were cared for by the same personnel with the same equipment showed no differences in outcomes when those of the same ages were compared. Interestingly the burn size distributions of both groups were the same and were similar to that reported from the general databases at the beginning of this chapter.[30]

Burn Etiologies

FIRE/FLAME

Flame is the predominant cause of burns (43%) in patients admitted to burn centers, particularly in the adult age group.[2] Misuse of fuels and flammable liquids is a common cause of burns, constituting 66% of flame injuries.[31] The predominant affected population is young men, and the distribution of burn sizes is similar to that of all burns.[32] However mortality rates are higher than in the general

burn population (50% increase), and length of hospital stay is up to twice as long as for other causes of burns. This might be related to a higher incidence of full-thickness burns due to the higher temperatures associated with gasoline, which results in more excision and grafting procedures, ICU care, and the like.[33] Because of these findings, the use of gasoline for purposes other than as a motor fuel, and any indoor use of a volatile petroleum product, should be discouraged as part of any prevention program.

Another commonly encountered cause of flame burns is that associated with automobile crashes. A comprehensive study done in Germany demonstrated that about 1% of car crashes had associated burns; these injuries were more common in frontal and high-energy collisions.[34] In a review of 178 patients who had been burned in an automobile crash, it was noted that slightly more than one-third had other injuries, most commonly involving the musculoskeletal system, and that approximately 1 in 6 had inhalation injury (1 in 3 of those who died).[35] A review of patients admitted to a referral burn center revealed that burns sustained while operating a vehicle involved an average of more than 30% TBSA and were associated with mechanical injuries (predominantly fractures) much more frequently than those burns incurred in the course of vehicle maintenance activities, which involved an average of less than 30% TBSA.[36]

Automotive-related flame burns can also be caused by fires and explosions resulting from "carburetor-priming" with liquid gasoline, although this is much less common now that almost all automobile engines are equipped with fuel injectors. The burns sustained in boating accidents are also most often flash burns due to an explosion of gasoline or butane and typically affect the face and hands.[37]

The ignition of clothing is the second leading cause of burn admissions for most ages. The fatality rate of patients with burns due to the ignition of clothing is second only to that of patients with burns incurred in house fires.[9] More than three-quarters of deaths due to the ignition of clothing occur in patients older than 64.[6] Clothing ignition deaths, which were a frequent cause of death in young girls, have decreased as clothing styles have changed and are now rare among children, with little overall gender difference at the present time.

SCALD

Burns due to hot liquids cause approximately 33% of all burns in any age group, but this incidence in much higher in children, particularly those under 4 years of age, at up to 60% of admissions.[38–40] These injuries are generally partial-thickness; however full-thickness injury can occur. In particular, full-thickness burns have a much higher incidence with hot oil burns. Young children are most commonly injured by pulling a container of hot liquid onto themselves,[40] while older children and adults are most commonly injured by improper handling of hot oil appliances.[41–43]

Burns from scalds and contacts with hot materials cause approximately 100 deaths per year.[6] The case fatality rate of scald injury is low (presumably due to the usually modest extent and limited depth of the burn), but scalds are major causes of morbidity and associated healthcare costs, particularly in children younger than 5 years of age and in the elderly.

CONTACT

Contact burns are the third most encountered cause of injury and are most common in children and young adults. For children, the incidence is higher due to lack of safety awareness and grasping hot objects. Another cause recently identified was contact burns due to glass-fronted fireplaces.[44] In this study, 402 children were identified with this injury in the United States in a 5-year period. This rate was 20 times higher than that estimated by the U.S. Consumer Product Safety Commission.

For younger adults, motorcycle exhaust pipes are another common cause of injury related to the use of vehicles. In Greece, the incidence of burns from motorcycle exhaust pipes has been reported to be 17/100,000 person-years, or 208/100,000 motorcycle-years. The highest occurrence was in children. In adults, the incidence is 60% higher in women than in men. As anticipated, the most frequent location of the burns was on the right leg below the knee, where contact with the exhaust pipe occurs. The authors concluded that a significant reduction of incidence could be achieved by wearing long pants and by the use of an external exhaust pipe shield.[45]

WORK-RELATED BURNS

Work-related burns account for 20–25% of all serious burns and also account for about 2% of all workplace injuries.[46] Interestingly, in a recent study from Michigan, accommodation and food services as well as the healthcare and social assistance industries accounted for more than 50% of the injuries.[47] Restaurant-related burns, particularly those due to deep fryers, represent a major and preventable source of occupational burn morbidity and, in restaurants, account for 12% of work-related injuries.[6] Other significant causes of work-related injuries are associated with electrical injuries, chemical injuries, and contact burns. Also as anticipated, the risk of burns due to hot tar is greatest for roofers and paving workers. Of all incidents involving roofers and sheet metal workers, 16% are burns caused by hot bitumen, and 17% of those injuries are of sufficient severity to prevent work for a variable period of time.

CHEMICAL BURNS

Chemicals are a well-known cause of burns, and these burns are generally caused by either acidic or alkali chemicals, although chemical burns can also occur with organic solvents. In a recent review of the literature for chemical burns, the reported percentage of burns related to chemical agents is between 2% and 10% of injuries. Most of those affected are men who were injured either in the workplace or domestic setting. Acids caused about 25% of the injuries and bases 55%.[48] The limited extent of burns reported from chemicals may be affected by many being treated as outpatients.

The greatest risk of injury due to strong acids occurs in patients who are involved in plating processes and fertilizer

manufacture, whereas the greatest risk from alkalis is associated with soap manufacturing and in the home with the use of oven cleaners. The greatest risk of organic solvent injuries is associated with the manufacture of dyes, fertilizers, plastics, and explosives, and that for hydrofluoric acid injury is associated with etching processes, petroleum refining, and air conditioner cleaning. Anhydrous ammonia injury is most common in agricultural workers and cement injury (an alkali injury with associated thermal injury) is most common in construction workers.

ELECTRICAL CURRENT INJURY

Electrical current is another cause of injury seen in burn centers. Approximately one-third of electrical current injuries occur in the home, with another one-quarter occurring on farms or industrial sites and the rest occurring in the occupational setting.[6] A once common cause of electrical injury by household current occurred in children who inserted uninsulated objects into electrical receptacles or bit or sucked on electrical cords in sockets, resulting in oral commissure burns;[49] this has significantly diminished with the universal adoption of alternating electrical current for household use. Low-voltage direct current injury can be caused by contact with automobile battery terminals or by defective or inappropriately used medical equipment such as electrical surgical or external pacing devices,[50] or defibrillators.[51] Although such injuries may involve the full thickness of the skin, they are characteristically of limited extent.

Employees of utility companies, electricians, construction workers (particularly those working with cranes), farm workers moving irrigation pipes, oil field workers, truck drivers, and individuals installing antennae are at greatest risk of work-related high-voltage electric injury.[52] The greatest incidence of electrical current injury occurs during the summer as a reflection of farm irrigation activity, construction work, and work on outdoor electrical systems and equipment.[53]

During the period 1994 to 2008, 26 patients with high-voltage injury and 30 with low-voltage injury were treated at a regional burn center. Mortality was only 3.6%, which is likely biased in that those who died at the scene of injury were not included.[54] In another study, about one-half of patients with high-voltage injury underwent fasciotomy, and, even so, amputation was necessary in almost all of these. Of note, about 15% developed some long-term neurologic deficit, and 3% developed cataracts.[55] Another study reported the outcome of 195 patients with high-voltage electrical injury treated at a single burn center during a 19-year period. A total of 187 (95.9%) of the 195 patients survived and were discharged. Fasciotomy was undertaken in the first 24 h following injury in 56 patients, and 80 patients underwent an amputation because of extensive tissue necrosis. The presence of hemochromogens in the urine predicted amputation with an overall accuracy of 73.3%.[56]

LIGHTNING BURNS

Death due to lightning strikes has now fallen to the third most common cause of death during storms[57] and is now down to less than 30 deaths per year in the United States. Most lightning strikes (70%) occur between clouds; however approximately 30% hit the ground or other site. In the United States, these are most common in Florida and the Southeast coast and occur most often in the warmer months. Only about 3–5% of injuries result from a direct lightning strike; instead most of the energy is mediated by other objects, such as the ground or a tree.[58] Most injuries in survivors are superficial, and deep injuries are rare.

Lightning injuries and deaths occur most often in individuals who work outside or participate in outdoor recreational activities. Thus men are five times more likely to be struck by lightning than are women.[59] In some older studies, the annual death rate from lightning was greatest among those aged 15–19 years (6 deaths per 10 million population; crude rate: 3 per 10 million) and is seven times greater in men than in women. Approximately 30% of those struck by lightning die, with the greatest risk of death being in those patients with cranial or leg burns. Fifty-two percent of patients who died from lightning injury were engaged in outdoor recreational activity, such as playing golf or fishing, and 25% were engaged in work activities when struck.[60]

FIREWORKS

Fireworks are another seasonal cause of burns. Approximately 8% of patients with fireworks injuries undergo hospitalization for care, and approximately 60% of those injuries are for burns of specific areas, mostly those of the hands, head, and eyes.[61] Other data estimate that 1.86–5.82 fireworks-related burns per 100,000 persons occurred in the United States during the Fourth of July holiday.[62] Sparklers, firecrackers, and bottle rockets caused the greatest number of burns.[63] Of note, the incidence of injuries has decreased by 30% over the past 25 years. Boys, especially those aged 10–14, are at the highest risk for fireworks-related injuries. Children aged 4 and under are at highest risk for sparkler-related injuries.[9] Proposed prevention measures include reducing the explosive units per package, package warnings, and limiting the sale of the devices to children.[64]

INTENTIONAL BURNS

Burns can be intentional, either self-inflicted or done purposefully by another. It is estimated that 4% of burns (published range 0.37–10%) are self-inflicted. The region of the world has great import in determining the rates of intentional burns, with a particularly high rate in young women in India and middle-aged men in Europe. The average burn size in intentional burns is larger than other causes, at approximately 20% TBSA. The reasons for intentional burns, specifically assaults, are reported to be due to conflict between persons including spouses, elderly abuse, and economic transactions. For self-inflicted injuries, these are related to domestic discord, difficulty between family members, and social distress from unemployment. Mortality rates worldwide for intentional burns are reported at 65%.[65] Rates for Europe and the United States are also higher, with a twofold increase in the risk of mortality compared to nonintentional injuries.[66] Data from the NBR in 2007 indicated that 3% of admitted burns were intentional,

with about 50% self-inflicted and the other 50% from assault. Similar to the prior report, burn size was on average 22% TBSA compared to 11% for nonintentional and exhibited a fourfold higher mortality rate.[67]

In some other studies, interesting findings were noted. In those with self-inflicted injuries, 43% occurred at home and another 33% occurred while in a psychiatric institution. Importantly 73% had a history of psychiatric disease; these were predominantly affective disorders or schizophrenia in the suicide attempts and personality disorders in self-mutilation. Also, 55% of suicide attempts had previously attempted suicide; 66% of the self-mutilators had made at least one previous attempt at self-mutilation. The authors concluded that the very fact of self-burning warranted psychiatric assessment.[68]

Assault by burning is most often caused by throwing liquid chemicals at the face of the intended victim or by the ignition of a flammable liquid with which the victim has been doused. These types of injuries are generally rare in the developed world but are quite common in low- and middle-income countries.[65] In those injuries that do occur in such places as the United States, most are African-American women who were unemployed and are associated with premorbid substance abuse.[69] Occasionally injuries will be induced by spouses characteristically dousing the face or genitalia.[70] In India, a common form of spouse abuse is burning by intentional ignition of clothing. When such burns are fatal, they have been called "dowry deaths" because they have been used to establish the widower's eligibility for a new bride and her dowry.

Child abuse represents a special form of burns perpetrated by parents, siblings, caregivers, or child care personnel. Child abuse has been associated with teenage parents, mental deficits in either the child or the abuser, illegitimacy, a single-parent household, and low socioeconomic status, although child abuse can occur in all economic groups. Abuse is usually inflicted on children younger than 2 years of age who, in addition to burns, may exhibit signs of poor hygiene, psychological deprivation, and nutritional impairment.[71] The most common form of child abuse involving burns is caused by hot water in bathing. In a recent report, it was noted that about 5% of pediatric burn admissions were associated with abuse, and most were due to scalds (90%). Mortality was double that of patients with nonintentional injuries (5.4% vs. 2.3%).[72]

A distribution typical of child abuse immersion scald burns (i.e., feet, posterior legs, buttocks, and hands) should heighten the suspicion of child abuse. The presence of such burns mandates a complete evaluation of the circumstances surrounding the injury and the home situation. The importance of identifying child abuse in the case of a burn injury resides in the fact that if such abuse goes undetected and the child is returned to the abusive environment, there is a high risk of fatality due to repeated abuse.

Elder abuse can also take the form of severe burn. A congressional report published in 1991 indicated that 2 million older Americans are abused each year, and some estimates claim a 4–10% incidence of neglect or abuse of the elderly.[73] A recent retrospective review of 28 patients 60 years and older admitted to a single burn center during a calendar year identified self-neglect in seven, neglect by others in three, and abuse by others in one.[74] Adult protective services were required in two cases. The authors of that study concluded that abuse was likely to be underreported because of poor understanding of risk factors and a low index of suspicion on the part of the entire spectrum of healthcare personnel.

HOSPITAL BURNS

Patients may also sustain burns while in the hospital for diagnosis and treatment of other disease. Approximately 2% of surgical anesthesia malpractice claims involve fire incidents, and 85% of these were in head and neck surgery. These were most commonly associated with the use of electrocautery around oxygen sources.[75,76] Application of excessively hot soaks or towels or inappropriate use of heat lamps or a heating blanket are other causes of burn injury to patients.[77] Localized high-energy ultrasound may also produce coagulative necrosis, as exemplified by full-thickness cutaneous injury and localized subcutaneous fat necrosis of the abdominal wall in a patient who had received focused-beam high-intensity ultrasound treatment for uterine fibroids.[78] A common cause of burn injury, particularly in disoriented hospital or nursing home patients, is the ignition of bed clothes and clothing by a burning cigarette. Smoking should be banned in healthcare facilities or at least restricted to adequately monitored situations.

Burn Patient Transport and Transfer

As noted earlier, distance between viable burn centers and variable population density implies that many burned patients undergo transfer to burn centers from other locations. For transfer across short distances and in congested urban areas, ground transportation is frequently the most expeditious. For longer distances, aeromedical transfer for major burns is often indicated when ground transportation takes more than 2 hours.[79] In the United States, helicopters are most frequently employed for distances of less than 200 miles. The instance of vibration, poor lightning, restricted space, and high noise make in-flight monitoring and therapeutic interventions difficult, a fact that emphasizes the importance of carefully evaluating the patient and modifying treatment prior to the transfer. If distances of more than 200 miles are considered, fixed-wing aircraft are often a better option. The patient compartment of such an aircraft should be well lighted, permit movement of attending personnel, and have some measure of temperature control. In general, burned patients travel best in the immediate period after the burn injury has occurred, as soon as hemodynamic and pulmonary stability has been attained. This is particularly true in those with inhalation injury, whereby an increased mortality rate was shown in those taking more than 16 hours to arrive at definitive care.[80]

Physician-to-physician case review to assess the patient's need for and ability to tolerate aeromedical transfer, prompt initiation of the aeromedical transfer mission, examination of the patient in the hospital of origin by a burn surgeon from the receiving hospital and correction of organ dysfunction prior to undertaking aeromedical transfer, and in-flight monitoring by burn-experienced personnel ensure

both continuity and quality of care during the transport procedure. During the first half of the Iraq/Afghanistan conflicts (2003–2007), the U.S. Army ISR Burn Care Flight Teams using such a regimen completed 380 patient transfers from theater to the burn center in San Antonio using dedicated burn transport teams including physicians, nurses, respiratory therapists, and support personnel. One-third of the patients (33.6%) received ventilatory support throughout the transport, but no in-flight deaths occurred.[81] This demonstrates that burned patients can be transported safely throughout the world if indicated.

Mass Casualties

Mass casualty incidents may be caused by forces of nature or by accidental or intentional explosions and conflagrations. Interest in man-made mass casualties has been heightened by recent terrorist activities and the threat of future incidents. The incidence of severe burns in a mass casualty incident varies with the cause of the incident, the magnitude of the inciting agent, and the site of occurrence (indoors vs. outdoors). The terrorist attacks in which airplanes laden with aviation fuel crashed into the Pentagon and the World Trade Center on September 11, 2001, produced 10 and 39 patients with burns, respectively, for treatment at burn centers.[82,83] Since then, many events have occurred throughout the world, with the most recent taking place at a festival in Taiwan in 2015, where 499 persons were burned who were between the ages of 12 and 38: 281 sustained burns over 40% TBSA. These patients were distributed between many hospitals, and the eventual mortality rate was 3%, akin to that normally seen in burn centers. The assembled response was massive, including thousands of providers, and was effectively coordinated at the federal level.[84] Another prominent burn event occurred in Bali, in 2002, caused by an explosion and fire that killed more than 200 people and generated 60 burn patients who, after triage and emergency care, were transported by aircraft to Australia and treated at various hospitals.[85] The casualties produced in terrorist attacks often have associated blast injury and mechanical trauma in addition to burns.

Recent nonterrorist mass casualty incidents have been of greater magnitude in terms of numbers of burn casualties. In the Station nightclub fire in Warwick, Rhode Island, in February 2003, 96 people died at the scene and 215 people were injured. Forty-seven of the 64 burned patients were evaluated at one burn center and admitted for definitive care.[86] Additionally an explosion at a pharmaceutical plant in North Carolina in January 2003 killed 3 and injured more than 30 to an extent that necessitated admission to a hospital. Ten of the injured patients, all with inhalation injury and 6 with associated mechanical trauma, required admission to the regional burn center.[87]

To deal effectively and efficiently with a mass casualty situation burn treatment facilities must have an operational and tested mass casualty disaster plan and be prepared to provide burn care to a highly variable number of patients injured in either natural or man-made disasters.[88] In reality, mass casualty events are likely to involve some form of burns, particularly in those with explosions. All regions should be prepared for such an event with established plans that are reviewed regularly and drilled.

Outcome Analysis in Burns

The importance of the extent of injury to burn outcomes was recognized by Holmes in 1860, and further evidence was produced to relate either measured area or the specific parts of the body to outcomes in the latter 19th and early 20th centuries.[89,90] Formal expression of burn size as a percentage of total body surface area, however, awaited the work of Berkow in 1924.[91] Although not well known, this single finding in accurately estimating severity of injury made burns the first form of trauma in which the injury was measured and easily communicated. This measurement, then, was the first "trauma score" and made assessing burn size the basis for the accurate prediction of mortality, direct comparison of populations of burned patients, and the measurement of the effects of treatment on outcomes.

The earliest comprehensive statistical technique used for such assessment was univariate probit analysis.[92,93] Before the age of desktop computing, this approach was quite laborious and thus uncommon. An early attempt at multivariate evaluation was made by Schwartz, who used probit plane analysis to estimate the relative contributions of partial- and full-thickness burns to mortality.[94] The advent of computers of suitable power and the further development of statistical techniques has reduced the difficulty of analyzing burn mortality, removed the necessity for arbitrary partitioning, and made these techniques much more accessible.

One of the first comprehensive analyses of this sort was done on a population of 8448 patients admitted for burn care to the U.S. Army ISR between January 1, 1950, and December 31, 1991. To ensure the validity of such studies, an important first step is to achieve uniformity among the population to be analyzed. Variables of interest include time from injury, burn size, and age; these patients were encountered between the day of injury and day 531 after burn (mean 5.86 days, median 1 day), with burns averaging 31% (range 1–100%, median 26%) TBSA. The ages were biphasic, with one peak at 1 year of age and another at age 20; the mean age of the entire population was 26.5 years (range 0–97 years, median 23 years). From this group, 7893 (93.4%) who had flame or scald burns were selected, excluding patients with electrical or chemical injuries. Some of these were from the Vietnam conflict and were first transferred to Japan and then selectively transferred to the Institute; arriving late at the Institute biased this cohort toward survival. To account for this, the analysis focused on the 4870 with flame or scald burns who reached the Institute on or before the second day after burn. Burn size in these patients averaged 34% TBSA (range 1–100%, median 29%), and age was again biphasic, with peaks at 1 and 21 years and a mean of 27.1 years (range 0–93 years, median 24 years).

Between 1950 and 1965, most of the admissions were young soldiers; mean age approximated 22.5 years and was relatively stable. During the succeeding decade, this value rose to an irregular plateau centering on 30 years of age, a

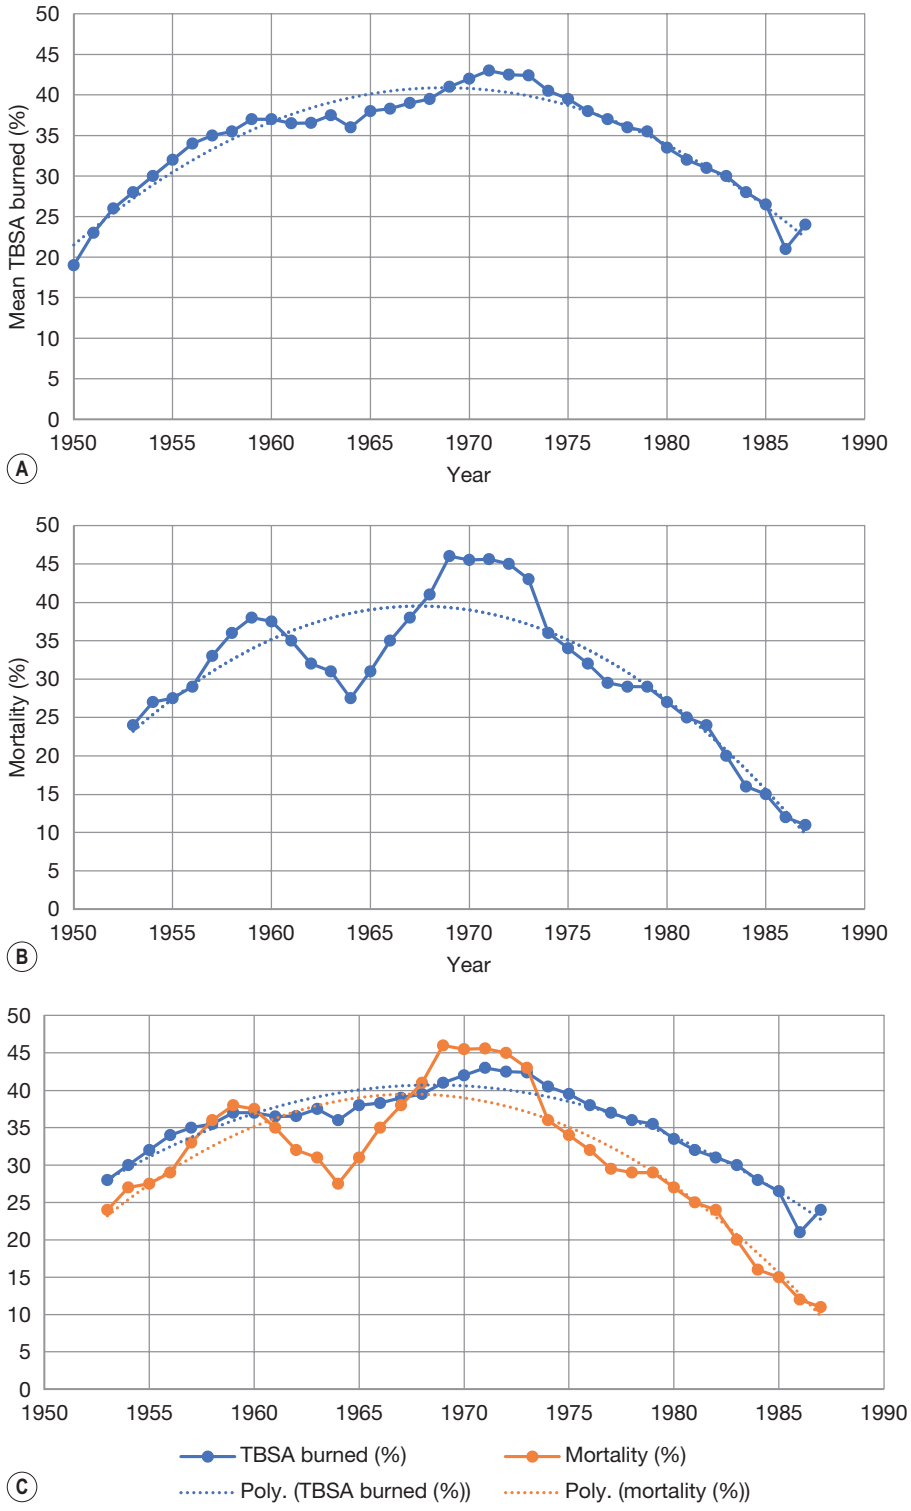

Fig. 3.5 U.S. Army Institute for Surgical Research Burn Incidence and Outcomes Data (1950–1988). Panel A describes the mean burn size encountered among admissions. The figure includes a polynomial trendline. Panel B shows the overall mortality rate and also includes a polynomial trendline. Panel C is a combination of these curves over time and shows both trendlines.

change reflecting a greater number of civilian admissions and increasing age in the military population.

Fig. 3.5A shows the variation in mean burn size during the study interval, and Fig. 3.5B shows the roughly parallel mortality. Mean burn size peaked in the two intervals spanning 1969 to 1974 and decreased steadily after that time. Mortality peaked at 46% during those years. The two datasets are shown together in Fig. 3.5C and suggest a crude index of the results of burn care in this population. When comparing the polynomial lines derived from

the data, it appears that a separation favoring improved survival occurred in about 1970. This was about the time of the development of effective topical antimicrobial chemotherapy.

Raw percent mortality, even in conjunction with burn size, is never an adequate index of the effectiveness of treatment since the frequency of death after burn injury is also determined by prior patient condition, age, inhalation injury, and the occurrence of pneumonia and burn wound sepsis. Each of these elements, except for prior condition, can be addressed in analysis, but only burn size, age, and the presence or absence of inhalation injury are known at the time of admission. Furthermore the definition of significant comorbidities and development of complications are constantly being revised, making addition of these to prediction formulas difficult, and this must be kept in mind by the reader.

For a uniform population of specific age, a plot of the relationship between burn size and percent mortality is S-shaped, or sigmoid: small burns produce relatively few deaths, but, generally, as burn size increases mortality rises steeply and then plateaus as it approaches its maximum of 100%. Of note, in our recent analysis presented early in the chapter (Fig. 3.4), this appears to be more linear as burn size increases when age is not considered. When age is added, children and young adults will fit this more accurately, and older adults will have a more first-order distribution. When these are added, the curve flattens, yielding that is seen in Fig. 3.5. Although this experience conforms with that of most burn centers in the United States, it should be noted that there are still many areas of the world where the survival of patients with burns of more than 40% TBSA is rare.

The U.S. Army Burn Center (at the U.S. Army ISR, Fort Sam Houston, Texas) is the second oldest continuously operating burn center in the United States. Thus data from this burn center provide an invaluable opportunity to understand long-term changes in patient care and their effects on outcome. To further address the changes previously found up to 1991, we analyzed changes in mortality risk occurring over time from 1950 to 2013. In this analysis, only patients admitted to the burn center on the day of burn or 1 or 2 days after burn were included. Furthermore only patients with fire/flame and scald injuries were included; those with electrical, chemical, or other thermal processes and exfoliative dermatitides were excluded. Patients of all ages and burn sizes were included. Mortality was assessed as death at any time during the index hospitalization at the burn center, regardless of cause.

Data were analyzed using binomial logistic regression (backward likelihood-ratio method). In the analysis, age was represented as cubic age function, given by the equation

$$\text{Age Function} = (-5 * \text{AGE} + 14 * \text{AGE}^2/100 - 7 * \text{AGE}^3/10000)/100$$

This permits use of a single term that captures the observation that the relationship between age and outcome is not linear but rather "bathtub-shaped," with a nadir at about 20 years and a leveling off in advanced age.[95] Year of admission was entered into the analysis as a categorical variable, permitting calculation of odds ratios for mortality for each individual year from 1950–2013.

A total of 9755 patients met study inclusion criteria and were analyzed. The mortality rate was 18.1%. The mean age was 31.6 years (standard deviation [SD] 19.8 years). Mean total burn size was 24.4% (SD 23.5%). Odds ratios of mortality as a function of year of admission are shown in Fig. 3.6. The graph is remarkable for two peaks in mortality risk, marked "A" and "B." Peak A, in the late 1950s and early 1960s, represents increased mortality associated with invasive Gram-negative burn wound infections. This peak was followed by a striking decrease in mortality risk in 1964 with the introduction of topical mafenide acetate cream for antimicrobial chemoprophylaxis. Peak B, in 1969–72, reflects the emergence of other virulent Gram-negative organisms less sensitive to mafenide acetate (e.g., *Klebsiella* spp.). With the introduction of silver sulfadiazine cream, first as a single agent and then as an alternating

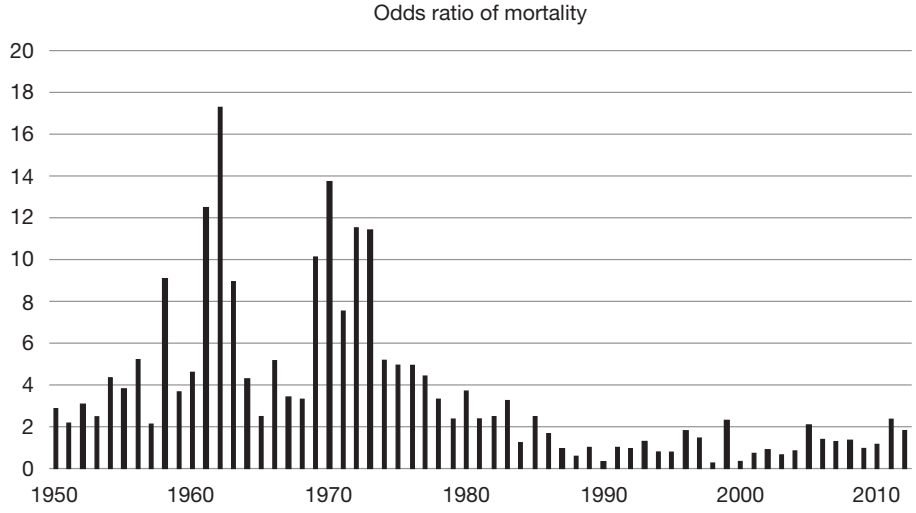

Fig. 3.6 Odds ratio of mortality distributed across a 63-year period from a single center (U.S. Army Institute of Surgical Research). These data show two spikes, in the 1960s and 1970s, that have subsequently significantly diminished in size to reach the current ratios.

agent along with mafenide acetate, a subsequent decline in mortality risk occurred. Further decreases in mortality risk were observed with the introduction and then essentially standardized use of burn wound excision in the late 1970s, enhanced infection control in the early 1980s, and improvements in mechanical ventilation in the early 1990s. The reduction in mortality risk has been maintained over the past two decades.

Conclusion

Much has been accomplished in acute burn care during the past half century, and further improvement in outcome will probably occur as inhalation injury and pneumonia come under better control and new wound coverage techniques are developed, but such improvement will be harder won and smaller in magnitude. Preservation of function, reconstruction, and rehabilitation, areas which have received less attention in the past, appear the more likely primary targets of future burn research and may be expected to materially enhance the quality of life for burn survivors.

4 Prevention of Burn Injuries

AUDRA T. CLARK, STEPHANIE CAMPBELL, and BRETT D. ARNOLDO

Introduction

Prevention is the cure for the epidemic disease of injury.[1] Burns are one of the most devastating of all injuries and a major global public health issue. Treatment of burn injuries has historically received more focus than burn prevention, but this perspective is starting to shift. Burn centers and other partners in burn prevention efforts face a number of challenges including scarce resources, legislative delays, and the need to develop high-quality research methodology to further define the ideal ways to educate and promote safety. Despite these challenges, the potential impact of burn injury prevention efforts is now being recognized and examined on a larger scale.

Injury Prevention Models

The science of injury prevention emerged in the middle of the 20th century. Injuries became recognized as avoidable events resulting from a combination of adverse environmental conditions, equipment, behavior, and personal risk factors, rather than unpredictable accidents.[2] William Haddon developed a system, known as the Haddon Matrix, to apply the principles of public health to the problem of road traffic safety.[3] Since its introduction, it has been used as a means of developing ideas to prevent injury of all types. The matrix enables analysis of the contributing factors of the injury in relationship to the phases of the injury event. The contributing factors studied are:

a. The host or injured person,
b. The agent or vehicle,
c. The physical environment,
d. The social environment.

The identified phases of an injury event are:

a. Pre-event: preventing the causative agent from reaching the susceptible host.
b. Event: includes transfer of the energy to the victim. Prevention efforts in this phase operate to reduce or completely prevent the injury.
c. Post-event: determines the outcome once the injury has occurred. This includes anything that limits ongoing damage or repairs the damage. This phase determines the ultimate outcome.[4]

The resulting matrix provides a tool to identify strategies and priorities for injury prevention, areas of needed research, and how to best allocate resources (Table 4.1). Haddon further described 10 general strategies for injury prevention and control (Box 4.1). Both of these models can and should be applied to burn prevention because they highlight that society is capable of reducing injury and can do so at more than one stage of an injury event.

Public health is the effort organized by society to protect, promote, and restore the people's health. The public health model of injury prevention and control is divided into:

- surveillance,
- interdisciplinary education and prevention programs,
- environmental modifications,
- regulatory action, and
- support of clinical interventions.[2]

Prevention strategies are commonly described as either passive or active. Passive or environmental intervention is a strategy that provides protection against injury and requires little to no cooperation or action from the individual at risk.[2] Examples of passive burn prevention strategies include building codes requiring smoke alarms, sprinkler installation, and factory-adjusted water heater temperature. Active prevention measures are voluntary, and they emphasize education to encourage people to modify unsafe behavior. Examples are home fire drill plans and wearing goggles and gloves when handling toxic chemicals. Passive prevention is more effective because active prevention can be a very difficult strategy to maintain, especially over a long period of time[5] (Fig. 4.1).

Identified prevention strategies can also be classified as primary, secondary, and tertiary, and these are similar to the Haddon Matrix phases of injury. Primary prevention is preventing the event from ever occurring. Secondary prevention includes reducing the severity of injury via acute care of the injury. Tertiary prevention concentrates on preventing or reducing disability.[6]

Burn Intervention Strategy

Prevention science has turned attention away from individual blame and the attitude that injuries are random "accidents" and toward the view that sociopolitical involvement is necessary.[7] All burn injuries should be viewed as preventable. Prevention programs should target high-risk groups and also be implemented with patience, persistence, and precision.[5] The current approaches to burn prevention will be discussed in the framework of the five E's of Injury Prevention: Epidemiology, Engineering, Enforcement, Education, and Evaluation (Fig. 4.2).[8]

- Epidemiology: identify the demographics and situations involved with burn injuries.
- Engineering: focuses on modification of the physical environment. Examples include fire-resistant

Table 4.1 The Haddon Matrix for Burn Control

Agent or Vector	Host	Environment	Physical	Social
Pre-event	Fire-safe cigarette	Control seizure	Nonslip tub surface	Legislation—factory preset water heater thermostats
Event	Sprinklers, smoke detectors	Flame-retardant cloths	Fire escapes	Fire drill education
Post-event	Water	First aid antibiotics	EMS	Emergency and rehabilitation services

Matrix adapted from Haddon W. Advances in the epidemiology of injuries as a basis for public policy. *Public Health Rep.* 1980;95:411–421.

Box 4.1 General Strategies for Burn Control

Prevent creation of the hazard (stop producing firecrackers)
Reduce amount of hazard (reduce chemical concentration in commercial products)
Prevent release of the hazard (child-resistant butane lighters)
Modify rate or spatial distribution of the hazard (vapor-ignition-resistant water heaters)
Separate release of the hazard in time or space (small spouts for hot water faucet)
Place barrier between the hazard and the host (install fence around electrical transformers, fire screen)
Modify nature of the hazard (use low conductors of heat)
Increase resistance of host to hazard (treat seizure disorder)
Begin to counter damage already done by hazard (first aid, rapid transport, and resuscitation)
Stabilization, repair/rehabilitation of host (provide acute care; burn center and rehabilitation)

upholstery and bedding, child-resistant multipurpose lighters, and insulated electric wire.
- Enforcement: influences behavior with laws, building codes, and regulations. Examples include requiring fire escapes and sprinklers/smoke alarms in motels, hotels, and homes.
- Education: influences behavior through knowledge and reasoning. Examples include fire safety education programs, public television programs.
- Evaluation: assessment of the impact of a prevention strategy and areas of success or reasons for failure.

Epidemiology

Prevention program planning begins with an assessment identifying the scope of the problem, the mechanisms of injury, and the populations at risk. With this information strategic designing and implementation can be directed at reducing the risk of injury or death. Epidemiologic data specific to burn injuries are accessible through multiple sources including the National Burn Repository, state and local health departments, and reports from the National Fire Protection Association (NFPA).[9]

OVERVIEW OF BURN INJURIES IN THE UNITED STATES

In the United States in 2014, the leading causes of injury deaths, in order of magnitude, were motor vehicle collisions, falls, drowning, and fire/burns.[10] This same year, fire departments responded to an estimated 1,298,000 fires, which is an increase of 4.7% from the previous year.[11] The American Burn Association estimates that, in 2016, there were 486,000 burn injuries that received medical treatment and 3275 fatalities due to fire or smoke inhalation. This represents a death due to fire every 2 hours and 41 minutes.[12] Approximately 40,000 people were hospitalized because of a burn injury. More than 60% of the acute hospitalizations for burn injury were admitted to the 128 burn centers in the United States. These centers average more than 200 admissions annually, while the other 4500 U.S. acute care hospitals average less than three burn admissions per year. In addition to the human cost, fires in 2014 in the United States resulted in $11.6 billion in property loss.[11]

COMMON MECHANISMS OF INJURY

The most common mechanisms of burns leading to admission to a burn center in 2015 were fire/flame (43%), scald (34%), contact (9%), electrical (4%), and chemical (3%). The most common places of these injuries were in the home (73%), at work (8%), on the street/highway (5%), and in recreational areas (5%).[12] The most common fire incident that firefighters were called for was outside fires, followed by structure fires and vehicle fires.[12]

House fires are by far the leading cause of fire deaths. In 2014, residential fires represented 83% of fatalities. The leading cause of home fires from 2007 to 2011 was cooking equipment, whereas the largest share of home fire deaths was caused by smoking materials.[13] Heating equipment was the second leading cause of home fires, deaths, and injuries. Sixty-four percent of the people killed and 51% of people injured in home fires were somehow involved in the ignition, such as leaving cooking unattended or a space heater or candle close to something flammable. About one-third (36%) of home fire deaths occurred while the victim was trying to escape and another third (34%) while the victim was sleeping. Only 3% of fire fatalities occurred while the person was engaged in fire control, but 35% of nonfatal injuries were sustained trying to control the fire. Smoke inhalation causes a larger share of deaths and injuries than do burns. From 2007 to 2011, 48% of fire deaths were due to smoke inhalation alone, 24% were due to both burns and smoke inhalation, and 28% were due to burns alone.[13]

HIGH-RISK POPULATIONS

Identifying susceptible population groups and significant risk factors is crucial in planning prevention strategies.[14] Studies conducted in both industrialized and developing nations have found similar risk factors including the extremes of age, low income, lack of education, unemployment, large families, single parents, illiteracy, low maternal education, substandard living conditions, not owning a home, not having a telephone, and overcrowding.[15–17] Prevention should aim at modifying these risk factors and targeting these vulnerable populations.[5,15,16,18,19]

In regards to age as a risk factor, infants and toddlers under the age of 4 years suffer a disproportionally higher number of burns.[18,20–22] The 2015 National Burn Repository Annual Report reveals that the most frequent cause of burn injuries in children under 5 is scalding.[23] In the United States, fires and burns were the third leading cause of unintentional injury death in 2006 for kids 1–9 years of age.[6] The incidence of burns decreases at the age of 4 years and starts to increase again after the age of 15, a phenomenon thought to be due to more exposure to hazards, risk-taking and experimentation, and initiation of employment during adolescence.[24] Children are also at risk for intentional burn injuries, which account for an estimated 10% of all abuse cases.[25] These victims are typically less than 2 years of age, and the most frequent mechanism of nonaccidental burn is a scald from immersion into hot water.

People over the age of 60 also represent a disproportionally higher percentage of hospitalizations due to burns.[26,27] This is attributed to slowed behavioral responses, mental and physical disabilities, isolation, and difficulty in accessing help. From 2007 to 2011, adults older than 65 were more than 2.4 times as likely as the general population to die in fires. For adults over 85, this increased to 3.6 times as likely.[13] A review from a U.S. burn center between 1990 and 1994 found that the most common cause of death for elderly women with burns was from cooking-relating injuries resulting in ignition of clothing.[28]

The risk of home fire death or injury in the United States also varies by race and socioeconomic status. African Americans were approximately twice as likely to be killed or injured in home fires as the overall population. The home fire death rate for African-American children under 15 years was four times higher than the rate for white children of the same age. This disturbing pattern also holds true for older African Americans over the age of 65 who had a home fire death rate three times as high as their white counterparts.[13]

Differences in fire incidence can also be seen regionally in the United States. The Northeast and the Midwest had the highest fire incident rate per thousand people at 4.6 and 4.4, respectively. The Midwest had the highest civilian death rate per million population at 12.5. Smaller communities have more fire incidents and deaths per capital, perhaps due to more limited access to fire departments and burn care centers. Communities of fewer than 2500 people had a fire rate of 10.3 events per thousand population and 19.8 deaths per million population, while communities with 10,000 or more had a rate of about 3 events per thousand population and about 8 deaths per million population.[11]

Continued epidemiological assessment of burn injuries at the national level is critical for purposes such as planning federal legislation efforts, providing statistics for public awareness campaigns, and helping learners understand the scope of the problem when providing burn prevention education. Knowledge of the state of burn injuries nationwide also provides a baseline for epidemiologic assessment at the local level. Burn centers and other safety advocates passionate about burn prevention often start local programs with limited time, staff, and funds. To maximize resources, careful planning begins with first identifying a burn injury, population, and mechanism of injury to be the focus of the local prevention strategy. Local epidemiologic data can be obtained through a burn center's registry program. Some local statistics may also be obtained through the state or city fire marshal's office.

Computerized mapping systems, or geographic information systems (GIS), have emerged over the past two decades as a potentially powerful epidemiological assessment tool for injury prevention. Using GIS, data can be geocoded by location and analyzed for spatial relationships between factors such as socioeconomic status, race, and injury rates.[29] In 2003, Williams et al. identified zip codes in St. Louis that had the highest frequencies of pediatric burn injuries and then used GIS to pinpoint specific block areas that were at the highest risk.[30] More recently, researchers from the University of Louisville School of Nursing and the Department of Geography and Geosciences partnered up to create a fire risk model using GIS. Primary maps of data for seven identified risk factors were combined using an overlaying technique to create a summation map (Fig. 4.3). A fire incidence map was also created (Fig. 4.4). Analysis showed a strong positive correlation between the high-risk

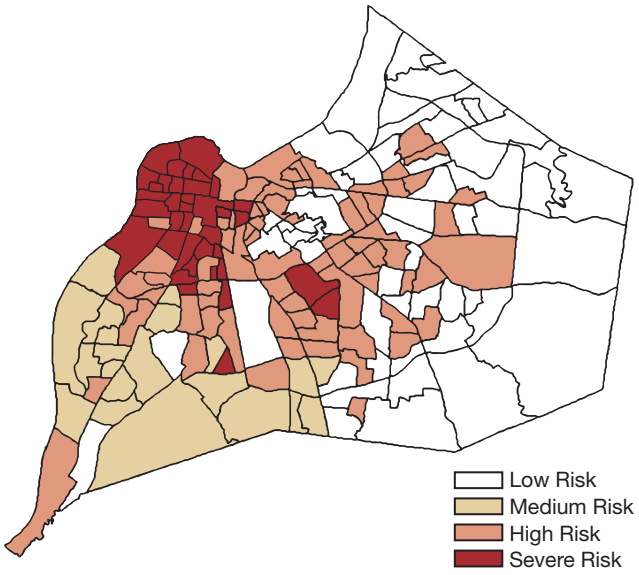

Fig. 4.3 The summed risk scores were separated into risk categories ranging from low to severe risk. The map shows each census tract's risk category based on a color gradient, where darker shading represents higher risk. (From Lehna C, Speller A, Hanchette C, Fahey E, Coty M-B. Development of a fire risk model to identify areas of increased potential for fire occurrences. *J Burn Care Res*. 2016;37(1):12–19.)

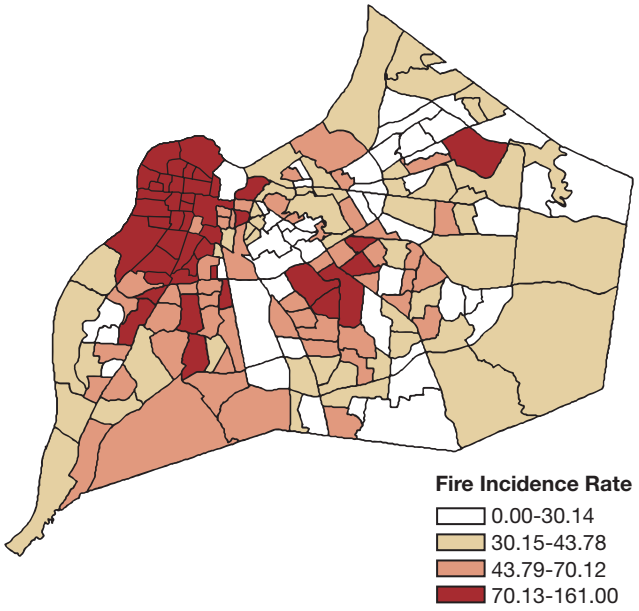

Fig. 4.4 The fire incidence rate for each census tract is shown with darker shading representing higher fire incidence rates. (From Lehna C, Speller A, Hanchette C, Fahey E, Coty M-B. Development of a fire risk model to identify areas of increased potential for fire occurrences. *J Burn Care Res*. 2016;37(1):12–19.)

areas on both the risk factor and fire incidence maps and identified census tracts that were potentially at the highest risk of experiencing fires (Fig. 4.5).[31] Prevention strategies can then be designed to target etiologies and population characteristics or behaviors that are specific to those areas. The use of GIS is an exciting example of how thoughtful epidemiological assessment could lead to the focused use of limited resources with the potential to have the greatest impact.[29]

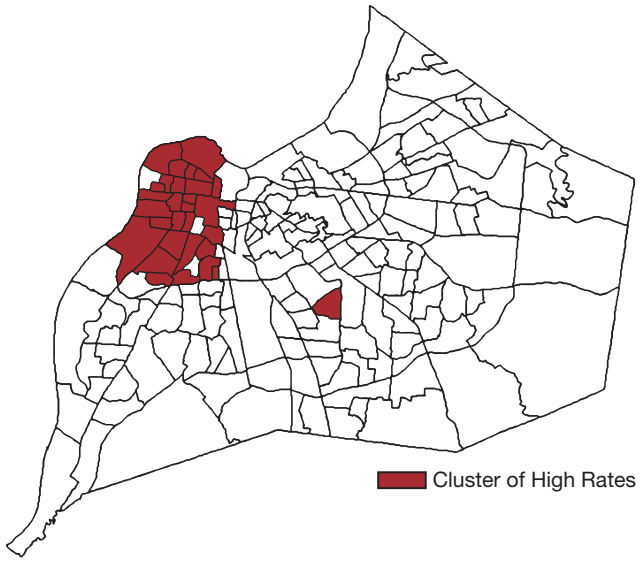

Fig. 4.5 Clusters of significantly high fire incidence rates are shown in shading. (From Lehna C, Speller A, Hanchette C, Fahey E, Coty M-B. Development of a fire risk model to identify areas of increased potential for fire occurrences. *J Burn Care Res*. 2016;37(1):12–19.)

Engineering and Enforcement

In several areas of burn prevention efforts, the manipulation of products or the physical environment (engineering) is closely linked with legislative efforts (enforcement). Engineering and enforcement strategies often require more resources and government involvement, but they are thought to be more effective than passive effort.[5] Smoke alarms, fire sprinklers, fabric flammability standards, fire-safe cigarettes, and water temperature controls are historical examples that may provide insight as the burn community examines where to focus resources in the future.

SMOKE ALARMS

Smoke alarms act as an early warning of fire, alerting residents of the need to exit a house or building. Fatalities from house fires decreased by almost half after the rise in popularity of smoke detectors in the 1980s and 1990s. This decline in home fire deaths is largely attributed to the widespread adoption of smoke alarms, although other notable changes during this time period included child-resistant lighters and flame-resistant upholsteries.[32] It has been reported that 96% to 97% of households now have at least one smoke alarm installed, leaving an estimated 5 million homes still unprotected. Households with no smoke alarms are twice as likely to experience a home fire fatality than are those with a working smoke alarm.[33] Most states have laws requiring smoke alarm installation for specific conditions such as new buildings, tenant buildings, and multiple family dwellings.[32] Some community-based efforts at providing and installing smoke alarms have been successful in reducing the risk of fire-related deaths and injury.

Operation Installation (OI), a Dallas-based community smoke alarm program, is an excellent example of how a partnership between community organizations can reduce risk of harm and death from fires. The program was designed, implemented, and evaluated through a collaboration of the Injury Prevention Center of Greater Dallas, the Dallas Fire Rescue Department, and the Dallas chapter of the American Red Cross. From 2001 to 2011, OI installed lithium-powered smoke alarms in 8134 homes located in high-risk areas. The incidence of house fire-related deaths and injuries in the program houses was then compared to the 24,346 nonprogram houses in the same census tracts, with an average of 5.2 years of follow-up. The adjusted analysis revealed that the incidence of house fire-related deaths and injuries in the OI houses was 68% lower.[34] This risk of fire-related injury or death in the OI houses was shown to begin increasing again at around 5 years after installation.[34] Ten years after installation, OI performed an evaluation on 198 smoke alarms and found that although 108 were still present, only 44 were still functioning. Most of the nonfunctioning smoke alarms had the battery removed or had been disconnected, revealing a potential area for targeted education and an indication that tamperproof smoke alarms could be useful.[35]

FIRE SPRINKLERS

Fire sprinklers are highly effective at reducing property damage and deaths from fires when present and working. From 2007 to 2011, only 10% of structure fires reported that fire sprinklers were present. Although most fire deaths and burn injuries occur in the home, only 6% of the structure fires with sprinklers present were houses. Having fire sprinklers installed in the home was shown to reduce the death rate per fire by 82%.[36] Despite this significant reduction in harm, only California and Maryland have currently passed statewide legislation requiring residential fire sprinklers in all new-construction one- and two-family homes. An example of using economic incentive as a complementary burn and fire prevention strategy is the reduction in home owner's insurance offered to some policy holders who install fire sprinklers in their home. One review concluded that the average discount in the United States for this safety feature is 7%.[37] While laws exist requiring the installation of automatic fire sprinklers in new nonresidential buildings, retrofitting older high-rise buildings is costly and not currently mandatory. In September 2015, the Fire Sprinkler Incentive Act was introduced into Congress. This legislation would strengthen the tax incentives for building owners by allowing 100% expensing of the cost of the automatic fire sprinkler system and a 15-year depreciation recovery.[38]

FABRIC FLAMMABILITY

Inspired by a series of injuries and deaths related to rayon-pile fabrics, the U.S. government formally recognized the risks of flammable clothing with the passage of the Flammability Fabrics Act in 1953.[39] This was the beginning of a passive prevention strategy to prevent burn injuries and deaths from clothing catching on fire. Although flammability standards were developed and standardized, there has been little evolution of these standards over the years. Between 1997 and 2006, there were still an average of 4300 burn injuries annually related to the ignition of clothing, and almost all of the garments involved were within the minimum clothing flammability standards. Despite the expansion of the initial legislation beyond clothing to other textiles (e.g., carpets, mattresses, upholstered furniture, tents, curtains, sleeping bags), it is estimated that 50% of fire deaths in the United States involved the ignition of materials included in the Flammable Fabrics Act.[40] The only notable evolution of these early efforts has occurred with children's sleepwear. In the 1970s, regulations were introduced that required children's clothing from size 0 to 14 be able to self-extinguish. The introduction of flame-resistant sleepwear demonstrated a significant decrease in the incidence of burn injuries and deaths related to children's pajamas in the 1970s and 1980s. It is believed that parents began to substitute other clothing as sleepwear due to limited flame-resistant pajama choices and also a desire for nontreated cotton fabrics. In 1996, restrictions were relaxed to allow exemptions for sleepwear for children 9 months and under and also for any tight-fitting sleepwear of any size. It is thought that tight-fitting clothing decreases the risk of the garment coming into contact with an ignition source and may also slow the burn of the material due to less oxygen between the clothing and the skin.[39] There have been no other major legislative or industry-driven efforts to improve the safety of fabrics offered to consumers, place additional warning labels, or educate the public regarding the flammability of fabrics. This is concerning because the number of clothing-related injuries and deaths has remained steady for decades. With 74% of burn injuries from clothing ignition related to daywear garments, and 75% of deaths in those 65 years and older, there is clear potential for growth in the area of both passive and active prevention strategies in this area.[40] Public understanding of the risks of flammable clothing and knowledge of current regulations is thought to be low.[41]

FIRE-SAFE CIGARETTES

Home fires originating from smoking materials comprise only 5% of all fires reported annually in the United States but are the leading cause of fire fatalities in the home.[42,43] An estimated two-thirds of deaths related to smoking involved the ignition of furniture upholstery or mattresses and bedding.[43] The idea of "fire-safe" or reduced ignition propensity (RIP) cigarettes was first proposed in the 1920s as a way to reduce the number of forest fires and was later recognized as a potential way to reduce the number of burn injuries and deaths related to smoking materials.[44] Design factors such as the circumference of the cigarette, type of paper used, and presence of a filter or accelerant can all influence the rate of burn. Assisted by legislative efforts addressing production and testing in the 1980s and 1990s, it was shown that slow-burning or self-extinguishing cigarettes could be produced without a large economic impact on manufacturers or a change in taste for consumers.[44] After years of failed bills attempting to require tobacco companies to produce safer cigarettes and a decade of stalled efforts to standardize testing for RIP cigarettes, legislation finally began to gain traction in 2003. By 2011, all 50

states had passed laws making RIP cigarettes mandatory (a cigarette must burn out 75% of the time when not in active use). In 2013, the National Fire Protection Agency released a report crediting this legislative effort with an astounding 30% reduction in smoking-material fire deaths from 2003 to 2011.[43] Although the long-term decrease in smoking-related fires seen over the past few decades is likely related to fewer people smoking, the decline in the smoking rate during the 2003 to 2011 time period was only 4%, leading researchers to believe that fire-safe cigarettes can be credited for this decrease in incidence.[43] Although the engineering to produce safer cigarettes was identified years ago, implementation did not happen until legislative enforcement occurred.

WATER TEMPERATURE REGULATIONS

According to the 2015 National Burn Repository Annual Report, 34% of burn admissions reported from 2005 to 2014 were scald injuries.[23] Most scald injuries are related to cooking or hot liquids in the kitchen, mechanisms that are often related to behavior and can be difficult to prevent with engineering or enforcement strategies. Estimates for the amount of burn injuries related to hot water from a tap vary from 12% to 25%.[45] There is an opportunity to prevent scald burns related to tap water with passive engineering and enforcement strategies. An animal study was performed to identify how long exposure to water at different temperatures took to result in a partial-thickness burn. If the temperature of the water was 140°F (60°C), it took only 3 seconds of exposure to result in a burn. When the water was decreased to 120°F (49°C), it took 10 minutes to cause significant thermal injury to the skin.[46] Historical efforts to reduce water temperature in facilities and homes include regulating the temperature setting of hot water heaters and requiring the instillation of antiscald devices at taps.[47] It was demonstrated in Washington state in the 1980s that requiring newly installed home hot water heaters to be set at 120°F significantly lowered the mean household water temperature and reduced the incidence of tap water injuries.[48] Despite evidence that this strategy can be effective, no nationally recognized and enforced standard exists today. Almost all U.S. states have legislation related to water temperature, but many do not regulate water temperature in the home. Types of facilities that are often subject to state regulations commonly include schools, child care facilities, and nursing care facilities. Although some plumbing codes at the city or state levels also address water temperature, these also vary widely in source, regulation, and enforcement.[47]

FIREWORKS REGULATION

Injuries from fireworks are a problem in several countries because they are commonly used during national holidays and traditional festivals.[49] In the United States, the Fourth of July has more fires reported than on any other day of the year.[50] Fireworks often result in hand burns, but flame burns also occur when clothes catch fire. In an attempt to decrease fireworks-related injuries, the United States prohibits the sale of certain types of fireworks including reloadable shells, cherry bombs, M-80 salutes, firecrackers containing more than 2 g of powder, and firework building kits.[45] The impact of legislation suggests a reduction in the number of fireworks-related injuries. In the United Kingdom, the number of firework injuries fell from 707 in 2001 to 494 in 2005, presumably due to the creation of firework legislation during that time.[51] After the repeal of a law banning private consumer fireworks in Minnesota in 2002, there was a 100% increase in the number of annual fireworks-related injuries.[52]

Education

Education is an active prevention process that requires behavior modification from the targeted population. Public education programs aimed at reducing the incidence and severity of burn injuries in the United States can be implemented at the local, state, regional, or national level. At the national level, the American Burn Association (ABA) sponsors Burn Awareness Week annually, a public campaign to promote safe practices and prevent burn injuries. The ABA Burn Prevention Committee also recently partnered with Safe Kids Worldwide, the International Association of Fire Fighters Charitable Foundation Burn Fund, the Federation of Burn Foundations, and the International Association of Fire Chiefs to create the National Scald Prevention Campaign. The website flashsplash.org provides scald prevention resources for burn centers, the public, and the media. Many burn centers used these resources for local prevention activities during Burn Awareness Week 2016.[53] The National Fire Protection Association also sponsors a Fire Prevention Week with a special emphasis on one area of prevention each year. Social media is also a rapidly evolving and widely accessible platform that may present novel ways for burn prevention education. In 2013, there were 21 videos on YouTube with technically accurate information regarding prevention and first aid for pediatric burns.[54] Use of the Internet and social media is a potentially effective and easy to way to disseminate information and raise public awareness regarding burn prevention and treatment, although validation of the material by qualified providers will be a challenge.

Many burn centers are providing general burn prevention education to the community through health fairs, public gatherings, and community classes. Some centers have assessed their community, identified specific educational gaps, and chosen to provide focused education to a target population.

In New York City, researchers noted that burns were the third leading cause of injury-related death among seniors 65 years and older. When surveyed, less than 20% of local seniors had received any fire safety education within the last 5 years. A community-based initiative was designed to reach older adults at recreational centers in this area. After reviewing the common etiologies for this age group, a presentation that focused on fire safety and the prevention of scald burns was designed. Over the course of several months, the presentation was given at 64 senior centers to 2196 older adults. Almost three-quarters of seniors who participated in and evaluated the program reported that they had learned something new about fire and burn safety. Eighty-five percent of respondents also reported a high

likelihood of incorporating the new knowledge into their daily lives.[55]

Firefighters have also recently been the target of an active prevention strategy. Thousands of firefighters suffer smoke inhalation or burn injuries, with an average of 100 fatalities each year.[56] A national program, It Happened in Seconds, was developed by a multidisciplinary team of burn professionals and firefighters to provide better situational awareness, instruction on the appropriate use of personal protective gear, and other strategies for burn prevention while working. The program was first taught to a group of core trainers representing different regions across the United States. As a result, more than 9000 firefighters had been through the course as of 2015. The impact of this program on local and national rates of firefighter burn injuries and death will be monitored.[56]

In another example of targeted education in burn prevention, a burn center identified that Amish children were at particularly high risk for scald burns and injuries related to the ignition of clothing or highly flammable materials. A lack of fire and burn education in Amish schools was also noted. A tool designed to improve burn prevention knowledge in Amish children, a storyboard with magnets, was created in collaboration with an Amish community and pilot tested. A subsequent multicenter pre- and post-testing of 15 Amish schools across eight states demonstrated that the tool was highly successful in increasing burn prevention knowledge in Amish children in grades 1 through 8.[57]

Another education strategy that should not be overlooked is the use of burn center staff to teach burn prevention education not only to patients and their families, but also to the community at large when participating in outreach events or engaging on social media. It is reasonable for burn center staff members to incorporate prevention teaching into their daily practice when caring for patients, although it is possible that many frontline staff have never received formal injury prevention training.[1] A multicenter assessment of the fire safety and burn prevention knowledge of multidisciplinary burn team members was recently performed and analyzed. While many of the respondents reported confidence in their level of prevention knowledge, the average score on the assessment was only 61.5%, indicating the need to provide more accurate information to burn center staff.[1] It is recommended that burn prevention programs should be supported by the burn center team and not solely the responsibility of a designated educator. Hospitals should consider prevention education for burn center staff to prepare them to provide updated information on the major fire safety and burn prevention topics in a variety of situations. The ABA Burn Prevention Committee provides several ways to increase fire safety and burn prevention knowledge, including a newsletter, prevention tip sheets, and other resources on the ABA website, and prevention-focused sessions at the ABA Annual Meeting.[1]

Evaluation

The evaluation of prevention programs is critical in the shift from anecdotal practices to evidence-based strategies. Evaluation should be viewed as a continuous component of any prevention program, rather than a rigid process used only after program implementation. Evaluation of epidemiologic data provides the focus for prevention programs. Once the target etiology and population is identified, potential strategies for reducing the incidence of injury must then be examined. As discussed previously, Haddon's Matrix can be used to organize strategies by injury factors into pre-event, event, and post-event. Each area then becomes a potential target for prevention intervention, and practical strategies to impact each area should be considered. Each strategy can then be assessed for feasibility and sustainability. When designing the program, it is essential to create measurable objectives to be evaluated after implementation.[58] Although historically scientific evaluations of burn prevention efforts were not prevalent in the literature, recent reviews suggest this is beginning to change. Determining if prevention strategies are reducing the incidence of burn injuries can be challenging, especially at the local level. It is important to remember that decreasing incidence is not the only metric available for analysis. Intermediate outcomes, such as an increase in knowledge or a change in behavior, may also be evaluated.[8] While it might take years to analyze the impact of a scald prevention campaign on the incidence of scald injuries in a community, an increase in behaviors known to prevent scald burns, such as using the back burners of the stove and turning the pot handles when cooking with children present, could be more quickly and easily evaluated. An increase in knowledge regarding scald prevention could be evaluated with a pre- and post-test. It should be noted that an increase in burn prevention knowledge has not always correlated with a behavior change or decrease in burn incidence.[5]

Global Burn Prevention

Although the focus of this chapter was primarily the United States, the global incidence of fire and burn injuries in comparison is noteworthy. Worldwide in 2004, it was estimated that approximately 11 million people sought care for burn injury, which exceeds the combined incidence of HIV and tuberculosis. Approximately 90% of burns injuries as well as burn deaths occur in low- to middle-income countries, with the highest prevalence in the Western Pacific, Eastern Mediterranean, and Southeast Asia regions.[18] These impoverished areas often suffer from substandard living conditions, overcrowding, and illiteracy, which have been shown to be risk factors for burns. They also often lack the needed infrastructure to reduce the incidence and minimize the damage of burns. Access to burn care is also often very limited.[15,16,59] It costs about U.S.$1,000 per patient per day to provide adequate burn care in the developed world, which is clearly not possible for most developing nations.[60,61]

The common mechanisms of burns are also often different between the developed and developing worlds. In the developing world, the use of kerosene lamps and stoves is much more common and will likely continue for years to come. There is slow progress in providing electricity to homes in low-income countries, but millions of people still depend on kerosene for heat, light, and cooking.[62] A review of 11,196 burn admissions in New Delhi, India, in 2002

found that more than 80% of burns were due to flames, and 35% of these were attributed to malfunctioning kerosene stoves.[59] A similar study in Sri Lanka found that 41% of accidental burns requiring medical attention were due to flame from a kerosene bottle lamp.[63] Three approaches to prevention of kerosene lamp and stove burns have been discussed and include educational campaigns teaching safe use, use of safer oil, and the provision of an inexpensive and safer lamp to families. A kerosene educational program in low-income South Africa resulted in a significant increase in self-reported knowledge and safety practices, but there are no data showing if this affected kerosene burn injury incidence.[62] The use of safer oil, such as coconut and sesame oil, has not been adopted because these alternatives are too heavy to rise to the top of wicks and do not provide as much heat and light. There is an ongoing program in Sri Lanka to provide safe and inexpensive kerosene lamps to poor families. The lamp was designed by a surgeon in the region in 1992. He designed it to be compact and heavy to avoid tipping over, with two flat sides to prevent rolling if it does tip over. It also has a screw top lid to prevent fuel spillage and much stronger glass. More than 775,000 "safe bottle lamps" were distributed in Sri Lanka as of 2010, and this has been credited in the media with a significant reduction in burn injuries and fires, although no formalized data have been collection.[60]

The proportionally high incidence of burns in the developing world highlights the importance of primary burn prevention efforts in these regions.[64] The World Health Organization has developed a Burn Plan that is organized into seven main components corresponding to the challenges in global burn prevention and care (advocacy, policy, data and measurement, research, prevention, services, capacity building). Accurate data on the incidence and causes of burn injuries are scarce for many developing countries, and incomplete reporting of burn events results in an underestimate of the extent of this public health issue. This understandably makes the development and enactment of effective burn prevention strategies very difficult, but very essential.

Future

The relatively small size of the burn community and the sometimes large geographic distance between neighboring burn centers can make it challenging for burn center staff to share prevention ideas and resources. An emerging theme in injury prevention literature is an emphasis on partnerships within a community. It is acknowledged that fire prevention and burn prevention efforts are often closely linked. Burn centers participating in prevention strategies can partner with local fire departments for joint projects and assist each other with efforts toward a common goal: reducing injuries and deaths from fire and flame. Other potential partners for burn center prevention programs include local and national safety associations and child advocacy organizations. Although difficult to evaluate, it has been noted that characteristics such as inclusivity, enthusiasm, and cultural competence among prevention program leaders can increase the success of the program.[65]

Burn injuries and deaths are a world health problem that represents a major global challenge. Coordination of prevention strategies on both national and international levels is necessary. Passive prevention programs are most effective but can be slow to implement and heavy on resources. Active prevention can be tedious and requires significant organizational support. Both measures should be utilized and are not mutually exclusive. Evaluation of the success of prevention efforts is also of utmost importance, although this can be quite difficult. Despite the many challenges, burns should be viewed as preventable, and efforts to decrease their incidence and severity should be continued at all levels. Prevention is an area of focus where creative and enthusiastic leaders have the opportunity to grow this movement by implementing innovative strategies, designing thoughtful evaluations, and sharing the results to move the science of burn injury prevention forward.

Introduction

Mass casualty events and disasters are marked by a period of mismatch (disproportion) between supply and demand. Rescue organizations must work to reduce the duration of this period of mismatch. During the acute phase, actions follow the principles of *disaster medicine*: The goal is to save as many lives as possible even if it means postponing care for an individual patient. After the mismatch between supply and demand has been addressed, the principles of *individual medicine* can be restored. One goal in mass casualty care is to minimize the period of time it takes to restore care to the individual medicine paradigm. This period's length depends on such structural aspects as the existence and validity of a disaster plan, a regard for disaster capacity in health planning, and the educational level of medical services. These facts are often neglected in disaster planning, from the political aspect of planning and from the practical aspect of disaster capacity.

Ideally, treatment should be based on the state of the art in medical science. During a disaster, treatment with the "best available means" may weaken the quality of care for individuals. Therefore, in mass casualties and disasters, the infrastructure of a country or region may be unable to cope with a higher number of victims of special trauma types while maintaining the state of the art. When it is predictable that the state of the art cannot be maintained in a jurisdiction because of dwindling resources, help from other jurisdictions must be planned and coordinated—the time for international cooperation has come! Such instances include mass casualties with burn injuries. Resources available for specialized treatment are limited, but the demands of state-of-the-art treatment are high, meaning that even a small number of victims from one accident can push an area's or country's burn treatment system to its limits.

The purpose of this chapter is to introduce concepts of disaster medicine as applied to burn patients. A glossary of disaster medicine terms is provided. Examples of major burn disasters and the lessons learned are described. Phases in the typical response to a disaster are summarized. Special aspects of emergency care during a disaster are discussed. The role of communication in disaster response is detailed. The strategic approach to matching burn resources and patients is considered. Finally, the special case of humanitarian crisis response is discussed. Every disaster we have studied is somewhat different. There is, however, a common theme running through all of them: Prior planning and realistic training are essential to success.

Definitions

A shared language is critical for the process of planning for and responding to a disaster. The following provides a basic vocabulary for burn mass casualty and disaster response.

Mass casualty event: an emergency in which there is a greater number of victims than can be accommodated by the rescue forces and their supplies.[1] Infrastructure in the affected area is intact. With force mobilization, the crisis can be mastered. The period of mismatch between supply and demand is short. The goal is to reestablish treatment according to principles of individual medicine as quickly as possible and without transferring the supply–demand mismatch from the scene to hospitals. The challenge to save as many lives as possible, even disregarding the medical needs of an individual, stands in contrast to the paradigms of individual medicine in which any individual life claims the maximum medical effort. The procedure for this challenge is selection of patients—triage, based on urgency of medical procedures, chance of success, and distribution among the available qualified treatment centers (see later discussion).

Disaster: an event in which infrastructure is at least partly destroyed or degraded and that cannot be handled by regional rescue means alone. The first goal is to reestablish the minimal level of infrastructure required to provide basic medical care. (This is different from mass burns treatment in a resource-poor country, where infrastructure never existed.) One way to treat burns successfully in a disaster is to bring infrastructure, staff, and materials to the area to treat burns. Another is to move victims to a place with existing infrastructure. The maximum treatment possible locally is determined by the degree of infrastructure and resources in, or brought to, the disaster area.

Although mass casualty events remain in the purview of local rescue organizations, disasters are for regional or national authorities. This means different ways of handling the situation and different funding resources.

Mass burn casualty disaster: defined by the American Burn Association (ABA) as "any catastrophic event in

which the number of burn victims exceeds the capacity of the local burn center to provide optimal burn care."[2] Capacity includes the availability of burn beds, burn surgeons, burn nurses, other support staff, operating rooms, equipment, supplies, and related resources. This definition is inapplicable where, as in Germany, a central burn-bed bureau always organizes the distribution of burn victims; the definition supposes a very different degree of preparedness in these countries.

Triage: the process of sorting individual patients into categories according to priority of treatment. An example of triage categories is delayed, immediate, minimal, and expectant (DIME). Several factors influence triage decisions; these include available resources, number of patients, the severity of injury of each patient, and the timeframe during which the injuries must be addressed. Triage is not a one-time event, but it should be repeated throughout the mass casualty event (see later).

Basic capacity: the normal number of patients who can be treated, based on the availability of burn beds, burn surgeons, burn nurses, other support staff, operating rooms, equipment, supplies, and related resources

Capacity utilization: the degree of utilization of burn beds in a center over a certain time. This should be expressed as use of intensive-care burn beds and other beds. The average value over a year gives an overview of a burn center's disaster capacity.

Actual capacity: the number of burn patients that a center can admit on an actual day. It varies daily, can depend on the season, and is likely to fluctuate with seasonal or accidental presence or absence of severe patients.

Surge capacity: the increased capacity available in mass casualties and disasters. In burns, it is defined by the ABA as the capacity to handle, in a disaster, 50% more than the normal maximum number of burn patients.[3] Surge capacity must be developed and maintained, requiring action by health systems. Surge capacity must include continued medical care for all other patients. Elective medical and surgical care can be postponed temporarily to maintain surge capacity. When capacity is breached, patients must be transferred safely to other treatment facilities.

Sustained capacity: the maximum capacity that a burn center can sustain over a longer time without lowering treatment quality.

Burn capacity of a health system: the total capacity of burns that can be treated in a national health system. This capacity should be known; it should take into account the various requirements of burn treatment, such as the number of victims needing intensive care. The average capacity utilization over the year is part of resource planning for a health system.

Time to establish surge capacity: how much time a burn center needs to rise to maximum surge capacity. A good parameter is the number of complete burn teams available at various hours. This number is highly important in a hospital's organization of care.

National Disaster Medical System (NDMS): manages a country's national medical system in disasters. In the United States, the NDMS is a function of the Federal Emergency Management Agency (FEMA) under the Department of Homeland Security. It acts as a partner of the U.S. Department of Health and Human Services (HHS), the Department of Defense (DoD), and the Department of Veterans Affairs (VA).[3] Other countries' structures are comparable. The U.S. NDMS has three functions: (1) medical response at the disaster site, (2) transport of patients to unaffected areas, and (3) definitive medical care in unaffected areas.

Burn specialty team (BST) or burn assessment team (BAT): a special form of disaster medical team that provides expertise in burns. In the United States, a BST consists of 15 burn-experienced medical and nonmedical staff. These teams do not exist in many countries. Such teams can be formed only when burn experts are numerous enough and not already engaged in other aspects of disaster response.

Technical relief: the general "civil defense" functions required to support disaster response. In Germany, these functions are provided by the Bundesanstalt Technisches Hilfswerk and include lighting, debris removal, search and rescue, flood mitigation, electricity, water supply, sewage disposal, catering, command center support, communications, logistics, equipment repair, and transportation of supplies. In the United States, these functions are provided by FEMA or by equivalent agencies at the state and local levels.

The Historical Record

Even with the best preparation, a disaster remains a disaster for a certain period; the goal is to minimize that period. Although retrospectively correcting problems is impossible, lessons learned from the past should be applied to the future. Recurring themes that appear in the following case studies include the following:

- Communication problems
- Need to send major burn patients to burn centers
- Need for central incident command post
- Movement of patients to hospitals by private vehicles
- Importance of control of traffic leaving the disaster area
- Lack of coordination of patient evacuation from the scene
- Value of retriage out of the disaster area to other burn centers
- Infection control problems; multidrug-resistant organisms
- Lack of experience in burns by nonburn providers
- Need for psychological support of providers
- Value of international teamwork

TERRORIST ATTACKS

New York City—September 11, 2001

In New York, two hijacked airliners were flown directly into the Twin Towers of the World Trade Center. Although many were injured or killed, few survivors had severe burns.[4] The victims were sent mainly to two burn centers, although more centers were easily reachable.[5] Nineteen were seen at New York Presbyterian Hospital; there, the victims' average

Fig. 5.1 New York, New York, 2001. Triage station set up by Burn Specialty Team 1 from Boston, Massachusetts. (Courtesy of Robert L. Sheridan, MD. Reprinted with permission from Sheridan R, Barillo D, Herndon D, et al. Burn specialty teams. *J Burn Care Rehabil* 2005;26:170-173.)

age was 44 years, and the burn size averaged 52.7%.[6] In total, 39 burns were reported by nine hospitals; 27 patients were admitted. Although enough burn beds within 1 hour's transport were available, only 26% of burned patients were triaged first to burn centers. Two thirds of burn injuries were ultimately treated in a burn center. The usual portion of burn victims triaged to burn centers in New York City in a year is 75.2%.[6] BST-1 from Boston, Massachusetts, responded to this event within hours (Fig. 5.1).

Kuta, Bali, Indonesia—October 12, 2002

A suicide bomber detonated a backpack bomb in a nightclub. People fled to the outside, where a car bomb exploded. There were 202 deaths and an additional 209 injured. The Australian Defence Force (ADF) initiated Operation Bali Assist, the largest Australian aeromedical evacuation since the Vietnam War.[7] An aeromedical staging facility (ASF) was prepared in a Bali airport hangar, whence 5 C-130 planes flew 61 Australian patients to Royal Darwin Hospital (RDH). Of the 61 patients, 28 had major injuries (Injury Severity Score >16). At RDH, 55 escharotomies were performed, along with 43 other surgical procedures. Three patients had been intubated in Bali; 12 more were intubated at RDH. Within 36 hours after first admission to RDH and 62 hours after the bombing, 48 patients were evacuated to burn centers. There were no "walking wounded." BATs were used for initial care at RDH.[8]

Eleven patients were transferred to Concord Repatriation General Hospital.[5] Burn injuries ranged from 15% to 85% total body surface area (TBSA), mostly full-thickness burns. All patients showed injuries from both the first and second blasts. There were complications from infections with *Acinetobacter baumannii* and *Pseudomonas aeruginosa* and from fragment injuries. Many ophthalmic injuries occurred, some being detected only later.

Royal Darwin Hospital received its first information about the incident from a patient who had been treated in Bali and then fled to Australia. The hospital learned nothing of the number of patients or the severity of injuries before the first wave of patients arrived.[9] Palmer et al[9] describe a need for improvement mainly in military–civilian communication. Communication in the hospital also was problematic: Mobile phones had no reception, there was no time to read electronic texts, and land lines were not mobile. ADF provided satellite phones to the medical staff for communication between the hospital in Bali and ADF.

Madrid, Spain—March 11, 2004

Bomb attacks on four commuter trains killed 191 and injured 2051 of 6000 persons present. Thirteen bomb bags each contained 10 kg of dynamite plus fragments. Three bombs failed to explode. Of the 191 dead, 175 died instantly, and 16 died later. It was not known that unexploded bombs remained on the trains while ambulance staff worked. Ambulance staff worked without coordination and were oblivious to overall medical priorities. Patients with only minor injuries were transported. Ambulances ran out of all medical supplies. No joint field medical command post was set up.

Patients were taken to 15 hospitals in Madrid and two field hospitals, ranging from 5 to 312 patients each.[10] Communication problems in hospitals[11] and among organizations arose. Only 33% of patients were transported in ambulances under medical control; 67% found their way to hospitals without triage and medical or organizational control. Most went to the nearest hospital, which received patients with both serious and minor injuries.[12] Of 312 patients taken to Gregorio Marañón University General Hospital, 45 had burns. The most common injuries were tympanic perforation (in 41%), chest injury (40%), fragment injury (36%), extremity fracture (18%), eye injury (16%), head injury (12%), abdominal injury (5%), and amputation (5%).

London, England—July 7, 2005

Four bombs in the transit system killed 56 (53 at the scene) and wounded 775.[13] Train bombs exploded in three locations; the fourth bomb exploded on a double-decker bus. The number of explosion sites was initially unclear because passengers left the subway at various exits. Triage was performed; 55 patients were classified as severely wounded (P1 and P2). Communication was difficult: All but one mobile-telephone network failed; radio communication between the scenes and ambulance control was very difficult. The fire brigade established an inner cordon and ascertained that there were no signs of chemical substances threatening the rescuers, but the presence or absence of more bombs was not confirmed before rescue work began. Patients mainly in triage groups 1 and 2 were transported to six university hospitals after minimal triage and treatment.[14]

INDOOR FIRES

Gothenburg, Sweden—October 30, 1998

Fire in an overcrowded discothèque during a Halloween party killed 61 teenagers at the scene; 2 died later; 235 were wounded (Fig. 5.2). Initial information was poor, resulting in incorrect alerts. There was no triage officer at the scene. Hospital disaster plans in some cases were unknown or not implemented. Preexisting disaster plans had the same

Fig. 5.2 Pope Air Force Base, North Carolina, 1994. Airport fire trucks extinguish a burning aircraft at the scene of the crash. Rescue efforts were aided by combat medics who were preparing to participate in parachute operations. (Reprinted with permission from the *Fayetteville Observer Times*.)

personnel simultaneously performing conflicting roles. Within 2 hours, 150 patients were admitted to four Swedish hospitals. Thirty-one patients presented with significant burn injuries; 11 patients were transferred secondarily to other burn centers in and outside Sweden.[15]

Despite the initial chaos at the scene, there were timely escharotomies and triage in the hospitals before transfer to burn centers. Inhalation injuries were diagnosed in 158; 54 of them were treated simply with suction and expectorants. In 51 of 61 deaths, carbon monoxide (CO) was the cause. Eleven patients were transferred secondarily to burn centers in four other cities, one in Norway.[16] All 11 had second- or third-degree burns of more than 20% of the TBSA.

Volendam, the Netherlands—January 1, 2001

A fire at a New Year's Eve party killed 8 and injured 203 of 350 present.[17] An early error in directing emergency traffic caused transportation chaos. Emergency-services tents were insufficiently staffed, and tent placement was problematic. In all, 241 patients went to hospitals: 110 by ambulance, 18 by bus, and 113 by self-referral to the nearest hospital.[18] Of 182 admitted, 112 went to intensive care units (ICUs). Nineteen hospitals provided initial care. The closest hospital, receiving 73 patients, was overwhelmed.

After primary treatment in the hospitals, burn specialists did tertiary triage, distributing patients to hospitals and burn centers in and outside the Netherlands. Burn center criteria were adapted on the basis of both burn extent and inhalation injury: The indications for burn center treatment were greater than 30% TBSA burn with inhalation injury.

Warwick, Rhode Island—February 20, 2003

Fire at The Station, a nightclub, killed 100 and injured 215 of 439 present. The building totally collapsed within 30 minutes. Rhode Island Hospital (RIH) first became aware of this incident from breaking news on television;[19] shortly after, RIH got official notification that 200–300 burn victims were expected. A triage site was established. Sixteen area hospitals evaluated 215 patients. Patients admitted to RIH numbered 47. TBSA averaged 18.8%. There were 33 burns of less than 20% TBSA, 12 with TBSA of 21–40%, and 2 of greater than 40% TBSA. Of 32 patients presenting with inhalation injuries, 28 required intubation; 12 needed escharotomies; and in just 6 weeks, 184 bronchoscopies were necessary.[20] Retrospective analysis called for improvement in communication with the disaster scene and in specific instructions for patient transport.[20]

Buenos Aires, Argentina—December 30, 2004

Fire at the overcrowded República Cromañón nightclub killed 194 and injured 714 of 3000 present.[21] CO and hydrogen cyanide poisoning were the main causes of death. At the scene, 46 ambulances and 8 fire crews sent the victims to the 8 closest hospitals, which were overwhelmed by critically ill patients within 2 hours. In Buenos Aires city, 38 hospitals were engaged and another 5 elsewhere in Buenos Aires province.

Ramos et al describes the experience of Argerich Hospital,[21] to which 74 patients were taken. All had inhalation injuries. There were no severe burn injuries. Eighteen patients (24%) were pronounced dead on arrival. Twenty-five showed respiratory insufficiency and reduced level of consciousness and were intubated. Initially, 22 patients were sent to the ICU; the 14 sent to the operating room for mechanical ventilation were transferred to other hospitals in Buenos Aires Province within 48 hours.

Kiss Nightclub Fire, Santa Maria, Rio Grande do Sul, Brazil—January 27, 2013

In this fire, 242 people were killed, and more than 630 others were wounded because of the use of fireworks. Firefighters had to create a hole in the outer wall to help people to escape. From the estimated 1200–1300 people present in the disco, 169 were hospitalized because of inhalation injuries and burns.[22] The extent of the disaster was not communicated to the response workers. Triage was hindered by crowded bystanders and victims. The military police had to hinder relatives from entering the disaster site that was filled with smoke and toxic gases. Many of them were in critical conditions, emergency departments (EDs) of 5 hospitals, and ICUs of 6 hospitals, and all of the emergency units were crowded. Fifty-four patients had to be transported by helicopters and ground transport to hospitals in Porto Alegre and Caxias do Sul and Cachoera do Sul and Canoas. Transport was supervised and coordinated by a Brazilian Air Force officer and the Brazilian government corporation responsible for operating the main commercial airports. The main issues were with command and control at the incident scene and the absence of a disaster plan.[23]

Colectiv Nightclub Fire, Bucharest, Romania—October 30, 2015[24]

Fire in the nightclub caused by fireworks during a show killed 26 on the spot, 38 died in hospitals, and 184 were injured. About 200–400 people present in the club were engulfed in a stampede when they realized there was fire. The fire started at 22:30, first and emergency call was sent over 112. The first ambulances arrived 12 minutes later. A field hospital was set up. Resuscitation of the unconscious

Fig. 5.4 Ufa, Russia, 1989: U.S. and Russian teams perform burn wound care. (Photo courtesy of U.S. Army.)

was tried; the effect was not described.[19] At 23:30, the police isolated a perimeter of several streets around the night club. Seventy-five special vehicles of the Inspectorate for Emergency Situations and 57 SMURD trucks and ambulances were in place. A total of 500 emergency service personal were mobilized. Victims accessed hospitals driven by bystanders, taxis, and ambulances. Twelve hospitals received between 57 and 15 victims each, and some had to be redistributed to other hospitals because of overburdening. Ventilation devices had to be moved from other hospitals to the places they were needed. After 1 week, victims were distributed to burn centers in Israel, The Netherlands, Belgium, Austria, the United Kingdom, Norway, Germany, and France. Patients died during or immediately after the transport because of the severity of their injuries.[24] In Bucharest, enzymatic debridement was used to reduce the logistic challenge. There were problems in identifying 29 of 146 hospitalized victims because of the severity of their burns. On March 14, 2016, the last victim treated in a Romanian hospital died.

TRANSPORTATION CRASHES

Alcanar, Spain—July 11, 1978

A tanker truck carrying liquefied flammable gas exploded beside the Los Alfaques campground, killing 102 at the scene and injuring 288; eventually, the dead totaled 215 (Fig. 5.3).[25,26] The burning tanker divided the scene into two parts. The 58 patients transported north to Barcelona received adequate care before transfer. The 82 patients taken south to Valencia received minimal treatment before and during transport. Both Valencia and Barcelona had state-of-the-art burn centers. There was no significant difference in age or the extent and depth of burns between these two groups. After the first 4 days, Barcelona's survival rate was 93%, and Valencia's was 45%. Ultimately, the mortality rate did not differ.

Lyce Diyarbakir, Turkey—July 21, 2014[27]

A driver of a liquid petroleum gas tanker lost control over the vehicle and caused an over roll followed by a boiling liquid expanding vapor explosion after 15 minutes. Sixty-nine patients were admitted mainly to Dicle University Faculty of Medicine and Diyarbakir Training and Research Hospital, including 62 male and 7 female patients. The average TBSA was 51 ± 32%, including 4 patients with minor burns (<2%), 9 with moderate burns (2–10%), and 56 with severe burns (>10%). In 75%, fasciotomies had to be performed. Twenty-seven (48%) required endotracheal intubation, and 13 (23%) needed tracheostomy. A total of 76% of the patients with severe burns had to be transferred to a burn ICU. Forty-seven (68%) of the patients were distributed to 14 different locations. The overall mortality rate was 49%. The length of hospital stay was 19.4 ± 19.8 days for the survivors and 6.4 ± 4.2 days for those who died.

Ramstein, West Germany—August 28, 1988

Aircraft collisions and crashes during an air show killed 70 and injured more than 1000 of 300,000 present (Fig. 5.4). Three pilots and 67 spectators died; 346 others had serious injuries. Cooperation was hindered by medical systems that were not adapted to each other. On day 1, 12 hospitals were treating the injured; on day 2, 28; and on day 3, 74.[28]

Outpatients numbered 213; 146 were admitted as inpatients; 84 others were transferred to ICUs. There were 112 with mechanical injuries only; 263 had isolated burn injuries; 68 had both mechanical and thermal injuries.[28] Patients with burns of less than 20% TBSA numbered 209 (79.5% of 263). Patients with TBSA of 20–49% numbered 37; 3 of them died. Six of 9 patients with TBSA of 50–70% died. Another 8 patients, with TBSA greater than 70%, died. Of the 68 patients with combined injuries, 55 had TBSA less than 20%. Three of the 9 with TBSA of 20–40% died. No patient with combined injuries and TBSA burns greater than 40% survived.

The burn center at Ludwigshafen received 28 victims. The existing emergency plan was activated; overstaffing occurred on the first day. Initial care in the burn unit was provided in the normal way, not according to emergency plans. Experienced burn teams evaluated the patients. The disaster plan worked, but incomplete initial documentation greatly increased the next days' workload. During

treatment, there were no problems with the expanded nursing staff. Qualified medics who worked double shifts for weeks were exhausted. Heavy use of burn beds caused cross-infection problems. The senior surgeon on duty on day 1 concluded that patients should have been transferred to other burn units, where free beds were available.[28]

Kerosene caused difficulties in respiration and in function of patients' kidneys, livers, and central nervous systems. Evaluating cyclic carbohydrates in the blood soon after the incident may be important for prognosis.[29]

Pope Air Force Base, North Carolina—March 23, 1994

Two planes collided in the air, attempting to land on the same runway. The C-130E was able to land; the F-16D, whose crew ejected, slid into a parked, fully fueled C-141 cargo plane with a crew aboard (see Fig. 5.2). Five hundred paratroopers, waiting 50–70 feet from the plane, were sprayed with a fireball of burning aviation fuel, with flying debris, and with the F-16's 20-mm ammunition, which began cooking off from the heat.[30] Fifteen to 30 minutes after the incident, casualties arrived at Womack Army Medical Center (WAMC), a 155-bed hospital 5 minutes away. Fifty-one patients were treated and released; of 55 admitted, 25 went to ICUs. Six patients needing urgent surgery were sent to nearby hospitals. Seven patients were sent to the closest civilian burn center, Jaycee Burn Center at the University of North Carolina at Chapel Hill.[31]

One U.S. Army Burn Flight Team arrived 4 hours after the accident and another after 9 hours. Escharotomies were reevaluated; some had to be repeated. Resuscitation was guided by urine output, but fluid amounts initially were not documented. Use of the Parkland formula (4 mL/kg/TBSA), rather than the modified Brooke formula (2 mL/kg/TBSA), along with untrained personnel's overestimation of TBSA, contributed to overresuscitation. Forty-one patients were transferred to the U.S. Army Institute of Surgical Research (USAISR) Burn Center for treatment, of whom 13 required mechanical ventilation. Patients assessed as having nonsurvivable injuries stayed at WAMC.

Points from Mozingo et al's[31] review include the following:

- Initially, patients with the largest burn sizes were transferred to a nearby civilian burn center. Most of them later died. This sapped resources in the burn center with little impact on outcome.
- Use of different resuscitation formulas caused difficulties.
- Patients with obviously lethal injuries were not transported. This did not meet expectations of the referring hospital (WAMC).
- Several burn victims remained at WAMC without burn specialists because all the burn specialists were needed at the USAISR.
- There was a lack of burn experience and training at WAMC. Knowledge deficits were noted in techniques (e.g., escharotomy).
- Training of nonsurgical staff in Advanced Trauma Life Support (ATLS) and Advanced Burn Life Support (ABLS) was needed because the surgical staff was busy doing emergency procedures.

EXPLOSIONS

San Juanico, Mexico—November 19, 1984[32]

An 11,000-m^3 mixture of propane and butane exploded in San Juan Ixhuatepec (population, 40,000), causing one of the most severe explosion disasters in history and registering 5 on the Richter scale. In a 25-acre (10-hectare; 100,000-m^2) area, 7000 persons needed medical help and 2000 required hospitalization, with 625 severe thermal injuries. Thirty-three hospitals were involved, with transportation by 363 ambulances and helicopters. Sixty thousand people were evacuated. About 23,000 needed help with smaller injuries, lodging, and food.

The magnitude of the event meant that during the first hour, total chaos reigned, and rescue work was unguided. Secondary explosions, heat from fire, and debris forced rescuers into temporary retreat to avoid risking more lives. Private vehicles fleeing the disaster zone obstructed relief and evacuation traffic. After triage and initial care, victims were distributed to 33 hospitals, most of them in Mexico City. Within 3 days, burn patients had been distributed to 12 hospitals with good burn facilities. After 5 days, only 300 of the 625 burn patients were still in burn units: 140 had died, and 185 had been sent to other hospitals. There were "rather few" very extensive and deep burns and very few who needed respirator care.

Centro Médico reported 37 severe burns admitted because of a silo explosion 3 days before and received 88 more burn patients from San Juanico. The facility mobilized additional staff and prepared additional beds near the burn unit. Only 2 of the 88 victims had airway injuries requiring tracheostomy and ventilation. This burn unit's usual capacity is 48 beds; the maximum number of patients simultaneously treated was 136. Fifteen patients died within 4 days, whose burns exceeded 60% TBSA.

Piper Alpha, North Sea—July 6, 1988[33]

An oil fire and gas explosion on an oil rig killed 167 and injured 189. Information about the event reached Aberdeen Royal Infirmary in Scotland by television. Sixty-three were rescued; of 22 who went to the hospital, 15 were admitted, 11 to the burn unit. There were severe thermal injuries from molten helmets on victims' heads. All patients had some degree of inhalation injury.

All patients were operated on within 72 hours. Operations were performed by two teams working in two areas simultaneously. The high number of dead took a grave toll on the medical and lay teams' psyches. Psychiatrists, psychologists, and social workers were engaged. The retrospective recommendation is to distribute patients among other units. News media were a problem, as was the administration's lack of awareness of the need to maintain the high staffing levels for a long time. Knowledge of basic burn procedures (e.g., escharotomies and the way to treat a burn) is important.

Bashkir Autonomous Soviet Socialist Republic—June 4, 1989

Two trains were passing a methane–propane pipeline when it exploded, killing 575 and injuring 623.[34] Intravenous (IV) fluid resuscitation was initiated for most patients. Those

with serious but potentially survivable injuries were then evacuated to Chelyabinsk, Sverdlovsk, and Ufa. Later, the military and Aeroflot took most of them to Gorky, Leningrad, and Moscow. Most had burns of 30–40% TBSA. Several international teams deployed to assist.[35] In Ufa, a team from Galveston, Texas, under Dr. David Herndon found four children with burns of 30–68% TBSA and 12 with moderate burn size (15–30% TBSA). The team began treatment in cooperation with Russian personnel; the earlier, conservative therapy was changed to an operative one, using dermatomes and meshers brought from Galveston. A U.S. Army team was deployed to treat adults in Ufa. The U.S. Army selected 28 patients for burn-wound excision and coverage. The team reported many infected wounds (see Fig. 5.3). A microbiological program was set up. Cross-infection between burn victims was common, mostly by multiresistant *Pseudomonas* and *Staphylococcus* spp. Local therapy was done with mafenide acetate and silver sulfadiazine (SSD) (see Fig. 5.4).[35] This effort was one of the very successful international joint operations in a burn disaster.[36]

Phases of Mass Casualty Events

CHAOS AND ALARM

Initially, information about the event is unavailable; even those involved often cannot verify the incident's dimensions and sometimes cannot even describe the location. False information leads to inaccurate alerts and is disastrous for all who then must cope with unexpected situations.[15,18] Questions to be answered include the exact time, place, and type of accident; the estimated number of casualties and expected pattern of injuries; hazards (e.g., contamination, toxic smoke); and the number of persons potentially exposed.

Immediately after the accident, victims often flee to the nearest hospitals, overcrowding them before any official alarm. This influences the execution of emergency plans because everyone is busy with arriving victims, and there may be no resources available to carry out those plans. Contaminated victims can bring severe risks to hospitals; this can cause a partial loss of medical resources.

ORGANIZATION

After verification, the incident command system and the in-field command post must be established and must coordinate the work of rescue, security, medical, and technical relief teams to enable working in the damaged area and to protect the teams and their work from hazards, violence, and distracting demands made by victims and their friends and relatives.

Medical care at the scene and in alerted hospitals should be established. First, the scene must be cleared of further hazards, or rescue workers must be outfitted for the risk. A cordon should be established to control victims' departure to hospitals and to prevent onlookers' and news media's interference in rescue work.

Traffic regulation must begin, and all teams must understand it: It must include movement and assembly of ambulances, fire trucks, and police cars; landing and take-off of helicopters; decontamination areas; areas for triage, treatment, and minor injuries; and a temporary morgue. Divide the scene into rescue areas, and make schedules for technical-support teams.

In this phase, cooperation among medical teams, fire brigades, police, and technical-relief teams is crucial. Local command, control, and communication (C3) structures must be established; they are the coordination hub for preclinical treatment. A central C3 structure coordinates preclinical and clinical treatment and transport and disseminates up-to-date information. At hospitals, disaster plans are implemented, and staff is called in.

SEARCH AND RESCUE

The first goal of search and rescue (SAR) is to bring victims to a safe casualty collection point (CCP) out of the way of imminent danger (hostile action or environmental hazards). In-field triage and tagging must occur at the CCP. This primary evaluation should take less than 30 seconds per patient and should be limited to life-threatening conditions.

TRIAGE AND FIRST AID

Triage is a process whereby patients are sorted according to treatment priority, the purpose of which is to do the greatest good for the greatest number. Several schemes exist to define levels of triage. The *Advanced Disaster Medical Response* course[37] is field oriented and outlines the following:

- Level 1 triage occurs at the point of injury.
- Level 2 triage occurs at the scene (or nearby) by the most experienced medical provider.
- Level 3 triage is performed to determine evacuation priorities.

The *Fundamental Disaster Management* course[37] is ICU oriented and describes the following levels of triage:

- Primary triage occurs at the scene.
- Secondary triage occurs upon arrival at the hospital.
- Tertiary triage occurs in the ICU.

Finally, the ABA approach is burn center oriented and defines the following:

- Primary triage is that occurring at the disaster scene or at the ED of the first receiving hospital.
- Secondary triage is the selection for transfer of burn patients from one burn center to another when surge capacity is reached.

Clearly, triage is not a one-time operation but has to be repeated at each step of the way. There are several different algorithms for triage. Paramedics may use simple triage and rapid treatment (START) in both emergency medicine and mass casualties. The sensitivity for START varies from 85%[38] to 62%.[39] Medic in-field triage is another approach. This is done in an established triage area by medics assisted by teams of helpers. It consists of a brief history (time of accident, mechanism of injury, condition, how the patient was found, primary measures taken, actual discomfort, pre-existing condition, medications, and allergies) and a quick head-to-toe examination:

Table 5.1 Triage Color Code and Urgency

Group	START	Medic Triage
1	Immediate	Immediate
2	Urgent	Urgent (2a and 2b)
3	Delayed	Delayed
4		Expectant
4	Expectant or dead	
No number, no color		Dead

- Physical examination—external bleeding; penetrating injuries; thermal burns; chemical burns; neurologic status; and investigation of head, spine, thorax, abdomen, pelvis, and extremities
- Vital signs, including respiration rate, pulse oximetry, and temperature
- Burn size is estimated by the rule of nines, and there is evaluation of suspected inhalation injury and of the need for intubation.

Triage classifies patients according to the following treatment urgency groups shown in Table 5.1. An easy-to-remember acronym is DIME, which stands for delayed, immediate, minimal, and expectant. The main factors to consider in burn patient triage are TBSA burn and age.

Emergency treatment at the scene is done in a treatment area by appropriately trained providers. Burns needing treatment for shock or intubation should be classified for urgent treatment. Because of the need to resuscitate as soon as possible, resuscitation should begin here!

In mass casualties, cardiopulmonary resuscitation (CPR) is not performed as it binds resources for mostly futile efforts for victims initially classified as dead (no ventilation after airway opened, no pulse). This is especially after rescue from indoor fires (because deadly CO poisoning can be assumed) and in the setting of massive trauma.[40]

Triage group 4 (in Austria, Germany, Switzerland, and some other countries) includes the unsalvageable, who deserve "expectant" treatment. This may be controversial because the duration of the disparity between supply and demand should be short and, when the period is over, this group's priority may change to 1 or 2. Group 4 needs staff at least for comfort care. Dead victims need neither staff nor transports in the acute phase.

If available, tags are attached to each patient. Tags are used not only to indicate triage category but also to provide each patient with a unique number. These tags facilitate victim identification and registration; tell about patients' history, medical treatment, injuries, urgency of treatment, and classification of injury; and specify the hospital for treatment. The tags must not be removed until all the following have occurred: hospital arrival, identifying the patient, and registering the tag number and treatment data.

INITIAL TRANSPORT

For burn patient transport from the scene to the hospital, ambulance heating should be maximized to avoid cooling the patients. Warming pads and extra blankets should be prepared and IV fluids warmed up. Ambulance doors should be kept closed to retain heat! The transport order must accord with urgency status determined in triage.

Transporting the dead steals resources from the living. The dead, and where they are found (important for identification[41]) should be registered; when they have to be removed, they should be taken to a temporary morgue.

One strategy for distributing patients from a mass casualty event is based on proximity to the scene and classifies hospitals as first, second, or third line. As much as possible, *first-line hospitals* (those closest to the scene) should be avoided. They will be overcrowded with people arriving as walking wounded or by private vehicles and will have been neither triaged nor registered.[3,16] *Second-line hospitals* are the main destinations for those in need of emergency treatment. *Third-line hospitals*, those far from the incident, are ideal for patients in triage group 3 ("delayed treatment," "walking wounded" with only minor burns). Mass transport means (e.g., buses) can be used.

BURN CENTER REFERRAL

Central incident command should already know the number of available burn beds and at least the number and locations of victims. Burn extent and severity, need for ventilator support, quality of treatment for shock, CO poisoning, and quality of escharotomies all must be evaluated with the goal of getting reliable data. BATs may play a role in this phase by gathering information from outlying hospitals and assisting in emergency care. With central collection and distribution of data, the best treatment option allowed by the resources available can be chosen for the patient. This can be supported by information technology (IT) solutions that enable central registration of burn cases.[42]

Depending on resource availability, burn patients are either distributed to burn centers with free resources or, when burn-center resources are limited, criteria for burn-center treatment must be established. These criteria should include burn size, age, and the need for ventilator support. The survival grid published by the ABA is recommended for this purpose.[2] Patients meeting these criteria are to be transported to burn units; the rest either stay in the primary hospital or are transferred to nonburn centers.

Whether to transport patients whose care has been classified as futile to burn centers must be decided in advance. They are a burden for the primary hospital in terms of workload, psychological effect, and legal aspects.[31] In burn centers, they tie up resources needed for treating patients who are likelier to survive. The pairing of two recommendations in the United States—to send any third-degree burn to a burn center and not to send to a burn center anyone with a severe, life-threatening, nonsurvivable burn—may produce conflict. At any rate, these patients, their relatives, and the staff caring for them need both psychosocial support and support from experienced burn personnel.

EVACUATION TO OTHER BURN CENTERS

Depending on the number of casualties and the available burn beds, it may be necessary to transfer patients out of the local burn center. There are three possible scenarios:

1. If the number of patients is within the local burn center's surge capacity, then the local burn center can do primary stabilization and treatment and afterwards can decide whether to distribute some patients to other burn centers.
2. If the number of patients exceeds the surge capacity of the local burn center but can be handled by the national system of burn centers, then initial care must occur in local trauma centers or burn centers. Dispersal of patients to national burn centers must come later.
3. If the number of victims exceeds national resources, international resources must be evaluated to determine which patients are to be treated in burn centers nationally and which could be evacuated internationally. This scenario can be facilitated by preexisting conventions and treaties.

SECONDARY TRANSPORT

During transport, the patient must be protected from bacterial contamination and from cooling. This requires special dressings and devices that prevent cooling. Klein and associates reported that the most common complications during air transport were loss of venous access and inability to secure an airway. Hypothermia below 35°C was reported in about 10%, mostly in patients with larger TBSA burns.[43]

TRANSPORT HOME

For patients whose treatment occurred far from their homes, transport to home hospitals should be arranged. Central disaster management must conduct a general survey of treatment centers to identify survivors and space available in the home area. Patients should be transported if they are stable and the situation in the home area is suitable. Transport funding must be obtained.

LONG-TERM FOLLOW-UP AND REHABILITATION

After treatment in a burn center, further care must be planned. Regular follow-ups, surgical interventions, rehabilitation, and psychosocial support must be initiated. These should be long-lasting measures to give the patient a point of care that she or he trusts.

Rehabilitation must be coordinated for all patients. The primary shortage in burn beds will be followed by a secondary shortage in rehabilitation centers. Follow-ups must be planned far into the future; projects should be established and funded. Care—physical, psychological, and social—should be given not only to the victims but also to their relatives.

DEBRIEFING

Debriefing is part of psychosocial preventive care in emergency response. Staff in mass casualties have a higher risk of illness than the average population. Contributing factors include the need to make triage decisions, bad information, lack of routine, lack of resources, inability to provide help, and contact with aggressive news media.[44,45] Debriefing allows those involved in the incident to overcome the event psychologically and to reflect on its effects. Optimally, it is conducted near the site of the event and begins within the first 24–72 hours. The preferred approach is one-on-one interviews and small-group sessions, after which the psychosocial specialist decides whether debriefing should be offered. It is suggested to contact people again after 4–6 weeks for reevaluation.[40]

The Critical Incident Stress Debriefing (CISD) system has three parts—preparation, attendance, and aftercare. CISD is offered by many institutions and organizations. Although minimum standards are rather clear, quality control is sometimes lacking.[40]

Emergency Care: Special Considerations in Disasters

FIRST AID

Bystanders, hurt and unhurt, give first aid according to their experience and training. Basic measures that can be performed by trained lay persons include the following:

- Stop bleeding.
- Open the airway.
- Extinguish fire on persons; cool wounds while preventing hypothermia.
- Prevent wound contamination.

In mass casualty events, clean polyethylene film (e.g., Saran wrap, a plastic wrap used for food) is suggested for protection of areas other than the face. This occlusive dressing prevents wound dehydration and evaporative heat loss. Care must be taken not to stop circulation or hinder ventilation.

FLUID RESUSCITATION

An approach to initial care of burn patients in EDs is provided in Tables 5.2 and 5.3. To simplify fluid resuscitation by nonburn providers, who possibly have to resuscitate a lot of patients at the same time, Chung et al[46] implemented a new formula known as the rule of 10 (for adult patients weighing between 40 and 80 kg):

- Estimate burn size to the nearest 10.
- % TBSA × 10 = Initial fluid rate in milliliters per hour.
- For every 10 kg above 80 kg, increase the rate by 100 milliliters per hour.

During the next hours, fluid administration should be adjusted to physiologic response. The target is a urinary output of 30–50 mL/h. The crystalloid infusion rate (e.g., lactated Ringer's solution [LRS]) is adjusted up and down by about 25% every hour or two to achieve this goal. The formula is *not* suitable for resuscitation of burned children (weighing <40 kg body weight); for children, a weight-based formula should be used along with a maintenance fluid.

Mass casualty events and disasters make it difficult to provide fluid resuscitation at the right time and in sufficient quantities. A 70-kg patient with a 40% TBSA burn, for example, needs approximately 6000 mL of LRS during the first 8 hours. Because supply is a bottleneck in disasters,

Table 5.2 Primary Assessment of Burns in Hospitals

  - Additional injury
  - (Trauma CT scan)

CO, Carbon monoxide; *CT,* computed tomography; *TBSA,* total burn surface area.

Table 5.3 Important Items During Primary Hospital Assessment in Burns

VENTILATION

- **If ventilation is impaired:** Check the need for intubation, tracheotomy, or coniotomy.
- **If patient is intubated and ventilation is disturbed:** Check tubus position; exclude pneumothorax; consider thoracic escharotomies and fasciotomies.
- **Check for inhalation injury and aspiration:** Bronchoscopy may be needed.
- **If carboxyhemoglobin is high:** Oxygen appliance is needed.

CIRCULATION

- If perfusion of extremities is disturbed or pressure is high: Check the need for escharotomy and fasciotomy.
- Recalculate TBSA.
- Recalculate fluid requirement: Present corrected fluid amount.
- If blood pressure is disturbed: Correct fluid administration. Other medication? Additional injuries?

ORGAN PERFUSION

- Check urine output.
- Core temperature: Warm up.

OTHER INJURIES

- Is other medical treatment (besides burn treatment) necessary? Complete the diagnosis and give treatment according to urgency.

LOCAL TREATMENT

- Clean; apply disinfectants: Take primary swabs.

NUTRITION

- Nasogastric or nasoenteric tube in intubated patients.

TBSA, Total burn surface area.

facility with how to resuscitate patients using fluids other than LRS may be important.

ORAL RESUSCITATION

Since the development of IV resuscitation formulas in the early 1950s, oral resuscitation in major burns (>15–20% TBSA) has been underused. This mainly reflects concerns about disturbed gastric emptying and impaired peristalsis after the burn injury, exacerbated by the side effects of opioid analgesics. In the early 1970s, Monafo resuscitated a small group of adults and children with burns of 22–95% TBSA using a 600-mOsm/L hypertonic oral solution.[47] In the 1990s, experience with early enteral feeding[48] demonstrated that, if feeding is begun no more than 2 hours postburn, the gastrointestinal effects are favorable, and even major burns could be managed with enteral, rather than parenteral, feeding.

Today, the main focus is on the World Health Organization's oral resuscitation solution (ORS). It is a small packet containing glucose, sodium, potassium, chloride, and buffer, with a slightly hypertonic osmolarity of 331 mmol/L when dissolved in water. It was first developed to treat the massive loss of volume and electrolytes in cholera, dysentery, and so on. With a feeding catheter placed in the intestine of 40% TBSA burned anesthetized pigs, Thomas et al demonstrated resuscitation with the WHO ORS according to the Parkland formula.[49] Michell et al reported similar results.[50] El-Sonbaty reported good results using WHO ORS for oral resuscitation of children with burns of 10–20% TBSA.[51] More research into both the ideal enteral fluid and the quantities to administer is necessary. But in early burn resuscitation in disasters with IV fluid shortages, there may be a role for oral rehydration solutions, such as the WHO ORS or one of the following:[52,53]

- 5.5 g of salt as undissolved tablets swallowed with 1 L of water
- 1 L of water with 1 tsp of salt (or 1/2 tsp of salt and 1/2 of baking soda) and 8 tsp of sugar
- 1 L of LR with 8 tsp of sugar.

The importance of beginning fluid resuscitation (orally, enterally, or intravenously) as early as possible must be emphasized.

AIRWAY MANAGEMENT

In burn disasters, oxygen and ventilators often are scarce, increasing the importance of correctly assessing which patients need oxygen or intubation.

OXYGEN

In disasters, oxygen (O_2) requirements rise rapidly. Delivering small bottles of liquid O_2 is logistically difficult; the available capacity is strained by the weight, space, and the need to refill bottles. Even hospitals' large bulk liquid-oxygen systems may be damaged or inaccessible. In such cases, alternatives must be implemented as soon as possible. Portable bulk systems (1000–5000 L of liquid oxygen) or mobile cylinder banks are helpful, but are often unavailable in disasters.

Two other options are portable oxygen generators (POGs) and nonportable oxygen generators, often used in military field hospitals. If electrical power is present, oxygen generators can deliver oxygen with a concentration of 93% or more. They can be connected to patients or ventilators. With a booster system to provide enough pressure, oxygen generators can be used to refill oxygen tanks.

For safe work with diminished resources, there are several requirements: organizing a sufficient supply, ensuring the right connections between the systems, rechecking different systems during exercises, and evaluating actual oxygen needs to minimize wasted gas.[54]

ANESTHESIA

In disasters with few fully equipped anesthesia workstations, relatively stable patients without threatened airways or inhalation injuries and no major surgery of thorax or abdomen can be managed safely with (1) ketamine, (2) ketamine and midazolam, or (3) ketamine and low-dose propofol.[55] Ketamine preserves spontaneous ventilation; airway reflexes are mostly intact. The drug induces dissociative anesthesia and is a potent analgesic. Increasing central sympathetic tone helps stabilize hemodynamics. It is a bronchodilator but increases mucus production. It therefore may require concomitant administration of glycopyrrolate or atropine. To avoid dysphoria and hallucinations, it can be combined with midazolam (0.03–0.15 mg/kg) or low-dose propofol (0.25–0.5 mg/kg). As a racemate, ketamine has a loading dose of 0.25–1 mg/kg IV or 0.5–2 mg/kg intramuscularly for analgesia; the anesthetic dose is 0.75–3 mg/kg IV. S (+) ketamine, with less psychomimetic effect, can be administered at half the dose of the racemate. The effect lasts 5–15 minutes.

Acute surgery of wounds on upper and lower limbs and reduction of open fractures can be done under peripheral single-shot regional anesthetic techniques if the region where the block must be performed is clean and not burned. The same can be done with smaller burns on the extremities.

The availability of ventilators and anesthesia machines depends on the scale of disaster. If field hospitals are required, providers must be familiar with the equipment available therein. First-line field anesthesia machines are draw-over systems. They are used in the forward deployed medical units in the army but also in civil units like the German Red Cross "ziviles Feldlazarett." Their main advantage is their extremely low weight (5 lb or 2.3 kg). For ventilation in a controlled mode, however, they have to be connected to a ventilator. Another disadvantage is their failure to meet American Society of Anesthesiologists (ASA) safety standards. Therefore, training with the devices is difficult and requires connection to the safety and monitoring systems of standard anesthesia machines.

Recently, field-deployable versions of standard anesthesia machines were developed and introduced. They are of a robust and lightweight design, are able to operate under extreme temperatures, have extended battery capacities, require little maintenance, and are able to ventilate in different modern ventilation modes. The same applies to some modern transport ventilators, which are easy to transport and able to replace a heavy ICU ventilator.

BLOOD

Few publications describe the responsiveness and efficacy of transfusion services in catastrophes and disasters. Blood supply is mentioned as scarce in the first and prolonged phases of disaster response.[12] But the 9/11 terror experience showed that an uncoordinated surge in blood donation may generate, several weeks later, an unusual drop in the supply.[56] Managing blood in disasters and catastrophes is therefore a tricky matter.[57]

Hospital blood banks possess a certain inventory, which usually is not more than the amount of blood products needed for 2–3 normal days, including additional units for major trauma. Burn disasters immediately deplete the available stocks and lead to urgent requests to the local blood center. Triaging mass casualties, especially in burn disasters, results in the dissemination of patients to different trauma centers, so that multiple hospital blood banks are involved. High-volume and high-priority requests concentrate in a spiraling sequence in one blood center, which is greatly strained to coordinate the distribution to its hospital blood banks.

Supplies are usually sufficient to meet the urgent first requests, but many blood centers hold an average of blood products to meet the regular demand of 1 week or less. Burn disasters are characterized by the urgent need for platelet products and erythrocyte concentrates in the early phase. A blood center's stocks may be depleted within hours—platelets first and then erythrocyte concentrates. Plasma products are usually available even in bigger disasters.

Deliveries from other blood centers and national coordination may help to mitigate the center's own insufficiency. More often, a blood center acts without information about the disaster and the estimated need for blood products. Communication between emergency services and blood centers is rare.

WOUND CARE AND ESCHAROTOMIES

Whereas courses such as ABLS emphasize early transfer of individual patients to a burn center, where debridement of wounds and escharotomies (if needed) are done by the burn experts, this may not be possible in a mass casualty event. Initial wound debridement should be thorough and aggressive and should use a surgical antiseptic such as chlorhexidine gluconate solution. After debridement, the patient should be prescribed a topical antimicrobial. SSD (Silvadene, Flamazine) has the advantage of widespread availability and familiarity. Mafenide acetate (Sulfamylon; Mylan Institutional, Rockford, IL) has the advantage of deep penetration into eschar. A silver-impregnated dressing (Silverlon; Argentum Medical, Geneva, IL; others) is a less labor-intensive option than the creams. For mass casualty situations, SSD with cerium nitrate (Flammacerium; Alliance Pharma, Chippenham, United Kingdom) is an attractive option based on the concept that the resulting eschar may permit a delay in excision with diminished ill effect.[58] An enzymatic debriding agent, NexoBrid (MediWound Ltd, Yavne, Israel), is under evaluation as a topical alternative to surgical wound debridement, which would be useful in mass casualty events.

Communication

Communication is an essential component of successful disaster response and a component that frequently

malfunctions during a crisis. Hospitals and burn centers often learn first of an incident through the media or other unofficial channels.[19] Victims arriving on their own sometimes give the first information.[9] News media also can be faster than the designed information structure sometimes video is a better source of information than mere words. When patients arrive tagged or telling certain stories, it indicates a mass casualty event. Measures to establish hospital preparedness should be taken, including checking supplies and the local situation and not allowing staff to go home after shifts until the situation is cleared.

Crisis communication is the exchange of information among public authorities, organizations, news media, and affected individuals and groups—before, during, and after a crisis.[59]

MEANS OF COMMUNICATION

In disasters and mass casualties, many factors increase the need for communication—and communication resources are limited. Sequential failure of various communication methods was described in many disasters such as Enschede,[60,61] London, and Madrid.[10,11] Communication problems are reported in almost all mass casualties and disasters.

Cellular Telephone

Cellular networks usually are overwhelmed because victims, news media, relatives, friends, and others all quickly begin dialing to or from cell phones. This leads to breakdown within minutes. Cell phones should not be used near explosive devices;[62] a 50-ft (15.2-m) safety radius is suggested. People trying to use cell phones may be endangered by security forces, who know that cell phones can be used to trigger bombs. In case of suspected bombs, cell phones can be jammed by security forces.[63] Amateur videos, often shot on cell phones, are important in mass casualties for reconstructions and intelligence.

Conventional Telephone

In most hospitals, the number of incoming and outgoing landlines is limited. A manual switchboard, as opposed to automatic switching, can become overloaded very quickly. For alerting staff, an alarm server with call-center function makes sense.

Voice over Internet Protocol

Voice over Internet Protocol (VoIP) permits conference calls. For security reasons, public VoIP systems are usually disabled in hospital IT systems.

Two-Way Radio

Reception and transmission can be poor or nonexistent indoors and underground (e.g., 9/11, London). In hospitals, the number of persons who can talk at the same place and time over one circuit can be limited, causing problems when an area includes many persons exchanging information.

Trunked Radio System

Such systems use computer control to allow almost unlimited talk groups with only a few channels. Relief units use trunked radio systems (TRSs) for intra- and interorganizational communication. In Europe, TRSs are being established for emergency organizations.

Satellite Telephone

Satellite phones are independent of local infrastructure and can be helpful in cases of uncertain or overloaded infrastructure. However, even a call made from a satellite phone will not go through if the telephone system at the receiving end is not functioning.

Internet

Internet communication is an option only if connections are intact.[64] The Internet can be helpful in building up information structures for victims' relatives and to provide information to large audiences.

Electronic News Media

These are important in disasters, especially when locales must be evacuated and when staff are needed. News reports sometimes constitute burn centers' first information source about incidents before the official alarm arrives.

COMMUNICATION WITH NEWS MEDIA

News media shape the public face of the disaster. Information should originate from a desire to be as correct and as complete as possible.[59] Training in crisis communication should be given. The central incident command should appoint spokespersons to provide regular, scheduled press conferences and bulletins. The press should be kept away from victims and their relatives. The hunt for headlines does not stop at the hospital door.

When spokespersons start their work, they should express first their concern about the situation and their condolences to those who have lost loved ones; they should provide assurance that everything possible is being done to help.

Methods of supplying information to the media include websites, press releases, press conferences, and radio and television interviews.

The media want people for interviews and photos. This should be kept in mind and prepared for, with forethought given to what aspects can be discussed without causing problems. The following is a list of things to avoid when interacting with the press:[59]

- Guessing; presenting your own theories; communicating falsehoods
- Becoming upset or angry
- Using jargon
- Discussing classified information
- Saying, "No comment"
- Speaking about issues outside your area of expertise.

Communication with the media should be done in an environment outfitted for information transfer by media and away from patient treatment areas.

COMMUNICATION WITH RELATIVES AND FRIENDS

Centers should be established at hospitals for friends and relatives to gather in private. Crisis counselors and communication tools (e.g., telephones) should be available here.

Access to this area should be restricted to identified relatives and friends. Information here should be exact, honest, and never speculative. A contact person for relatives and friends should be nominated. Relatives coming to visit their badly injured loved ones should be given psychosocial help and should be supported by the offer of guest rooms and continuous, fact-based information. Patients and relatives should be protected from news media, which often constitute a big problem in this phase.

Strategies for Distribution of Patients and Resources

Fundamental to disaster planning and response are strategies for admitting burn patients, for redistributing burn patients away from the disaster zone, and for bringing additional resources into the disaster zone. Strategies differ by country, depending on the resources available. A fundamental principle in any successful disaster strategy is that of a *tiered response*. This means that higher and higher tiers of support are brought into play as the magnitude of the event increases. Most mass casualty events are handled at the local level; regional, national, and then international resources are programmed as needed.

THE ROLE OF BURN CENTERS

Individual-medicine criteria for admitting to burn centers are rather extensive. For example, the German-Speaking Association for Burn Treatment (DGV) and the European Burns Association (EBA) have guidelines stating that burns in functionally or aesthetically important areas should be treated in burn centers regardless of their degree and extent. According to the ABA, all third-degree burns should be treated in burn centers. It may not be possible to follow these guidelines in mass casualties and disasters, at least not initially; the available burn beds must be filled by victims who will get the maximum survival advantage from burn center treatment.

In theory, admitting all burn patients to burn centers is reasonable in resource-rich jurisdictions, with many burn centers, many burn beds, and lots of staff. In reality, the availability of burn beds varies among nations. Usually it can be assumed that burn beds are in short supply and high demand. Even in the United States, many burn centers have fewer than 15 beds[65] and even fewer ICU beds.

The advantages of admitting all burn patients to burn centers are lost when the number of victims is so high that quality cannot be maintained. Burn center staff then get tied up treating many patients with non-life-threatening burns. Likewise, admitting only the most severely burned patients to burn centers is of little use, as demonstrated in the case of Pope Air Force Base. There, an influx of lethally injured patients monopolized the Jaycee Center's resources. Burn beds are scarce and so must be reserved for victims with the best chance of survival. The ABA published a benefit-to-resource ratio table to optimize this process.

Transferring patients elsewhere can be reasonable even for burn centers because surge capacity cannot be maintained indefinitely. "Medical vanity" should never be a reason to avoid transferring patients elsewhere. Workload above the normal capacity can cause complications, such as an infection control problem.[28]

THE ROLE OF TRAUMA CENTERS

Trauma centers will always be part of disaster response. Trauma centers, being much more numerous than burn centers, can cope more easily with initial treatment of an unknown number of casualties.[66] In special cases, patients with combination injuries (e.g., mechanical injuries) may benefit from transfer to a trauma unit.

Although initial care of burns is part of ATLS, many emergency doctors, trauma surgeons, and other medical personnel are not experienced in burns.[31] Trauma centers without burn units therefore need support from experts and seem to be the place where BATs can be most effective. BATs act as experts and can support other surgeons. Because they are busy not with details but with directing treatment by others, they are in a position to improve results. They also can help determine the extent and severity of burns for central data collection and for redistribution of patients to burn centers or other hospitals. This assumes that BATs are readily deployable on short notice.[3,8]

THE ROLE OF BURN-BED DATABASES

Burn-bed databases are a necessity for knowing quickly who should go where. These databases should include the different burn-bed types (adult or pediatric; ICU or ward). It takes too much time during an incident to ask each center individually how many beds are free for use; therefore, an online system is preferable.

At present, few data exist on the real availability of burn beds in case of disaster. Germany has the highest ratio of burn beds to population. In the Enschede fireworks explosion, Germany could offer 19 burn ICU beds of 127 for adults and 15 for children.[61] There are national burn-bed bureaus in Germany and the United Kingdom, and there are networking facilities for cooperation (e.g., the Mediterranean Burns Club).

THE ROLE OF INTERNATIONAL COOPERATION

Transfer of burn patients across international boundaries has worked well in some mass casualty events, particularly in Europe. The European Union has a "Community Mechanism for Civil Protection," which regulates disaster support among nations both in and outside the European Union. This process covers sending disaster-relief staff to countries with disasters, but it does not address transferring victims to other countries. There are exchange treaties between some countries, and there is actual cross-border hospital cooperation, but there is no general regulation thereof.

Humanitarian Crises

A humanitarian crisis is an event causing critical threats to health, safety, or human well-being, usually over a wide area. For burn injuries, armed conflicts and natural disasters are the likeliest forms. Natural disasters can not only be directly linked to fire (as in wildfires) but also cause burn

injuries through atypical use of energy: When people are not used to open fire but they need it because their electricity resource has failed, burn incidence rises. The same happens when people try to get electricity by throwing wires over power lines. After a severe storm, the increased use of internal-combustion emergency generators and internal-combustion power saws causes a higher rate of burn injuries and of burns related to burn accelerants.[67]

In disasters and humanitarian crises, medical treatment can often begin only after minimal infrastructure and order are reestablished. Where looting or political or religious rivalry occurs, medical work can be dangerous.[68] Therefore, cooperation with security forces, at least in the early stages, may be necessary.[69] Minimum requirements for work are shelter, safe water, food, and electricity.[70] One of the basic problems in medical aid work in disasters and low-resource countries is sterility: There usually is a high rate of infections with hepatitis and HIV, which must not be spread.[71] It may be helpful to conceptualize burn injuries during a humanitarian crisis as follows:

- Those that can be treated with minimal efforts (e.g., by clean dressings and available analgesics).
- Those that are not survivable without specialized care. Such specialized care must first be instituted.
- Those that cannot be treated successfully in this environment. Patients must be transported to facilities where successful treatment can be performed and is funded, or they are deemed futile, and "comfort care" should be provided.

To prepare medical systems for burn treatment during a humanitarian crisis, history provides data on what interventions are most likely to improve outcome at the lowest cost. At the end of World War II, only 50% of young adult patients survived burns of greater than 40% TBSA.[72] Stepwise improvements in survival were the result of the following advances:[73]

- Fluid resuscitation techniques
- Safe blood support
- Topical antibacterial treatment with mafenide acetate or silver-containing products
- Early excision and grafting; cadaver skin as a temporary skin substitute
- Enteral nutrition
- Improvements in mechanical ventilation and general critical care.

In other words, relatively low-cost interventions (e.g., prevention of invasive Gram-negative burn wound infection by use of topical antimicrobial burn creams and basic hygiene) are likely to have a greater impact than some of the higher cost, high-tech interventions.[74]

Conclusions

Recent events have raised worldwide awareness of burn disasters. Ongoing wars and terrorist attacks, along with several indoor fires, have shown that preparedness for such events is necessary.[75,76] No one is immune to such risks. The question is not whether such disasters will happen but when they will happen and how we can cope.

Preparedness requires plans, and it requires staff, stuff, and structure (the three Ss). Plans include international disaster plans, national disaster plans, coordinated disaster plans at the state level, and local disaster plans for locales and institutions. Structure is the national or international health system. Stuff is emergency supplies ready for disasters. Staff includes medical, paramedical, rescue, and technical-relief organizations. On the basis of these plans, legal preconditions must be established, and resources must be planned and funded. Both the planning and the execution require money, which is an investment in a society's future and security.

Burn societies can aid this procedure because they comprise the experts in these fields. Planning without the experts in burn treatment is futile, but working on their own, burn experts lack the resources to plan for mass casualties.

Disaster drills for hospitals and rescue organizations must be performed realistically. Education in burn treatment (e.g., Advanced Burn Life Support (ABLS), Emergency Management of Severe Burns (EMSB)) is essential for effective coping with mass casualties—not only for medical staff but also for hospital administrations. Burn surgeons are scarce in burn disasters, and surgeons are not the only personnel to be trained. We encourage readers to learn from the experiences described in this chapter; we hope that these experiences will motivate them to plan assiduously and to train diligently.

6 Care of Outpatient Burns

CHARLES D. VOIGT, MARIO CELIS, and DAVID W. VOIGT

Introduction

Many small burn injuries can be treated in the outpatient clinic once it is determined that there are no other injuries, complicating medical problems, or suspicion of abuse. As with burn care in the hospital setting, the goals of outpatient burn care are to adequately heal wounds with minimal scarring or deformity, as well as reducing pain, the risk of infection, and impaired function. To achieve these, outpatient burn care encompasses wound management, rehabilitation, and psychosocial support.

Outpatient burn care extends to follow-up treatment of patients with larger burns following discharge. Care for these patients is similar, with evaluation for proper wound healing and monitoring for areas that may need surgical revision, along with ongoing physical and psychosocial therapy and scar control management.

Who Can Be Managed as an Outpatient?

Patients should be carefully evaluated to determine whether outpatient management of the burn would be sufficient for the course of medical treatment. Careful medical history and physical examination will help to guide decision-making whether the patient should be admitted or can be treated as an outpatient. Important factors to note include the extent and depth of burn injury, cause of the burn, associated trauma, and premorbid diseases. Patients who require intravenous fluid resuscitation should be treated in the hospital, as should those in whom it will be difficult to properly manage pain as an outpatient. However, once resuscitated and pain controlled with oral pain medication, subsequent treatment may be performed in the community setting depending upon the severity of the burn injury. The American Burn Association (ABA) provides guidelines to assist in identifying patients who should be referred for treatment at a burn center, and this will be discussed in more detail later (Table 6.1).

PERCENT OF THE BURN

The ABA recommends referral to a dedicated burn center for all patients with greater than 10% total body surface area (TBSA) burn.[1] The TBSA may be estimated by using the Wallace "rule-of-nines"(2), or the "rule-of-palm," which estimates the body surface area involvement by using the size of the patient's palm and fingers, with the thumb extended and all fingers adducted, as a guide to estimate approximately 1% of the TBSA for that patient. The rule-of-palm is useful especially in children who, because of their body proportions, do not follow the rule-of-nines. A more accurate method of estimating burn size is the Lund-Browder chart.[1] It is important to note that hand size may overestimate the size of the burn,[2] and both the rule-of-nines and Lund-Browder chart may have significant error when estimating the burn size of obese patients.[3,4] Therefore, it is important to understand that these methods of determining burn involvement are not exact and to know the limits of your facility and staff.

DEPTH OF THE BURN

The depth of the burn injury is important to note during the evaluation of the patient because it is recommended that any patient with a third-degree burn be referred to a burn center due to the additional care needed. First-degree burns and third-degree, full-thickness burns are relatively easy to identify at the time of presentation. First-degree burns, like sunburns, only involve the epidermis and are dry, painful, and do not blister. Third-degree burns involve the epidermis, dermis, and the subcutaneous tissues. These wounds can appear black, white, or leathery, and they will not blanch to the touch or be sensate or painful (Fig. 6.1). It is still possible to elicit pain because manipulation of a full-thickness burn may stimulate the edges of the burn, which is inflamed and sensate. Second-degree burns can be divided into superficial partial-thickness and deep partial-thickness injuries. The difference between these two can be subtle during the initial evaluation. All partial-thickness burns will be painful and moist and can have blisters (Fig. 6.2). However superficial wounds will have clear fluid in blisters, and deeper wounds may have bloody fluid with late presentation. Superficial wounds will also blanch to pressure as opposed to deeper wounds. Occasionally wounds that appear perfused with ruptured blisters that initially appear to be superficial may progress to a more severe injury due to thrombosis of the small blood vessels in the wound, leading to the wound becoming a deeper injury.[5,6] Superficial partial-thickness wounds will heal within 3 weeks, while deep partial-thickness wounds may take longer to heal or require excision and grafting.

Burn injuries can be divided into three zones (Fig. 6.3). At the point of greatest damage is the zone of coagulation, in which there is irreversible tissue damage. Surrounding this is the zone of stasis, an area of the wound that can potentially necrose with inadequate treatment or heal if the area is properly perfused. Should the patient be underresuscitated, this region of the burn wound may progress to become part of the zone of coagulation. The third zone, at the edge of the burn injury, is the zone of hyperemia, which will likely heal with treatment if the region maintains perfusion and infection is not involved.[7]

Table 6.1 American Burn Association Burn Center Referral Criteria.

BURN INJURIES THAT SHOULD BE REFERRED TO A BURN CENTER INCLUDE:

1. Partial thickness burns greater than 10% total body surface area (TBSA)
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention

Fig. 6.1 Third-degree burn. Note the leathery appearance of this burn.

Fig. 6.2 Second-degree burn.

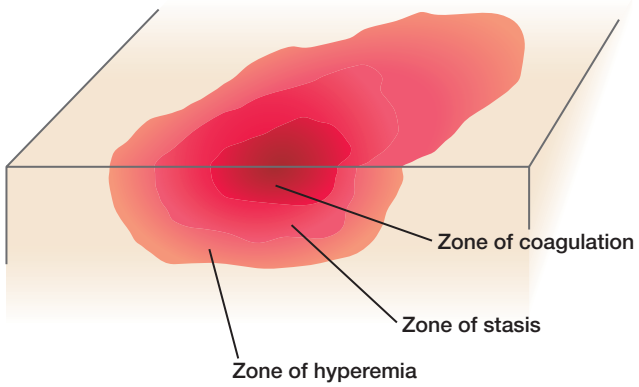

Fig. 6.3 Zones of injury.

DISTRIBUTION OF THE BURN

According to ABA guidelines, burns involving the hands, feet, face, genitalia, and perineum, and those that cross major joints should also be treated in a burn center.[8] Lasting damage to these areas can have a severe impact on patient outcomes. Impairments to the hands can affect grip and can therefore have deleterious effects upon the ability to work or handle activities of daily living. Burns of the feet or those that cross joints can severely limit mobility, while burns to the face can impair vision and the ability to eat, as well as having an emotional impact due to altered appearance. Finally burns to the genitalia and perineum can restrict patient autonomy, hindering urinary and sexual function or the ability to defecate. While burns to these areas may not necessitate specific inpatient treatment, they should be treated at a burn center with the proper resources to handle the special reconstructive and rehabilitative needs of these patients.

Special consideration should be given to burns that are completely circumferential around a part of the body, such as a limb or the trunk. Due to the tissues beneath the wound becoming edematous, circumferential wounds can cause increased pressure, resulting in compartment syndrome and leading to ischemia.[9] The classic symptoms are the five "P's" which are pain, pallor, paresthesia, pulselessness, and paralysis. The physician should have a high index of suspicion for compartment syndrome, which necessitates inpatient treatment.

INJURING AGENT

Electricity

Fatal cardiac dysrhythmias are a major risk following electrical injury; therefore all patients with electrical injuries should have an electrocardiogram (ECG) performed, and all meet the criteria for referral to a burn center. Injuries due to low voltages are usually smaller, therefore, these patients, as long as no ECG abnormalities are present and no loss of consciousness occurred, can be treated as an outpatient should there be no other indication for admission.[10] The presence of dysrhythmia, ECG abnormalities, or a history of loss of consciousness is grounds for admission to the hospital for monitoring. A common means of injury from

Fig. 6.4 Labial burn.

low-voltage energy sources is that of children sucking on a defective electrical cord, resulting in damage to the lips, tongue, gums, or dentition. Such patients may need admission because oral intake may be hindered. Such injuries to the mouth are at risk of resulting in rupture of either the superior or inferior labial arteries, especially from days 4 through 7 post burn (Fig. 6.4). If treating as an outpatient, the caregiver should be educated on this risk and instructed in proper first aid, which consists of pinching the labial commissure between the index finger and thumb.

All patients exposed to high-voltage electricity should be referred to a burn center due to increased deep-tissue injury and subsequent increased amputation rates, organ failure, and mortality as compared to patients with comparable TBSA thermal burns.[10]

Chemicals

While not caused by thermal injury, chemical burns are treated by burn surgeons, and chemical injury is one of the criteria for referral to a burn center. Initial management of a patient with a chemical injury involves brushing off dry chemicals and copious flushing of areas affected by wet chemicals.[11,12] The author recommends flushing until the patient is pain-free, and, with alkaline exposure, until the skin pH is 7, which is the pH of water. The normal skin pH is around 5, but once the pH has reached 7 further injury seems unlikely. As with thermal injuries, prompt irrigation of chemical injuries results in decreased full-thickness injury as well as shorter hospital stays.[13] Irrigation of the chemical burn may need to continue in excess of 1 hour.[14] In the author's experience, it often takes longer in alkaline exposures to reach a pH of 7.

Specific considerations need to be made depending on the causative substance. Phenol compounds do not flush well with water, so polyethylene glycol or vegetable oil followed by water lavage may be used. Water needs to be avoided if metallic sodium or potassium is suspected because the resultant exothermic chemical reaction may worsen the burn injury. Hydrofluoric acid injuries are treated with calcium following water lavage, and a calcium gel can be used to cover the injury. Some recommend that the tissues should be injected with calcium gluconate to alleviate pain as well as prevent tissue necrosis.[15] The author uses intra-arterial calcium gluconate, slowly injecting into the artery supplying the affected part until the patient is pain-free. This may have to be repeated in a few hours. Dermal exposure to hydrofluoric acid results in the absorption of the dissociated fluoride anion and subsequent insoluble salt formation by binding with calcium and magnesium. The patient may then develop hypocalcemia and hypomagnesemia accompanied by hyperkalemia due to potassium efflux from cells. Hypocalcemia is the main cause of death following hydrofluoric acid poisoning via the induction of fatal dysrhythmias. As little as 1% TBSA exposure to 50% concentration hydrofluoric acid or 5% TBSA exposure to any concentration is enough to result in potentially fatal hypocalcemia.[16] Identification of the chemical and communication with local poison control centers is recommended if needed. After the appropriate removal of the causative chemical, treatment is the same as for any other wound.

RESPIRATORY COMPLICATIONS

Inhalation injury is one of the criteria for referral to a burn center, and the physician must have a high index of suspicion concerning inhalation injury and carbon monoxide poisoning based on the circumstances surrounding the burn injury because there may be little to no exterior sign of injury.[17,18] The sequelae of both of these complications may not be initially present and may develop over time. Of note, airway obstruction may occur following burns of the oropharynx, face, or neck as the tissues of the upper airway become edematous.[19] Therefore, observation is warranted if there is any suspicion of inhalation injury.

ASSOCIATED TRAUMA

Due to the often accidental nature of burn injuries, there is frequently concomitant trauma at the time of presentation. Assessment should be made whether the associated trauma or the burn injury is of greater threat to the patient's morbidity or mortality, with the decision of the need for direct admission or stabilization and referral to a burn center made at the discretion of the treating physician.[8]

COMORBID DISORDERS

A comprehensive medical history of the burned patient should be performed to identify those with preexisting medical conditions that would complicate the ability to properly care for the patient in a community setting or have an impact on recovery, morbidity, and mortality.

The stress of the burn may exacerbate previous medical conditions such as diabetes mellitus, asthma, or coronary artery disease.

SOCIAL CIRCUMSTANCES

Proper outpatient management of burns requires that there are sufficient resources available to care for the wound and provide for proper follow-up care. Such resources

include either persons, such as family members or visiting nurses, who can assist with dressing changes, as well as the ability to easily access medical care and receive proper rehabilitation and psychosocial services. Should these resources be unavailable to the patient in the community setting, referral to a burn center should be considered.

Of serious concern when considering the social circumstances surrounding the patient is the possibility that the injury was nonaccidental. If there is any suspicion that the injury to the patient was intentional, admission to the hospital and notification of the proper agencies is warranted for their protection (Figs. 6.5 and 6.6).

HOSPITAL RESOURCES

Available resources should be taken into account in the decision-making process. Pediatric burn patients should be treated at hospitals with qualified personnel and equipment to treat children.

Fig. 6.5 Nonaccidental scald burn. Note the area that is not burned on this child. She was held down in a tub of hot water. The area of the buttocks that is not burned was in contact with the bottom of the tub and the heat had dissipated, thus not burning the child.

Fig. 6.6 Nonaccidental contact burn. This burn was caused by a clothes iron; note the triangular shape.

Management of Minor Burns

COOLING THE BURN

First aid for burn wounds should begin with removing clothing from the burned area and subsequently cooling the wound with cool, running tap water or saline.[20–22] The burn wound should be cooled as close to the time of injury as possible because damage continues while the tissue remains above 44°C.[23] A study by Rajan et al. has shown that even cooling initiated 60 min following burn injury will still have a beneficial effect on burn wound outcomes.[24] Excessive cooling, such as through the use of ice, may actually result in a deeper wound when compared to uncooled burn wounds in an animal model.[25]

Cooling is also important in the first aid of thermal injuries because cooling stabilizes mast cells in the skin, resulting in decreased histamine release and subsequent reduced edema of the burn wound. The application of cool, moist compresses can also be effective in relieving the pain associated with partial-thickness burns.[26–29] While patients with large surface area involvement may experience hypothermia if too aggressively cooled, patients who are eligible to be treated as an outpatient, with a smaller TBSA, should have little risk of this occurring. It is still prudent to monitor the patient's core temperature during active cooling.

A limit to the surface area that is cooled is arbitrary, but a practical limit is about 10% of the TBSA. A recent study concluded that 20 min was the optimal time to cool a burn.[30]

PAIN CONTROL

First-line treatment for pain in the emergency setting is usually narcotics. Intravenous doses of morphine can be given incrementally to titrate for the desired effect. Other pain relief options include acetaminophen with codeine, oxycodone, or similar analgesics that can be used individually or in combination. However due to growing concerns about the overuse of opioids and the risk of addiction and overdose, the physician may consider the use of medications such as acetaminophen or nonsteroidal antiinflammatories (NSAIDs), especially in smaller burns that are more appropriate for outpatient management. Partial-thickness wounds are the most painful burn wounds because the injury leaves the wound without epidermis. The pain is severe initially, but will partially subside in the following hours. During dressing changes or physical activity when the wound is manipulated, pain will again be exacerbated. Wounds with eschar will not be painful unless the eschar is removed or separated, exposing the viable tissue beneath.[31] Therefore additional analgesia may be required during physical activity and dressing changes. Should oral medication be unable to control the patient's pain, the patient should be admitted for adequate pain management. For additional information on management of pain in the burn patient, see Chapter 63.

BLISTERS

There is no clear consensus on the management of blisters, and therefore treatment depends on the experience of the

burn care team. Options for blister management include leaving the blister intact,[32] removing the blistered skin during the initial wound care,[33] removing the blister at a later time,[34] or aspirating the fluid from the blister.[32] Laboratory studies suggest that blister fluid may have detrimental effects via suppression of immunologic responses and inhibited fibrinolysis.[33] Others advocate that the blister can be left intact to serve as a biological wound dressing, with spontaneous resorption of the blister fluid beginning within 1 week. The devitalized skin from a ruptured blister can also be left in place in a similar fashion to serve as a dressing. The author removes blisters that are felt likely to rupture on their own and leaves the others intact, but covers them with an antimicrobial dressing.

CLEANSING THE WOUND

For thermal injuries, cleansing of the burn would should be performed using room temperature to tepid (100°F) sterile water or normal saline with a mild soap. In injuries involving tar or asphalt, cooling should be performed first, and the solidified tar or asphalt should be removed through the use of a solvent. Solvents with affinity for the substance to be removed should be used. One such product is Medi-Sol Adhesive Remover, a nontoxic, nonirritating, citrus-based Category I Medical Device solvent approved by the U.S. Food and Drug Administration (FDA), which has been shown to be effective in the removal of both tar and asphalt.[35] Other options include using polysorbates (a class of emulsifiers), which can be used on their own or in conjunction with topical antibiotics, and topical antibiotics in petroleum jelly. However these options may require multiple applications to be effective.[36,37] The author prefers the use of mineral oil because it is inexpensive and works well without causing additional skin irritation.[38]

TOPICAL AGENTS

Antibacterial agents are used to prevent burn wound infections.[39] Prophylactic use of topical agents such as these have not shown benefit in preventing infections or septicemia versus other dressing options, such as petrolatum-impregnated gauze[40,41]; however the author recommends that these substances should be used when the physician has suspicion that an infection is present. Should topical antimicrobial agents be warranted, there are several options available. A popular agent used in the treatment of burn wounds is 1% silver sulfadiazine, which has antiseptic properties due to the presence of silver, but also results in delayed wound healing.[42,43] This delay in wound healing has been shown to be alleviated through the co-administration of nystatin or aloe vera in an animal model.[44] Use of silver sulfadiazine should be discontinued once reepithelialization is noted because the agent impairs epithelialization. If the wound is covered with eschar, however, silver sulfadiazine may be used with few side effects. Care must be taken that the patient is not allergic to sulfa products or that the patient is not pregnant, nursing, or an infant under 2 months of age due to the risk of kernicterus.

Combinations of antibiotics in ointments have been of increasing interest because there have been no noted effects on wound healing in these medications. Examples include triple-antibiotic ointment (containing neomycin, bacitracin zinc, and polymyxin B sulfate) and Polysporin (containing polymyxin B sulfate and bacitracin zinc), which both have coverage against gram-positive cocci and some aerobic gram-negative bacilli. When using these compounds, small superficial pustules may form on uninjured or healed skin due to yeast. Discontinuation of the compound will clear these pustules. When compared to petrolatum-impregnated gauze alone, the addition of a topical antibiotic ointment may decrease odors. For partial-thickness facial burns, bacitracin can be applied several times a day without a secondary dressing, making it less likely the patient will attract unwanted attention from strangers.

DRESSING THE WOUND

There are few comparative studies concerning available wound dressing options therefore individual preference and comfort will be the determining factors in which option is selected. Wound dressings primarily serve to protect the wound from the outside environment, decrease pain, absorb drainage, and provide a moist environment to promote wound healing. Whatever dressing is used, as long as these qualities are met, the wound should properly heal. As Ambroise Paré said, "*Je le pansai, Dieu le guérit*" ("I treated him, but God healed him").[45]

Management of first-degree wounds may include the use of emollients or light dressings if needed. Follow-up care should monitor how the wound is healing.

Second-degree wounds can be managed with daily washing of the wound, along with the use of emollients and dressings that are changed daily. Alternatively these wounds can be covered with a polyurethane foam dressing, biologic dressing (discussed later), a silver-impregnated dressing, alginate dressing, or a 3% bismuth tribromophenate and USP petrolatum gauze. These allow for longer intervals between dressing changes and outpatient visits, and they are helpful in areas that require long travel times for patients to be seen in the outpatient setting. As with first-degree wounds, follow-up care of second-degree burns should monitor the progression of wound healing. Third-degree wounds, if small, will heal by epithelial ingrowth and contraction. However most will require referral for surgical intervention.

Patients should be seen at follow-up within several days in order to examine the progression of wound healing. The follow-up visit also serves to confirm the patient's adherence to wound care instructions and provides the opportunity to ensure the proper resources are available to the patient to provide an adequate environment for proper healing. Should any concerns arise, changes to the treatment plan, including types of dressing or frequency of visits, may be needed to optimize care. Otherwise, weekly intervals of follow-up visits provide adequate wound observation.

SYNTHETIC WOUND DRESSINGS

Synthetic wound dressings are popular in the treatment of superficial, partial-thickness burn wounds because they reduce pain, reduce healing time, and cost less than their biologic alternatives. There are many products in this category, with the following discussion representing a small

selection of what is available. Choice of dressing is at the discretion of the provider based on personal preference and experience.

Mepitel

Mepitel is a wound contact dressing that adheres to dry skin but not to the wound bed. After application, it can be left in place for up to 2 weeks. Secondary dressings may be placed on top of the Mepitel. These secondary dressings may then be changed when necessary, leaving the Mepitel in place and not disturbing the wound bed.[46] In a comparison with silver sulfadiazine, Mepitel has been shown to decrease healing times in pediatric burn patients.[47]

Mepilex AG

Mepilex AG is a synthetic wound dressing commonly used in the treatment of partial-thickness burn wounds. It is composed of three layers, with a silicone layer facing the wound, an absorbant polyurethane foam layer, and a protective waterproof film to keep the wound environment moist while allowing gases to permeate the dressing.[48] The foam layer in this dressing contains silver sulfate, providing antimicrobial action. After cleansing of the wound, the dressing is cut to size and applied onto the burn wound, followed by wrapping with gauze and elastic bandages to hold the dressing in place. Follow-up visits for dressing changes can be scheduled for every 3–7 days. In a recent randomized study comparing Mepilex AG with silver sulfadiazine, it was shown that a significantly higher number of burn wounds treated with Mepilex AG had healed after 1 week, although overall healing rates were similar.[48] In the same study, patients with Mepilex AG reported less pain associated with dressing changes.

Acticoat

Acticoat is a dressing composed of three layers, with an inner layer of rayon/polyester and outer layers of polyethylene coated with elemental silver. This silver is ionized into its bactericidal form when the dressing is moistened. The dressing can be left in place longer, requiring dressing changes every 3–7 days depending on which form of Acticoat is chosen. The dressing must be kept moist to be active. Studies suggest that Acticoat may reduce healing time when compared with silver sulfadiazine.[49,50]

TheraBond 3D

TheraBond 3D is a woven, silver-impregnated fabric with a perforated wound contact surface. The dressing is designed to allow fluid and exudate from the wound to be transferred through the dressing to an absorbent, secondary dressing. This dressing can be left in place for up to 14 days.[51]

Silverlon

Silverlon is a silver-nylon dressing that has been used extensively in the treatment of burn wounds in the military.[52] Similar to other listed wound dressings, Silverlon may be left in place for 3–7 days between dressing changes.

Suprathel

Suprathel is a newer synthetic burn wound dressing consisting of a thin, porous membrane composed of polylactic acid. The porous nature of the membrane prevents the accumulation of excess wound exudate. When applied to the wound surface, Suprathel becomes translucent, allowing for the wound to be visually inspected for healing and infection without removal of the dressing. The dressing is applied to the burn wound after débridement and is left in place without changing because it will detach on its own as reepithelialization occurs. Petroleum gauze is placed on top of the Suprathel, which is then held in place by gauze and elastic bandages. During follow-up visits, everything except the Suprathel and petroleum gauze may be removed and changed to allow inspection of the wound. In unpublished data from our institution comparing Suprathel with Mepilex AG, Suprathel was shown to be a safe alternative wound dressing with similar healing time; however it has significant advantages, such as reduced pain and decreased wound bed disturbance due to the ability to leave the dressing in place. These results are similar to those reported in comparison with other wound dressings.[53–56]

Hydrocolloid Dressings

Hydrocolloid dressings are composed of cross-linked matrix gelatin, pectin, and carboxymethyl-cellulose and can be formulated in wafers, pastes, or powders. They adhere to the burn wound on their own and provide a moist environment by trapping water in the matrix, thereby promoting wound healing. Compared with 1% silver sulfadiazine, these dressings show improvements in wound healing and reductions in pain and number of dressing changes.[57,58] Such dressings can be used for small partial-thickness burns and can be left in place for several days.

SYNTHETIC TISSUE-ENGINEERED WOUND DRESSINGS

Biobrane

Biobrane is a biosynthetic skin consisting of an outer silicone membrane and an inner nylon mesh bonded with porcine dermal collagen. This dressing allows gases to permeate it, but not liquids or bacteria.[59] This helps to keep the burn wound moist to improve healing, but care must be taken to not cover infected wounds or those with eschar or debris. The wound must also have sensation and appropriate capillary blanching and refill; thus, its use for partial-thickness wounds. When used in this manner, compared to 1% silver sulfadiazine, Biobrane resulted in decreased pain, reduced pain medication requirements, and decreased healing time.[42,60] At the time of writing, Biobrane is not currently available in the United States, but the manufacturer indicates that it, or a newer product called PermeaDerm, will be available shortly.

After cleansing the wound, Biobrane is applied so that it overlaps itself and is fixed to the surrounding unburned skin with sterile strips of tape or with drops of cyanoacrylate adhesive. Then the wound is dressed and splints applied if the wound crosses a joint to prevent shearing. Within a day, the Biobrane should be adherent to the wound surface, although any loose sections can be trimmed and new Biobrane applied. At follow-up, sterile fluid accumulating underneath the Biobrane can be aspirated and purulent fluid drained by opening the Biobrane. After reepithelialization, the Biobrane can be removed gently.

BIOLOGIC WOUND DRESSINGS

Allogenic Amnion

Allogenic amnion is a biologic wound dressing composed of the innermost fetal amniotic membranes whose first reported use was in 1910,[61,62] although its use as a temporary burn wound covering was first described in 1952.[63] Following donor screening, the amniotic membrane is harvested during caesarian section, and the donor tissue is screened for transmissible diseases.[62,64] For additional information on the harvesting of amnion, see Chapter 14. Amnion can be used in the treatment in partial-thickness burns, where it has been shown to promote wound healing, relieve pain, reduce scar formation, and reduce burn wound infections.[62,63,65–70] It can also be used as a temporary dressing to protect a clean, excised wound prior to skin grafting.[71]

Xenograft

In the treatment of partial-thickness burns, porcine xenograft reduces pain and decreases hypertrophic scarring.[72,73] It has been shown to be as effective as either human allograft or human fibroblast-derived temporary skin substitute, with the advantage of being more cost-effective.[74] The application is the same as discussed in the section on Biobrane.

Allograft

The authors do not recommend the use of allograft in small burn wounds, such as those that would be treated in an outpatient setting, due to high cost and limited supply. The application and use is the same as for xenograft, just discussed.

ELEVATION OF THE BURNED PART

Edema is one of the main sources of pain following burn injury, therefore reduction of this edema is an effective method of pain control. Injured extremities may be kept immobile by the patient in an effort to reduce discomfort, but this may result in exacerbation of edema and therefore pain. To relieve edema, injured parts should be placed slightly above the level of the heart. Regular exercise and physical therapy are also important factors in reducing edema. Should edema persist for longer than 3 days in patients with small burns, the likely culprit is immobilization and dependent positioning.

INFECTION AND USE OF SYSTEMIC ANTIBIOTICS

The use of prophylactic topical or systemic antibiotics has not been shown to decrease the incidence of burn wound infections, sepsis, or mortality[40,75] and should therefore only be used when there is clinical suspicion for infection. Although the risk of developing sepsis is quite low in patients who are able to be treated in the outpatient setting, patients should be instructed in the warning signs for infection before discharge. Patients should be advised to contact the physician should they experience temperatures higher than 38°C, malaise, increasing pain, erythema, foul odor, or anorexia.

Wounds should be examined both at follow-up by the physician and by those performing dressing changes in the outpatient setting to monitor for changes in the appearance. Early discolorations are likely to occur in the first few days following injury after injured blood vessels thrombose and wound perfusion is decreased. Discolorations, including black or gray spots, are suspicious for infection, and patients should be admitted and wound biopsies and microbiological studies performed for proper treatment of the infection.[76]

VACCINATIONS

All burn wounds are susceptible to tetanus infection.[77] If the patient has not received a dose of tetanus toxoid within the past 5 years, then tetanus immunization should be administered. For patients who have received less than three doses or have unknown immunization status, both tetanus toxoid and tetanus immune globulin can be given.[78]

INSTRUCTIONS AND FOLLOW-UP CARE

Before discharge from emergency care, patients should be instructed in proper techniques for wound care, positioning, and physical therapy. Warning signs of infection should also be described, and patients should be instructed about whom to contact for appropriate medical care if signs of infection occur. Finally physicians should ensure that patients have adequate pain medication and wound dressings.

DEFINITIVE WOUND CLOSURE

The goal for wound closure is to have all burn wounds healed within 1 month, which is easily attainable by the outpatient with smaller burns. Burn wounds that heal spontaneously within 3 weeks will have better outcomes, such as improved elasticity and reduced risk of hypertrophic scarring or pigmentation changes. Poorly healing wounds that take longer, however, have increased risk of scarring[79] or pigmentation alterations. In addition, wounds that take a very long time to heal spontaneously may have unstable epithelium. Careful attention should be paid to the rate of wound healing during follow-up appointments because wounds that are healing slowly may have improved outcomes with excision of necrotic and granulation tissue with subsequent grafting.[80–82] At 10 days after burn injury, partial-thickness wounds without necrotic tissue that show evidence of squamous reepithelialization should heal within the month. Reepithelialization can be recognized by small opalescent islands of epithelium scattered across the wound. If these features are not seen, the partial-thickness wound may be a deeper injury that would benefit from surgery. The author tells patients, "If your burn heals in less than 2 weeks, it is better off without an operation. If it takes more than 3 weeks, it is better off with an operation."

PRURITUS

Itching is a common sequela of healing burn wounds and may persist after the wound has healed. Pruritus causes significant distress in burn patients, and resultant scratching may result in reopened wounds. Pruritus is more common in children, most frequently affects the lower extremities compared to the upper extremities, and rarely involves the

face.[83] Environmental triggers may bring on or exacerbate pruritus, including heat, physical activity, or stress. For most patients, the pruritus is worst immediately following wound healing and diminishes after healing is complete, sometimes lasting up to 18 months. In those with persistent itching, one should consider an ongoing psychosocial trigger.

Pruritus is a primary sensory modality that has multiple causative factors, such as the increased synthesis of histamine in burn wounds, as well as bradykinin and endopeptides.[84–86] Management of itching may include antihistamines, cool compresses, or lotions as needed. Most commonly, the initial treatment is diphenhydramine hydrochloride,[83] which also provides mild sedation that may be of benefit. Other antihistamines, such as cyproheptadine or hydroxyzine hydrochloride, may also be used as the physician feels appropriate. Analgesics may alter the perception of itching, and combinations of the two medications may be considered. Environmental treatments may include air conditioning, cool compresses, and loose fitting, soft cotton clothing. Other options include aloe vera, which is antiinflammatory and antimicrobial,[87] or skin moisturizing creams that are free of alcohol. Penicillin may even be used in the management of pruritus; Phillips and Robson[88] noted in a study of post-burn hypertrophic scars that these scars were more frequently colonized with β-hemolytic streptococcus, *Staphylococcus aureus*, and *S. epidermidis.* Because inflammation is a major source of pruritus, 250 mg of oral penicillin was given twice daily along with topical aloe vera to reduce itching. For further information on the treatment of pruritus in burns, see Chapter 63.

TRAUMATIC BLISTERS IN REEPITHELIALIZED WOUNDS

During reepithelialization, the thin epithelium may be easily damaged by itching or trauma brought about by, for example, movement, resulting in traumatic blisters that may rupture. As healing progresses, this epithelium will strengthen and traumatic blisters will stop occurring. Ruptured blisters can be left exposed to form a crust, or a light dressing may be applied.

REHABILITATIVE PHYSICAL CARE

Prior to discharge, plans for rehabilitative care should be made for the patient to ensure that there is access to this necessary part of burn treatment. Although burns treated in the community tend to be of smaller area, rehabilitation should still be utilized to preserve and restore both strength and function in the burned area.[89] The patient should also be instructed in range of motion and strength exercises to perform on his or her own.

Strength, range of motion, and function should be continually assessed at follow-up visits, and if there are compliance issues or worsening function, referral for physical and occupational therapy may be warranted. Depending on the location of the burn injury, supervised therapy might be indicated initially, such as in burns that cross joints or those that involve the hands or feet. When treating those with burns of the face, speech pathologists may need to be referred. Just as with patients treated in the hospital, outpatients should be monitored for hypertrophic scarring and contractures, as surgical intervention may be required.[89]

Outpatient Treatment of Moderate and Major Burns

Some patients with larger burns may be treated with outpatient care later in the course of their treatment.[90] Physicians may opt for this course due to the advantages of decreased costs and increased physical and emotional comfort for the patient, along with decreased exposure to drug-resistant organisms. Outpatient treatment may be appropriate for patients when intravenous fluid resuscitation has been completed, the patient is able to receive adequate nutrition enterally, pain is controlled, and there is no present wound or systemic infection. Should these conditions be met, the physician may opt to complete wound care and physical and occupational therapy in the ambulatory setting.

Conclusion

This chapter discussed the options for outpatient management of the burn patient. Depending on the expertise of the treating physician and the resources of the facility, some or all the options may be available. If the patient fails to meet criteria for referral to a burn center and does not require admission for another reason, outpatient management is appropriate, following these recommendations for immediate treatment:

- Wash the wound with soap and water.
- Dress with an appropriate dressing, as discussed earlier.
- Place the wound in Xeroform with a secondary dressing; having the patient follow-up in 24–48 hours is reasonable.
- If the Xeroform is adherent, it can be left in place and trimmed as it lifts off; if not, an alternate dressing should be considered.
- Another option is to use a silver-impregnated dressing.
- Depending on the dressing selected, the patient may follow-up in 3–7 days.
- If resources are available, daily to twice-daily wound cleansing and dressing changes may be utilized with follow-up in 1–3 days.
- Burns that do not heal in 2 weeks should be referred to a designated burn center for evaluation.

7 Prehospital Management, Transportation, and Emergency Care

RONALD P. MLCAK, MICHAEL C. BUFFALO, and CARLOS J. JIMENEZ

Introduction

Advances in trauma and burn management over the past three decades have resulted in improved survival and reduced morbidity from major burns. The cost of such care, however, is high; it requires conservation of resources such that only a limited number of burn intensive care units with the capabilities of caring for such labor-intensive patients can be found; hence, regional burn care has evolved. This regionalization has led to the need for effective prehospital management, transportation, and emergency care. Progress in the development of rapid, effective transport systems has resulted in marked improvement in the clinical course and survival for victims of thermal trauma.

For burn victims, there are usually two phases of transport. The first is the entry of the burn patient into the emergency medical system with treatment at the scene and transport to the initial care facility. The second phase is the assessment and stabilization of the patient at the initial care facility and transportation to the burn intensive care unit.[1] With this perspective in mind, this chapter reviews current principles of optimal prehospital management, transportation, and emergency care.

Prehospital Care

Immediate burn care by first responders is important and can vastly alter outcomes, and it can significantly limit burn progression and depth. The goal of prehospital care should be to ease the burning process as well as prevent further complications and secondary injuries from burn shock. Identifying burn patients appropriately for immediate transfer is an important step in reducing the morbidity and mortality.[2] Prior to any specific treatment, a patient must be removed from the source of injury and the burning process stopped. As the patient is removed from the injuring source, care must be taken so that a rescuer does not become another victim.[3] All caregivers should be aware of the possibility that they may be injured by contact with the patient or the patient's clothing. Universal precautions, including wearing gloves, gowns, masks, and protective eye wear, should be used whenever there is likely contact with blood or body fluids. Burning clothing should be removed as soon as possible to prevent further injury.[4] It has been shown that prompt removal of clothing after scald injuries may reduce postburn morbidity.[5] All rings, watches, jewelry, and belts should be removed because they can retain heat and produce a tourniquet-like effect with digital vascular ischemia.[5] If water is readily available, it should be poured directly on the burned area. Early cooling can reduce the depth of the burn and reduce pain, but cooling measures must be used with caution since a significant drop in body temperature may result in hypothermia with ventricular fibrillation or asystole.[6] Cold water treatment over large body surfaces has been shown to trigger clinically relevant hypothermia.[6] Ice or ice packs should never be used because they may cause further injury to the skin or produce hypothermia.

Initial management of chemical burns involves removing saturated clothing, brushing the skin if the agent is a powder, and irrigation with copious amounts of water, taking care not to spread chemical on burns to adjacent unburned areas. Irrigation with water should continue from the scene of the accident through emergency evaluation in the hospital. Efforts to neutralize chemicals are contraindicated due to the additional generation of heat, which would further contribute to tissue damage. A rescuer must be careful not to come in contact with the chemical (i.e., gloves, eye protectors, etc. should be worn).

Removal of a victim from an electrical current is best accomplished by turning off the current and by using a nonconductor to separate the victim from the source.[7]

Onsite Assessment of a Burned Patient

Assessment of a burned patient is divided into primary and secondary surveys. In the primary survey, immediate life-threatening conditions are quickly identified and treated. The primary survey is a rapid, systematic approach to identify life-threatening conditions. The secondary survey is a more thorough head-to-toe evaluation of the patient. Initial management of a burned patient should be the same as for any other trauma patient, with attention directed at airway, breathing, circulation, and cervical spine immobilization.

PRIMARY ASSESSMENT

Exposure to heated gases and smoke from the combustion of a variety of materials results in damage to the respiratory tract. Direct heat to the upper airways results in edema

formation, which may obstruct the airway. Initially, 100% humidified oxygen should be given to all patients when no obvious signs of respiratory distress are present. Upper airway obstruction may develop rapidly following injury, and the respiratory status must be continually monitored in order to assess the need for airway control and ventilator support. Progressive hoarseness is a sign of impending airway obstruction. Endotracheal intubation should be done early before edema obliterates the anatomy of the area. Intubation should be performed by the most experienced provider.[4,8]

The patient's chest should be exposed in order to adequately assess ventilatory exchange. Circumferential burns may restrict breathing and chest movement. Airway patency alone does not assure adequate ventilation. After an airway is established, breathing must be assessed in order to ensure adequate chest expansion. Impaired ventilation and poor oxygenation may be due to smoke inhalation or carbon monoxide intoxication. Endotracheal intubation is necessary for unconscious patients, for those in acute respiratory distress, or for patients with burns of the face or neck that may result in edema, which causes obstruction of the airway.[4,8] The nasal route is the recommended site of intubation. Assisted ventilation with 100% humidified oxygen is required for all intubated patients.

Blood pressure is not the most accurate method of monitoring a patient with a large burn because of the pathophysiologic changes that accompany such an injury. Blood pressure may be difficult to ascertain because of edema in the extremities. A pulse rate may be somewhat more helpful in monitoring the appropriateness of fluid resuscitation.[9]

If a burn victim was in an explosion or deceleration accident, there is the possibility of a spinal cord injury. Appropriate cervical spine stabilization must be accomplished by whatever means necessary, including a cervical collar to keep the head immobilized until the condition can be evaluated.

SECONDARY ASSESSMENT

After completing a primary assessment, a thorough head-to-toe evaluation of the patient is imperative.[10] A careful determination of trauma other than obvious burn wounds should be made. As long as no immediate life-threatening injury or hazard is present, a secondary examination can be performed before moving the patient; precautions such as cervical collars, backboards, and splints should be used.[11] Secondary assessment should examine the patient's past medical history, medications, allergies, and the mechanisms of injury. Any suspicion of nonaccidental injury should lead to immediate admission of a child to the hospital, irrespective of how trivial the burn injury is, and notification of social services.[12]

There should never be a delay in transporting burn victims to an emergency facility due to an inability to establish intravenous (IV) access. If the local/regional emergency medical system (EMS) protocol prescribes that an IV line is started, then that protocol should be followed. The American Burn Association recommends that if a patient is less than 60 min from a hospital, an IV is not essential and can be deferred until a patient is at the hospital. If an IV line is established, Ringer's lactate (LR) solution should be infused at the following rates:

- 14 years and older: 500 mL/h
- 6–13 years old: 250 mL/h
- 5 years and younger: 125 mL/h

Prehospital care of wounds is basic and simple because it requires only protection from the environment with an application of a clean dressing or sheet to cover the involved part. Covering wounds is the first step in diminishing pain. If it is approved for use by local/regional EMS, narcotics may be given for pain, but only intravenously in small doses and only enough to control pain.[13] It has been shown that despite training of medical staff, provision for analgesia for children with burns is lacking and needs further clarification.[14] Intramuscular (IM) or subcutaneous routes should never be used because fluid resuscitation could result in unpredictable patterns of uptake.[5] No topical antimicrobial agents should be applied in the field.[5,15] The patient should then be wrapped in a clean sheet and blanket to minimize heat loss and to control temperature during transport.

Transport to Hospital Emergency Department

Rapid, uncontrolled transport of a burn victim is not the highest priority, except in cases where other life-threatening conditions coexist. In the majority of accidents involving major burns, ground transportation of victims to a hospital is available and appropriate. Helicopter transport is of greatest use when the distance between an accident and a hospital is 30–150 miles or when a patient's condition warrants.[15] Whatever the mode of transport, it should be of appropriate size and have emergency equipment available as well as trained personnel, such as a nurse, physician, paramedic, or respiratory therapist.

An estimate of burn size and depth assists in making a determination of severity, prognosis, and disposition of a patient. Burn size directly affects fluid resuscitation, nutritional support, and surgical interventions. The size of a burn wound is most frequently estimated by using the rule-of-nines method (Fig. 7.1). The American Burn Association identifies certain injuries as usually requiring a referral to a burn center. Patients with these burns should be treated in a specialized burn facility after initial assessment and treatment at an emergency department. Questions about specific patients should be resolved by consultation with a burn center physician (Box 7.1).[4,16]

Keeping the Patient Warm and Dry

Hypothermia is detrimental to traumatized patients and can be avoided or at least minimized by the use of sheets and blankets. Wet dressings should be avoided.

Pain Control

The degree of pain experienced initially by the burn victim is inversely proportional to the severity of the injury.[11] No medication for pain relief should be given intramuscularly or subcutaneously. For mild pain, acetaminophen 650 mg orally every 4–6 hours may be given. For severe pain, morphine, 1–4 mg intravenously every 2–4 hours, is the drug

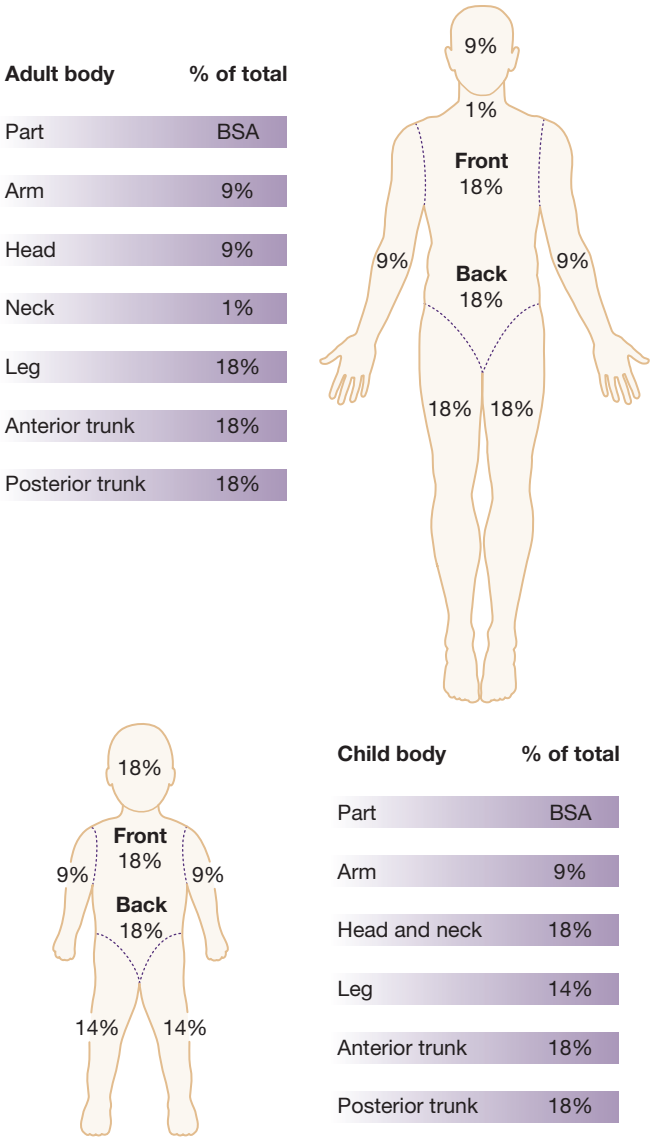

Fig. 7.1 Estimation of burn size using the rule-of-nines. (From American Burn Association. *Advanced Burn Life Support Providers Manual*. Chicago, IL: American Burn Association; 2011)

Box 7.1 Criteria for Transfer of a Burn Patient to a Burn Center

- Second-degree burns >10% total body surface area (TBSA)
- Third-degree burns
- Burns that involve the face, hands, feet, genitalia, perineum, and major joints
- Chemical burns
- Electrical burns including lightning injuries
- Any burn with concomitant trauma in which the burn injuries pose the greatest risk to the patient
- Inhalation injury
- Patients with pre-existing medical disorders that could complicate management, prolong recovery, or affect mortality
- Hospitals without qualified personnel or equipment for the care of critically burned children

From American Burn Association. Advanced Burn Life Supporters Manual. *Chicago, IL: American Burn Association; 2011.*

of choice, although meperidine (Demerol) 10–40 mg by IV push every 2–4 hours may be used.[5] Recommendations for tetanus prophylaxis are based on the patient's immunization history. All patients with burns should receive 0.5 mL of tetanus toxoid. If prior immunization is absent or unclear, or if the last booster was more than 10 years ago, 250 units of tetanus immunoglobulin is also given.[5]

Transferring a Burn Patient

The appearance of burned skin is rather obvious and has the potential to mask or cover any other potential injuries that the burn patient could have. The burn patient is a trauma patient with burns and should be promptly and effectively evaluated to include other potential injuries. It is important to establish effective communication between the transferring unit and the receiving center. The American Burn Association has referral guidelines that identify those patients needing to be transferred to a burn center.[7,16]

Once the need to transfer the patient is identified, the transferring process begins. The doctor-to-doctor referral process starts with the initial care facility. Available phone numbers and doctor information should be available to centers, and the center should promptly call and ask for all the information needed for the transfer.

The referring physician should give a brief and concise history of the event that includes the time of injury and all resuscitation efforts prior to the call. The ABCs of trauma resuscitation should be discussed and the most current vital signs and physical examination findings should be presented. The accepting facility should then fill out an intake form that details all the information. Understanding the patient's current status is essential for a successful and uneventful transfer. It is imperative that physicians participate in the process by adding to the already available information gathered by other personnel.

Transferring a patient without the needed information can potentially lead to bad outcomes and/or unnecessary expense. For example, a burn patient with an underlying anoxic brain injury could be transferred to a burn center when instead the diagnosis of brain death could have been made at the initial care facility.

Physicians can access patient information utilizing different technologies. Although a doctor-to-doctor phone call is preferred by many, today's technology allows patient data, including pictures and laboratory results as well as any other clinical information needed to further assess the patient's needs, to be transferred.[17] While some physicians still prefer the immediacy of the telephone, secure electronic messaging tools are beginning to supplement phone calls and beepers to facilitate communication among physicians.[7,18]

Privacy and Security Issues

Perhaps the most fundamental choice physicians must make when selecting tools to communicate electronically with each other and with patients is how they will manage the privacy and security of the information exchanged.

The Health Insurance Portability and Accountability Act (HIPAA) is technology neutral, in that it does not require any set form of encryption or information safeguarding. It is also scalable, in that it allows small practices to do what they can afford to do without requiring them to purchase expensive communication security systems.[17,19]

For electronic communications, the physician should have an informed consent form signed by each patient specific to the form of communication being used, such as e-mail. The form should verify the patient's e-mail address; should discuss the security risks involved (e.g., that other parties on the patient's end might have access to their e-mail accounts and that standard [unencrypted, nonsecure] e-mail can be intercepted by unintended parties); should discuss allowable content of the communication; and should include a provision to hold the physician harmless if security is breached.

While there is no private right of action under the HIPAA (i.e., a patient cannot sue physicians for breach of HIPAA's privacy or security provisions), the federal agencies that oversee the HIPAA have recently announced plans to step up their audits, and they could conduct an inquiry if a patient files a complaint. Although federal investigations seem more likely to focus on hospitals than physician offices, carelessness could also have legal repercussions. For example, information could be sent to the wrong recipient because of failure to verify the address field before sending the message. Physicians using standard e-mail should use as many practical safeguards as possible to minimize liability exposure. This could include a privacy and security disclaimer footer on each e-mail, requesting the patient's permission before continuing to respond to certain issues by e-mail, limiting the amount of medical detail in the messages, and password-protecting e-mail access on office and home workstations, as well as on portable devices such as PDAs and Blackberries, in case they are lost.

Another way to alleviate security or HIPAA compliance concerns is to leave out protected health information (PHI) in standard e-mail: data that both personally identifies a patient and reveals a specific diagnosis or condition. While standard e-mail works and is offered free of charge by service providers such as Yahoo, Gmail, Comcast, and many others, vendors of secure messaging networks are quick to point out multiple deficiencies (Box 7.2).

Box 7.2 Deficiencies of Electronic Mail Services for the Transmission of Medical Information

- Lack of encryption or authentication
- Can be used by anyone to access a physician if they simply know the physician's e-mail address
- Have no "terms of service" or legal disclaimers to protect physicians
- Can easily expose patient e-mail addresses and identities to unintended third parties
- Can breach patient privacy by using employer e-mail networks
- Offer no charge capture function
- Have no template or medical records features
- Lack of consistency with HIPAA or medical liability insurance company standards

Whether or not electronic communication is encrypted or secure, physicians should guard against being lulled by the casual nature of e-mail which, unlike a conversation or phone call, is not erased from a computer's hard drive when deleted and is potentially discoverable in litigation.

In the future, the use of telemedicine may allow more accurate and timely access to critical information that may adjunct the care given during the golden hour of trauma care. In the absence of a skilled burn specialist, the use of telemedicine services can expedite the process and aid in the treatment plan. Telemedicine has already gained acceptance and support from many public funding projects. It is considered user-friendly, almost infinitely adaptable, and cost effective.[20]

Transportation Guidelines

The primary purpose of any transport teams is not to bring a patient to an intensive care unit but to bring that level of care to the patient as soon as possible. Therefore, the critical time involved in a transport scenario is the time it takes to get the team to the patient. The time involved in transporting a patient back to a burn center becomes secondary. Communication and teamwork are the keynotes to an effective transport system.

When transportation is required from a referring facility to a specialized burn center, a patient can be fairly well stabilized before being moved. Initially, the referring facility should be informed that all patient referrals require physician-to-physician discussion. Pertinent information needed includes patient demographic data, time, date, cause and extent of burn injury, weight and height, baseline vital signs, neurological status, laboratory data, respiratory status, previous medical and surgical history, and allergies.

A referring hospital is informed of specific treatment protocols regarding patient management prior to transfer. To ensure patient stability, the following guidelines are offered:

- Establish two IV sites, preferably in an unburned upper extremity, and secure IV tubes with sutures.
- Insert a Foley catheter and monitor for acceptable urine output (30 mL/h adult; 1 mL/kg/h child.
- Insert a nasogastric tube and ensure that the patient remains NPO.
- Maintain body temperature between 38°C and 39.0°C (taken rectally).
- Stop all narcotics.
- For burns less than 24 hours old, only use LR solution. The staff physician will advise on the infusion rate, which is calculated based on the percentage of total body surface area burned.

Following physician-to-physician contact and collection of all pertinent information, the physicians will make recommendations regarding an appropriate mode of transportation. The options are based on distance to a referring unit, patient complexity, and comprehensiveness of medical care required. Options include:

- Full medical intensive care unit transport with a complete team consisting of a physician, a nurse, and a respiratory therapist from the burn facility

- Medical intensive care transport via fixed wing aircraft or helicopter with a team from the referring facility
- Private plane with medical personnel to attend patient
- Commercial airline
- Private ground ambulance
- Transport van with appropriate personnel.

TRANSPORT TEAM COMPOSITION

Because stabilization and care for a burned patient is so specialized, team selection is of the utmost importance. Traditionally, these patients were placed in an ambulance with an emergency medical technician and transported with little effort made to stabilize the patient prior to transfer. As levels of care and technology have evolved, the need for specialized transport personnel has increased. Today most transport teams are made up of one or more of the following healthcare members: a registered nurse, a respiratory therapist, and/or a staff physician or house resident. Because a large number of burned patients require some type of respiratory support due to inhalation injury or carbon monoxide intoxication, the respiratory therapist and nurse team have proved to be an effective combination. The background and training of nurses and therapists differ in many ways, so such a team provides a larger scope of knowledge and experience when both are utilized. Team members ideally should be cross-trained so that each member can function at the other's level of expertise.

TRAINING AND SELECTION

Because the transport team will work in a high-stress environment, often with life-or-death consequences, these individuals must be carefully selected. The selection process should involve interviews with a nursing administrator, a director of respiratory therapy, and a medical director of a transport program.

Minimum requirements for transport team members should include:

- Transport nurse qualifications:
  - a registered nurse;
  - minimum of 6 months burn care experience;
  - current cardiopulmonary resuscitation (CPR) certification;
  - advanced cardiac life support (ACLS) or pediatric advanced life support (PALS) certification;
  - ability to demonstrate clinical competency;
  - observation of two transports;
  - a valid passport for international response.
- Transport respiratory therapist qualifications:
  - registered respiratory therapist with 6 months burn care experience;
  - licensed by appropriate regulatory agency as a respiratory care practitioner;
  - have current BLS;
  - ACLS or PALS certification;
  - ability to demonstrate clinical competency;
  - observation of two transports;
  - demonstrate a working knowledge of transport equipment;
  - a valid passport for international response.

Because all the care rendered by a transport team outside a hospital is given as an extension of care from a transporting/receiving facility, specific steps must be taken to protect staff and physicians from medical liability and to provide consistent care for all patients. Strict protocols are used to guide all patient care; team members should be in constant communication with an attending physician regarding a patient's condition and the interventions to be considered. Team members must be proficient in a number of procedures that may be needed during transport or while stabilizing a patient prior to transport. To keep up with current technology and changes, team members should be included in discussions of recent transports and current management techniques so that they can discuss patient care issues, receive ongoing in-service education, and participate in a review of the quality of transports.

MODES OF TRANSPORTATION

Once the need for transport of a burned patient is established, the decision must be made concerning what type of transportation vehicle is to be used (Table 7.1). There are two models of transport commonly used: ground (ambulance/transport vehicle), air (helicopter, fixed wing), or a combination of both. Factors to be considered when selecting a mode of transportation are the condition of the patient and the distance involved. The level of the severity of the burn mandates the speed with which the team must arrive in order to stabilize and transport a patient.

Ground Transport

Ground transport should be considered to cover distances of 70 miles or less; however sometimes a patient's condition may require air transport, particularly helicopter transport, even though the distance is within the 70-mile range. The ground transport vehicle should be modified with special equipment needed for intensive care transport, and there must be enough room to comfortably seat team members and hold equipment.

Air Transport

Air transport is used primarily when long distances or the critical nature of an injury separate a team from a patient. Air transport does, however, present its own unique set of problems. Aviation physiology is a specialty unto itself, and the gas laws play an important role in air transport and must be taken into consideration.

Dalton's law states that, in a mixture of gases, the total pressure exerted by the mixture is equal to the sum of the pressures each would exert alone.[21] This is important when changing a patient's altitude because as altitude increases, barometric pressure decreases. The percentage of nitrogen, oxygen, and carbon dioxide remain the same, but the partial pressures exert change.[22]

Altitude is an important factor in the oxygenation of a transported patient, and constant monitoring by a team is required under such circumstances. Boyle's law states that the volume of gas is inversely proportional to the pressure to which it is subject at a constant temperature. This gas law significantly affects patients with air leaks and free air in the abdomen because, as altitude increases, the volume of air in closed cavities also increases.[23] For this reason, all

Table 7.1 Transport Criteria: Mode and Team Composition, Burns ≤6 Days Postburn

Weight (kg)	% Burn	Distance (miles)	Team[a]	Transport Mode
≤3	Any	≤75	C	Van, helicopter
		76–250	C	Turboprop airplane
		≥251	C	Learjet
3.1–20	≤10	≤75	N-RT	Van, helicopter
		76–500	N-RT	Commercial flight or turboprop airplane
		≥501	N-RT	Commercial airplane or Learjet
	>10	≤75	C	Van, helicopter
		76–250	C	Turboprop airplane
		≥251	C	Learjet
≥20	≤20	≤75	N	Commercial flight or turboprop airplane
		76–500	N-RT	
		≥501	N-RT	Commercial airplane or Learjet
	>20	≤75	N	Van, helicopter
		76–500	C	Turboprop plane
		≥501	C	Jet

If any of the following criteria exist, the transport shall be changed to the fastest mode with a complete team:

- depressed mental status;
- drug depression;
- respiratory support;
- unstable cardiovascular system;
- presence of associated diseases;
- decreased urine output/unresponsiveness to appropriate fluid administration;
- absent or marginal venous access;
- hypothermia unresponsive to corrective measures.

[a]C, complete team (doctor, nurse, respiratory therapist); N, nurse; RT, respiratory therapist.

air that can be reached should be evacuated prior to an increase in altitude. Intrathoracic air and gastric air must be removed via functional chest tubes or nasogastric tubes and periodically checked during transport. Other factors that should be considered during air transport are reduced cabin pressure, turbulence, noise and vibration, changes in barometric pressure, and acceleration/deceleration forces. Physiologic changes that affect a patient and team members include middle ear dysfunction, pressure-related problems with sinuses, air expansion in a gastrointestinal tract, and motion sickness. Utilizing transport vehicles that have pressurized cabins can reduce or eliminate most of these problems.[21–23]

Helicopters and Fixed-Wing Aircraft. Helicopters and fixed-wing aircraft have both advantages and disadvantages related to patient care. Helicopters are widely used for short-distance medical air transport. Medical helicopters, because they are usually based on hospital premises, have no need to use airport facilities or ambulance services and therefore reduce team response time. Helicopters are able to land close to a referring hospital. Additionally, helicopters provide ease in loading and unloading patients and equipment.[24] The disadvantages of helicopter transport include its limited range, usually less than 150 miles,[24] and its nonpressurized cabin, which limits the altitude at which patients can be safely carried. The low-altitude capabilities also subject the aircraft to variability in weather (i.e., fog, rain, and reduced visibility); therefore, helicopter flights experience much more interference due to weather. Other disadvantages include noise, vibrations, reduced air speed, small working space, lower weight accommodation, and high maintenance requirements.[24]

When long distances must be traveled (more than 150 miles) or when increased altitude is necessary, fixed-wing aircraft are considered a viable mode of transport for patients. The advantages of using fixed-wing aircraft include long-range capabilities, increased speed, ability to fly in most weather conditions, control of cabin pressure and temperature, larger cabin space, and more liberal weight restrictions. Disadvantages of fixed-wing aircraft include the need for an airport with adequate runway length, difficulty in loading and unloading patients and equipment, and the pressure of air turbulence and noise.

EQUIPMENT

Because medical equipment used in intensive care units has evolved tremendously in the past 10 years, there is no reason that these advances should not be extended to the equipment used in a transport program. The transport team must be able to provide ICU-level care whenever needed. Most hospitals are well stocked and able to provide necessary supplies for initial patient stabilization and resuscitation; however, specialty items relating to the care of burn patients may not be present or adequate to meet the needs of burn victims. It is imperative that adequate equipment be available to handle any situation that may arise during a transport process (Fig. 7.2). Extra battery packs and electrical converters on fixed-wing aircraft are recommended

Fig. 7.2 Typical equipment used in transport of a patient.

due to long transport times and delays caused by unforeseeable circumstances of weather or logistics.

Portable Monitor

A portable electrocardiogram (ECG) monitor capable of monitoring two pressure channels should accompany all patients in transport. This allows for continuous monitoring of heart rate, rhythm, and arterial blood pressure. The second pressure channel may be used for patients with a pulmonary artery catheter or those who need intracranial pressure monitoring. This monitor should be small and lightweight but able to provide a display bright enough to be seen from several feet away. The monitor should have its own rechargeable power supply that continuously charges while connected to an alternating current (AC) power supply. One suitable unit is the Protocol Systems Propaq 106 portable monitor. This monitor has two pressure channels; it provides a continuous display of ECG; heart rate; and systolic, diastolic, and mean blood pressure; it can display temperature and oxygen saturation; and it is also capable of operating a non invasive blood pressure cuff. High and low alarms for each monitored parameter can be set, silenced, or disabled by a trained operator.

Infusion Pump

Continuous delivery of fluids and pharmacological agents must not be interrupted during transport. Infusion pumps can be easily attached to stretchers and are usually capable of operating for several hours on internal batteries. These devices should have alarms to warn of infusion problems and should be as small and lightweight as possible.

Ventilator

Size, weight, and oxygen consumption are the primary concerns in selecting transport ventilators. A weight under 5 pounds (2.2 kg) is desirable, and a ventilator's dimensions should make it easy to mount or to place on a bed. Orientation of controls should be along a single plane, and inadvertent movement of dials should be difficult.[23] The ventilator breathing circuit and exhalation valve should be kept simple, and incorrect assembly should be impossible. One type of transport ventilator that has become popular is the TXP transport ventilator. The TXP transport ventilator (Percussionaire Corporation, Sand Point, ID) is a portable pressure-limited time-cycled ventilator and is approved for in-flight use by the US Air Force. The transport ventilator weighs 1.5 pounds (0.68 kg), can be set to provide respiratory rates of between 6 and 250 breaths per minute and provides tidal volumes of between 5 and 1500 cc. This ventilator is powered entirely by oxygen and requires no electrical power. All timing circuit gases are delivered to the patient so that operation of the ventilator does not consume additional oxygen. The inhale to exhale (I:E) ratios are preset at the factory from 1 : 1 at frequencies of 250 cycles per minute to 1 : 5 at a rate of 6 cycles per minute. As a result, breath stacking and undesired overinflation due to air trapping may be avoided.[23–25]

Stabilization

One of the primary reasons for a specialized transport team is so that a patient can be transported in as stable condition as possible. Current practice has evolved to embrace the concept that events during the first few hours following burn injury may affect the eventual outcome of the patient; this is especially true with regard to fluid management and inhalation injury. Stabilization techniques performed by the transport team have been expanded to include procedures that are usually not performed by nursing or respiratory personnel. Such techniques include interpreting radiographs and laboratory results and then conferring with fellow team members, referring physicians, and the team's own medical staff to arrive at a diagnosis and plan for stabilization. The transport team may perform such procedures as venous cannulation, endotracheal intubation, arterial blood gas interpretation, and management of mechanical ventilators. Team members may request new radiographs to assess catheter or endotracheal tube placement or to assess the pulmonary system's condition. Team members may aid in the diagnosis of air leaks (pneumothorax) and evacuate the pleural space of the lung by needle aspiration as indicated. All of these procedures may be immediately necessary and life-saving. Cross-training of all team members so that they are able to perform the others' jobs is recommended to safeguard patients in the event that any team member becomes incapacitated during transport. All these skills can be learned via experience in a burn intensive care unit, through formal training seminars, and via a thorough orientation program. Mature judgment, excellent clinical skills, and the ability to function under stress are characteristics needed when selecting candidates for a transport program.

Patient Assessment Prior to Transport to a Specialized Burn Care Unit From a Referring Hospital

Initial assessment on arrival of a flight team should include a list of standard procedures for determining a burned patient's current condition. First, a thorough review of the patient's history concerning the accident and past medical

history must be done. This process provides the transport team with an excellent base from which to begin to formulate a plan of action. The patient will certainly have been diagnosed by a referring physician; however a transport team often finds problems overlooked in initial evaluations. Since burn care is a specialized field, modes of treatment may vary greatly outside the burn treatment community. Frequently, a referring hospital is not well-versed in the treatment of burn victims and should not be expected to display the expertise found among clinicians who work with such patients every day. Thus the next step in stabilizing a burn patient is a physical assessment done by the transport team. These procedures should always be performed in the same order and in a structured fashion. Assessment of a burn patient begins with the ABCs of a primary survey, including airway, breathing, circulation, cervical spine immobilization, and a brief baseline neurological examination. All patients should be placed on supplemental oxygen prior to transport in order to minimize the effects of altitude changes on oxygenation. Two IV lines should be started peripherally with a 16-gauge catheter or larger. Ideally, IV lines should be placed in nonburned areas but may be placed through a burn if they are the only sites available for cannulation. Intravenous lines should be sutured in place because venous access may not be available after the onset of generalized edema. The fluid of choice for initial resuscitation is LR solution.

In addition to initial stabilization procedures, blood should be obtained for initial laboratory studies if not already done. Initial diagnostic studies include hematocrit, electrolytes, urinalysis, chest X-ray, arterial blood gas, and carboxyhemoglobin levels. Any correction of laboratory values must be done prior to transfer and verified with repeat studies. ECG monitoring should be instituted on any patient prior to transfer. Placement of electrode patches may be a problem because the adhesive will not stick to burned skin. If alternative sites for placement cannot be found, an option for monitoring is to insert skin staples and attach the monitor leads to them with alligator clips. This provides a stable monitoring system, particularly for the agitated or restless patient who may displace needle electrodes. A Foley catheter with an urometer should be placed to accurately monitor urine output. Acceptable hydration is indicated by a urine output of more than 30 mL/h in an adult (5 mL/kg/h) and at least 1 mL/kg/h in a child.

With the exception of escharotomies, open chest wounds, and actively bleeding wounds, management during transport consists of simply covering wounds with a topical antimicrobial agent or a biological dressing. Wet dressings are contraindicated because of the decreased thermoregulatory capacity of patients sustaining large burns and the possibility of hypothermia. To combat the problem of a gastric ileus, a nasogastric tube should be inserted in all burn patients in order to decompress the stomach. This is especially important for patients being transferred at high altitudes. Hypothermia can be avoided or minimized by the use of heated blankets and/or aluminized Mylar space blankets. The patient's rectal temperature must be kept between 37.5°C and 39.0°C.

A clear, concise, chronological record of the mechanism of injury and assessment of airway, breathing, and circulation should be kept in the field and en route to the hospital. This information is vital for a referring facility to better understand and anticipate the condition of the patient. Additionally, all treatments, including invasive procedures, must be recorded, along with a patient's response to these interventions.

Summary

Burn injuries present a major challenge to a health care team, but an orderly, systematic approach can simplify stabilization and management. A clear understanding of the pathophysiology of burn injuries is essential for providing quality burn care in the prehospital setting, at the receiving health care facility, and at the referring hospital prior to transport. After a patient has been rescued from an injury-causing agent, assessment of the burn victim begins with a primary survey. Life-threatening injuries must be treated first, followed by a secondary survey, which documents and treats other injuries or problems. Intravenous access may be established in concert with logical/regional medical control and appropriate fluid resuscitation begun. Burn wounds should be covered with clean, dry sheets, and the patient should be kept warm with blankets to prevent hypothermia. The patient should be transported to an emergency room in the most appropriate mode available.

At the local hospital, it should be determined if a burn patient needs burn center care according to the American Burn Association Guidelines. In preparing to organize the transfer of a burn victim, consideration must be given to the continued monitoring and management of the patient during transport. In transferring burn patients, the same priorities developed for prehospital management remain valid. During initial assessment and treatment and throughout transport, the transport team must ensure that the patient has adequate airway/breathing, circulation, fluid resuscitation, urine output, and pain control. Ideally, transport of burn victims will occur through an organized, protocol-driven plan that includes specialized transport mechanisms and personnel. Successful transport of burn victims, whether in the prehospital phase or during interhospital transfer, requires careful attention to treatment priorities, protocols, and details.

8 Pathophysiology of Burn Shock and Burn Edema

PAUL WURZER, DEREK CULNAN, LEOPOLDO C. CANCIO, and GEORGE C. KRAMER

Introduction and Historical Notes

Extensive cutaneous thermal injury invariably results in the severe derangements of cardiovascular function and end-organ perfusion known as *burn shock*. Shock is an abnormal physiologic state in which tissue perfusion is insufficient for oxygen and nutrient delivery and cellular waste removal. Before the 19th century, investigators demonstrated that, after a burn, fluid is lost from the blood and the blood becomes thicker; in 1897, saline infusions for severe burns were first advocated.[1,2] Frank Underhill derived a more complete understanding of burn pathophysiology[3] when he demonstrated that unresuscitated burn shock was associated with increased hematocrit values, which are secondary to fluid and electrolyte loss after burn injury. Thus increased hematocrit values after severe burn injury are a consequence of a plasma volume deficit. Cope and Moore[4] furthered these finding, demonstrating that the hypovolemia of burn injury resulted from fluid and protein translocation into both burned and unburned tissues.

Animal and clinical studies have established the importance of fluid resuscitation for burn shock. Investigations have focused on correcting the rapid and massive fluid sequestration in the burn wound and the resultant hypovolemia. The literature contains a large experimental and clinical database on the circulatory and microcirculatory alterations associated with burn shock and edema generation in both the burn wound and unburned tissues. Substantial research has focused on identifying and defining the mechanisms and effects of the many inflammatory mediators produced and released after burn injury.[4]

Burn shock occurs from the coalescence of three cardinal causes: (1) hypovolemia resulting from intravascular fluid leaking into the interstitial space causing burn edema, (2) cardiac depression due to humoral factors and loss of preload, and (3) increased systemic vascular resistance. Later in the resuscitation process vasoplegia can replace the increase in system vascular resistance. Burn shock is a complex process of circulatory and microcirculatory dysfunction that is not easily or fully repaired by fluid resuscitation. Severe burn injury results in significant distributive shock and substantial tissue trauma, both of which cause the formation and release of many local and systemic mediators.[5–7] Burn shock results from the interplay of direct tissue injury, hypovolemia, and the release of multiple mediators of inflammation, with effects on both the microcirculation and the function of the heart and lungs. Subsequently burn shock continues as a significant pathophysiologic state even if hypovolemia is corrected. Increases in pulmonary and systemic vascular resistance (PVR, SVR) and myocardial depression occur despite adequate preload and volume support.[7–11] Such cardiovascular dysfunctions can further exacerbate the whole-body inflammatory response into a vicious cycle of accelerating organ dysfunction.[6,7,12]

This chapter examines our current understanding of the pathophysiology of the early events in burn shock, focusing on the many facets of the microcirculatory, organ, and systemic effects resulting directly from burns and circulating mediators. Intracellular pathways are not presented.

Inflammatory shock mediators, both local and systemic, that are implicated in the pathogenesis of burn shock include histamine, serotonin, bradykinin, nitric oxide, oxygen radicals, tumor necrosis factor (TNF), interleukins, and products of the eicosanoid acid cascade including prostaglandins and thromboxanes. Additionally certain hormones and mediators of cardiovascular function are elevated several fold after burn injury: these include epinephrine, norepinephrine, vasopressin, angiotensin II, and neuropeptide-Y. Other mediators and unknown factors yet to be defined are also involved.

Hypovolemia and Rapid Edema Formation

Burn injury causes extravasation of plasma into the burn wound. Extensive burn injuries are hypovolemic in nature and are characterized by hemodynamic changes similar to those that occur after hemorrhage, including decreased plasma volume, cardiac output, and urine output and an increased SVR with resultant reduced peripheral blood flow.[5,7,13–15] However, whereas in hemorrhage there is a fall in hematocrit with blood loss due to autotransfusion of interstitial fluid into the vasculature, in burn shock hematocrit may rise due to plasma extravasation. This is particularly common when fluid therapy is inadequate.

As in the treatment of other forms of hypovolemic shock, the primary initial therapeutic goal is to promptly restore intravascular volume and to preserve tissue perfusion and minimize tissue ischemia. However burn resuscitation is complicated not only by severe burn wound edema, but also by extravasated and sequestered fluid and protein in unburned soft tissue. Large volumes of resuscitation solutions are required to maintain intravascular volume during the first several hours after an extensive burn.

Note: The opinions or assertions contained herein are the private views of the authors, and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.

Edema develops when the rate at which fluid is filtered out of the capillaries exceeds the flow in the lymph vessels. Edema formation often follows a biphasic pattern. An immediate and rapid increase in the water content of burned tissue is seen in the first hour after burn injury.[15,18] A second and more gradual increase in fluid flux of both the burned skin and unburned soft tissue occurs during the first 12–24 hours after burn injury.[6,16] The amount of edema formation in burned skin depends on the type and extent of injury,[14,16] on whether fluid resuscitation is provided, and on the type and volume of fluid administered.[17] Fluid resuscitation elevates blood flow and capillary pressure thereby contributing to further fluid extravasation. Without sustained IV replacement of intravascular fluid losses edema formation is somewhat self-limited, as tissue blood flow and capillary pressure decrease.

Edema formation in thermally injured skin is characterized by an extremely rapid onset. Tissue water content can double within the first hour after burn.[14,18] Leape found a 70–80% increase in water content in a full-thickness burn wound 30 minutes after burn injury, with 90% of this change occurring in the first 5 minutes.[15,19,20] There was only a modest increase in burn wound water content after the first hour in nonresuscitated animals. In resuscitated animals or animals with small wounds, adequate tissue perfusion continues to "feed" the edema for several hours. Demling et al.[16] used dichromatic absorptiometry to measure edema development during the first week after an experimental partial-thickness burn injury on one hind limb in sheep. Although edema formation was rapid, with more than 50% occurring in the first hour, maximum water content was not present until 12–24 hours after burn injury. The mass of the burned tissue is significantly less than that of the remainder of the body. As such most fluid shifts likely occur from the blood into the unburned tissue due to the humoral actions of inflammatory mediators causing endothelial activation and glycocalyx injury.

Normal Microcirculatory Fluid Exchange

An understanding of the physiologic mechanisms of the rapid formation of burn edema requires an understanding of the mechanisms of microvascular fluid balance. Under physiologic steady-state conditions blood pressure in capillaries causes filtration of fluid into the interstitial space. The bulk of the filtrate is removed from the interstitial space by lymphatic drainage.[21–23] Fluid transport across the microcirculatory wall in normal and pathological states has been described by the original "classic" Starling equation that did not include the glycocalyx:

$$J_v = K_f[(P_c - P_{if}) - \sigma(\pi_p - \pi_{if})]$$

Starling sought to explain the interaction of physical forces that govern fluid transfer between intravascular and extravascular compartments. J_v is the flux (flow rate) of fluid that crosses the microvasculature barrier. K_f is the capillary filtration coefficient, which is the product of the surface area and hydraulic conductivity (water permeability) of the capillary wall; P_c is the capillary hydrostatic pressure; P_{if} is the interstitial fluid hydrostatic pressure; π_p is the colloid osmotic pressure of plasma; π_{if} is the colloid osmotic pressure of interstitial fluid; σ is the osmotic reflection coefficient. Edema occurs when the lymphatic drainage rate (J_L) does not keep pace with the increased J_v (Fig. 8.1). Fig. 8.1 shows the key structures and microvascular forces of the classic Starling equation.

There is now evidence that suggests the plasma colloid osmotic pressure does not exert its full effect at the capillary wall because of a protective barrier that excludes protein: the glycocalyx on the luminal endothelium.[24–26] The effective colloid osmotic absorptive force is generated by the gradient across the glycocalyx. However the role of the glycocalyx in burns is largely unexplored. It remains useful

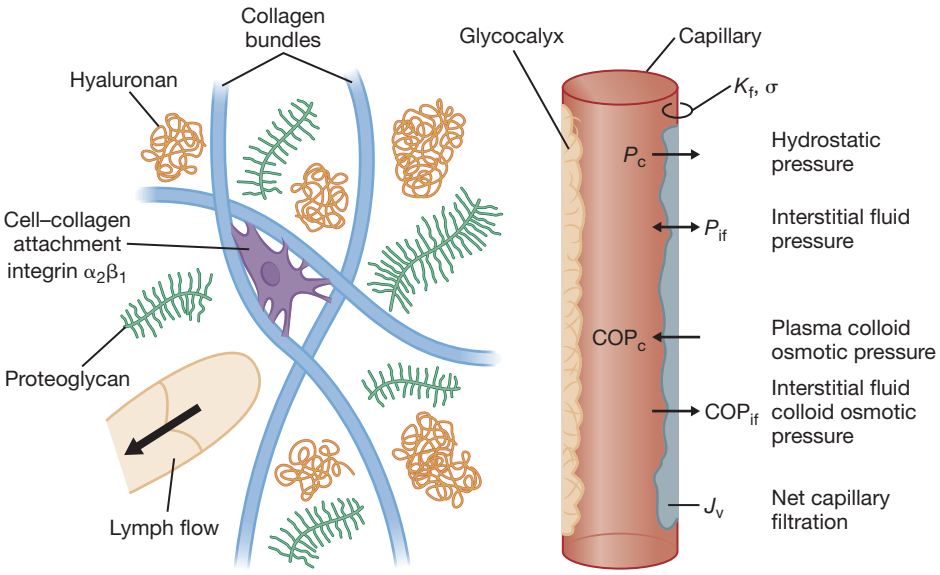

Fig. 8.1 The classic Starling equation and microvascular forces.

to review each term of the classic Starling equation and its role in burn edema before addressing the possible the implications of a modified Starling equation.

Mechanisms of Burn Edema

Transvascular blood-to-tissue transport of fluid and protein increase with elevation in K_f, P_c, or π_{if}, and with decreases in P_{if}, or σ. Burn edema is unique in its rapidity compared to other types of edema because it is only in burn edema that all of these variables change significantly in the direction required to increase fluid filtration. Each Starling variable is discussed individually next.

CAPILLARY FILTRATION COEFFICIENT (K_f)

Burn injury causes direct and indirect mediator-modulated changes in the permeability of the blood–tissue barrier of the capillaries and venules. Arturson and Mellander[27] showed that, in the scalded hindlimb of dogs, K_f immediately increased two to three times, suggesting that the hydraulic conductivity (water permeability) of the capillary wall increased. K_f is a function of both hydraulic conductivity and the capillary surface area. Thus local vasodilation and microvascular recruitment contribute to the increased K_f in addition to increased hydraulic conductivity. Measuring K_f and the rate of edema formation (J_v) allowed Arturson and Mellander to determine the changes in transcapillary forces necessary to account for the increased capillary filtration. Their calculations indicated that a transcapillary pressure gradient of 100–250 mm Hg was required to explain the extremely rapid edema formation that occurred in the first 10 minutes after a scald injury. They concluded that only a small fraction of the early formation of burn edema could be attributed to the changes in K_f and permeability. They further suggested that osmotically active molecules generating sufficiently large osmotic reabsorption pressures are released from burn-damaged cells. This hypothesis was never confirmed, and subsequent studies described herein show that large increases in filtration forces result from an increased P_c, and from a large decrease in P_{if} (Table 8.1).

CAPILLARY PRESSURE (P_c)

In most forms of shock, arteriolar vasoconstriction results in transfer of less arterial pressure to the capillaries; capillary and venous pressures decrease. However in studies using the vascular occlusion technique in the scalded hindlimb of dogs, P_c doubled from approximately 25 mm Hg to approximately 50 mm Hg during the first 30 minutes after burn injury and slowly returned to baseline over 3 hours.[28]

INTERSTITIAL HYDROSTATIC PRESSURE (P_{if})

Burned tissue has been demonstrated to have a significantly decreased interstitial hydrostatic pressure. Using micropipettes and a tissue oncometer, Lund[29] reported that dermal P_{if} was rapidly reduced from its normal value of −1 mm Hg to less than −100 mm Hg in isolated nonperfused samples of skin. This large negative interstitial hydrostatic pressure constitutes a powerful "suction force" or imbibition pressure promoting microvascular fluid filtration and sustained burn wound edema. In vivo measurements show a temporary reduction of −20 to −30 mmHg; the less negative P_{if} in vivo is due to the continued tissue perfusion and fluid extravasation that relieves the imbibition pressure. Kinsky[30] reported a continued negative pressure providing a partial explanation for the sustained edema during the first 4 hours post injury.

The mechanism for the large decrease in P_{if} is due, at least in part, to the release of cellular tension exerted on the collagen and microfibril networks in the connective tissue via the collagen-binding β_1-integrins. This tends to expand the interstitial space and induces the imbibition pressure. The integrins are transmembrane adhesion receptors that mediate cell–cell and cell–matrix adhesion, thereby allowing the glycosaminoglycan ground substance, which is normally underhydrated, to expand and take up fluid.[31] McGee et al. confirmed this hydration potential with T2-weighted MRI[32] and noted that it is reversible by application of negative pressure treatment. This supports the mechanism of interfascial rather than colloidal osmotic fluid transfer as a mechanism for burn edema and supports the collagen structural transitions as therapeutic targets.[33]

OSMOTIC REFLECTION COEFFICIENT (σ)

The osmotic reflection coefficient is an index of the proportion of the full osmotic pressure generated by the concentration gradient of plasma proteins across the microvascular blood-to-tissue barrier. A value of $\sigma = 1.0$ represents a barrier impermeable to protein but permeable to water and $\sigma = 0$ represents a barrier that is completely permeable to

Table 8.1 Effect of Burn Injury on Changes in the Classic Starling Equation Variables

Variable	Normal or Baseline	Post-Burn	Δ	References
P_c	~25 mm Hg	~50 mm Hg	↑ ~25 mm Hg	28
Π_P	25–30 mm Hg	15 to 18 mm Hg	↓ ~10 mm Hg	22, 36, 37
P_{if}	−2 to 0 mm Hg	~100 mm Hg non-resuscitated non-perfused skin and −5 mm Hg perfused skin	↓ ~100 mm Hg ↓ 3–5 mm Hg	29, 30
Π_{if}	10–15 mm Hg	13–18 mm Hg in burn wound ↓ and with resuscitation hypoproteinemia in unburned skin	↑ ~3 mm Hg	22, 35, 37
σ	~0.9	~0.5	↓ ~0.4	22, 28, 34, 35
K_f	~0.003 mL/min/mm Hg/100 g (leg)	↑ 2–5×		27

protein and water. The reflection coefficient is traditionally attributed to the endothelial cellular junctions but may well be primarily determined by the glycocalyx. In skin, the normal σ of albumin is reported to be 0.85–0.99.[22,34] Thermal injury causes an increase in capillary permeability to protein, resulting in a reduced σ, an effective reduction in the absorptive oncotic gradient across the microvascular barrier, and a resulting increase in net fluid filtration. Lymph sampled from burned skin has shown elevated protein concentrations consistent with the large and sustained increases in capillary permeability,[14,34,35] whereas a transient and smaller increase in microvascular permeability occurs over 8–12 hours following injury in other soft tissue not directly burned.[35] Pitt et al.[28] estimated the σ for skin from dog hindpaw using a lymph wash-down technique and reported a normal σ of 0.87 for albumin and a reduction to 0.45 after scald injury.

PLASMA COLLOID OSMOTIC PRESSURE (π_p)

The normal plasma protein concentration of 6–8 g/dL and its associated π_p of 25–30 mm Hg, would produce a significant transcapillary absorptive force counterbalancing the other Starling forces that favor filtration.[13,22] However, the glycocalyx blocks most of the impact of π_p on transendothelial fluid movement,[24–26] as described later. Plasma colloid osmotic pressure decreases in nonresuscitated burn-injured animals as protein-rich fluid extravasates into burn wounds and a significant volume of protein-poor interstitial fluid initially enters the circulation from transvascular reabsorption and lymph of unburned tissue, such as skeletal muscle.[13,36–38] Plasma is further diluted and π_p is further reduced after crystalloid resuscitation. Increased fluid filtration is less due to the fall in π_p and more likely attributed to increased K_f, reductions in P_{if} and σ due to a damaged glycocalyx. Initial therapy with colloid solution has always been advocated by some clinicians[6] but is often delayed 8–24 hours after injury based on the reasoning that normalization of microvascular protein permeability in injured tissue must occur before colloid therapy is cost effective.[7] However, the ability of plasma protein and, in particular, albumin to repair the permeability of the glycocalyx suggests a rationale for the earlier use of albumin therapy for burn resuscitation. Evidence for the use of albumin for resuscitation is also covered in Chapter 9 on burn resuscitation.[39–41] Animal studies have shown that albumin use during burn resuscitation does not reduce the edema in the tissue of burn wounds, but it does reduce total fluid needs and thus reduces edema in unburned tissues.[42] Furthermore, as discussed later, albumin can have a trophic effect on the endovascular glycocalyx, acting to stabilize it.

INTERSTITIAL COLLOID OSMOTIC PRESSURE (π_{if})

The π_{if} in skin is normally 10–15 mm Hg or about one-half that of plasma.[13,22] Experimental studies in animals using lymph as representative of interstitial fluid suggest that the colloid osmotic pressure in lymph from burned skin initially increases 4–8 mm Hg after burn injury.[35] With crystalloid resuscitation, π_p and π_{if} decrease because the protein concentration of microvascular filtrate remains less than that of plasma despite an increased permeability. The osmotic reflection coefficient, σ, decreases with burns but never equals zero; thus protein concentration in capillary filtrate is always less than in plasma even in burn-injured skin.[35] Compared to unburned skin, the π_i remains significantly higher in the burn wound, supporting the view that sustained increases in protein permeability contribute to the persistence of burn edema.[13,22,30] However, compared with the large changes in P_c and particularly P_{if}, increased microvascular protein permeability is not the predominant mechanism for the early, rapid rate of edema formation in injured skin.[43]

ENDOTHELIAL DYSFUNCTION AND THE GLYCOCALYX

Demling and colleagues[44,45] suggested that the edema caused by burns and hypoproteinemia alone could be partially attributed to alterations in the structure of interstitium increasing water transport and hydraulic conductivity across the entire blood–tissue–lymph barrier. Similar changes occur when hypoproteinemia is induced by plasmapheresis. Several clinical and animal studies have established that maintaining higher levels of total plasma protein concentration can ameliorate the overall net fluid retention and edema.[6,46,47] Endothelial activation and endothelial dysfunction play a major role in burn edema and the resultant distributive shock, particularly as it pertains to edema remote from the area of direct thermal trauma. Turk et al. prospectively investigated the endothelial dysfunction associated with burn injury in a cohort of burned patients in which they demonstrated an in vivo alteration of flow-mediated dilation reaching a nadir on post burn day 7. These clinical data support experimental findings on endothelial dysfunction after burn injury.[48] The value of colloid osmotic pressure under the glycocalyx (π_g) before or after burn injury has not been measured.

Plasma is further diluted and π_p is further reduced after crystalloid resuscitation. Increased fluid filtration is less due to the fall in π_p and more likely attributed to increased K_f and reductions in P_{if} and σ due to a damaged glycocalyx.

Many of these changes in endothelial and interstitial function can be attributed to the glycocalyx—a glycoprotein and polysaccharides layer on the luminal side of endothelial cells that maintains the barrier between the endothelium and plasma by reducing the osmotic gradient and thereby reducing filtration. The thickness of the glycocalyx varies from 20 nm in capillaries to 3000 nm in larger vessels. Based on studies of the glycocalyx, the paradigm of the classic Starling equation of microcirculatory forces has been challenged, and a revised equation has been proposed. Levick and Michel, along with others, proposed the revised Starling equation shown here and in Fig. 8.2:[25,49–51]

$$Jv = K_f[(P_c - P_{if}) - \sigma(\pi_p - \pi_g)]$$

In the revised Starling equation the fluid flux across the blood–tissue barrier is driven primarily by differences in hydrostatic pressures, $(P_c - P_{if})$ and by a colloid osmotic gradient between the fluid in the glycocalyx and just below the glycocalyx $(\pi_p - \pi_g)$. Further studies by Kozar et al.[52] have demonstrated that crystalloid resuscitation of hemorrhagic shock in rats causes a loss of glycocalyx that can be

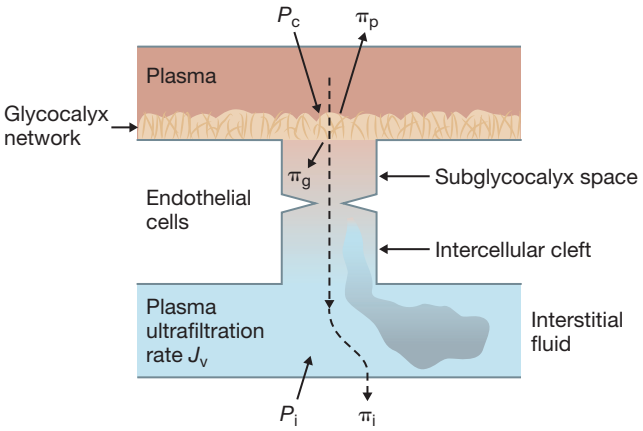

Fig. 8.2 The forces of the New Starling Equation taking into account the role of the glycocalyx.

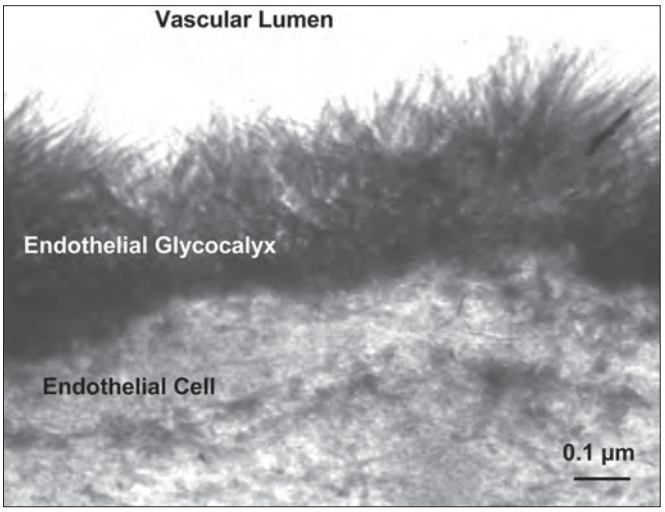

Fig. 8.3 A healthy vascular endothelium showing the fuzz-like coat of transmembrane and membrane bound molecules of the glycocalyx.

largely prevented by plasma resuscitation. Fig. 8.3 shows a photomicrograph of the glycocalyx.

Unburned Tissue

Generalized edema in soft tissues not directly injured is another characteristic of large cutaneous burns. Brouhard et al.[53] reported increased water content in unburned skin even after a 10% total body surface area (TBSA) burn, with the peak edema occurring 12 hours postburn. Arturson reported an increased transvascular fluid flux (lymph flow) from unburned tissue and a transient increase in permeability as measured by an increase in the lymph concentration of plasma protein and macromolecular dextran infused as a tracer.[14,34] Harms et al.[35] extended these findings by measuring changes in lymph flow and protein transport in noninjured soft tissue for 3 days after injury. They found that skin and muscle permeability (flank lymph from sheep) were elevated for up to 12 hours postburn for molecules the size of albumin and immunoglobulin G, but the microvascular permeability of the lung (lymph from caudal mediastinal node) showed no increase. Maximum increased lymph flow and tissue water content were observed to correlate with the severe hypoproteinemia that occurred during the early resuscitation period of a 40% burn injury in sheep.[7,54]

The mechanism by which burn injury induces microvascular hyperpermeability remote from the injury has been the subject of extensive study utilizing plasma from burned animals transfused into unburned recipients by Kremer et al.[55] These transfusions cause endothelial activation, albumin leakage, and leukocyte adhesion and rolling via an undefined transfused circulating factor. This model allows testing of the effects of various inhibitory and therapeutic agents in ameliorating the resultant physiologic derangements. High-dose vitamin C, an antioxidant, administered to the recipient rat was found to significantly reduce capillary leakage but not leukocyte-endothelial interactions.[55,56] Ketanserin, a 5-HT_{2a} antagonist, reduced plasma extravasation and leukocyte-endothelial interactions after burn plasma transfer.[57] These findings were further confirmed with the serotoninergic receptor-blocking agents cinanserin and methysergide.[58,59] When the burn wounds of donor burned rats were bathed in cerium nitrate, a topical antimicrobial and putative anti-inflammatory agent, the resulting plasma no longer induced injury in transfused rats.[60] In further burn plasma transfer studies Hernekamp et al.[61,62] also demonstrated that the cholinergic anti-inflammatory pathway stimulated by cbp-choline or pretreatment with physostigmine can similarly attenuate albumin efflux and leukocyte adhesions.

Altered Cellular Membranes and Cellular Edema

In addition to a loss of microvascular barrier integrity, thermal injury also causes changes in the cellular membrane. In skeletal muscle cellular transmembrane potentials decrease at sites distant from the injury.[9] It would be expected that the directly injured cell would have a damaged cell membrane thus increasing sodium and potassium fluxes and resulting in cellular swelling. However this process also occurs in cells that are not directly heat-injured. Micropuncture techniques in hemorrhaged animals have demonstrated partial depolarization in the skeletal muscle membrane potential of −90 mV to levels of −70 to −80 mV; cell death occurs at −60 mV. These shock-induced decreases in membrane potentials are associated with increases in intracellular water and sodium.[63–65] Similar alterations in skeletal membrane functions and cellular edema have been reported in hemorrhagic shock[63,65] and in cardiac, liver, and endothelial cells.[66–68] Action potentials become dampened or nonexistent, with likely delays in signal propagation in nerves, brain, skeletal muscle, heart, diaphragm, and gastrointestinal organs. Encephalopathy, muscle weakness, impaired cardiac contractility, and gut dysfunction are associated with major burn injury and may be due in part to reduced membrane potentials.

Early investigators of this phenomenon postulated that a decrease in adenosine triphosphate (ATP) levels or ATPase activity was the mechanism for membrane depolarization.

However more recent research suggests that it may result from an increased sodium conductance in membranes or that an increase in sodium–hydrogen antiporter activity is the primary mechanism.[64,67] Resuscitation of hemorrhage rapidly restores depolarized membrane potentials to normal, but resuscitation of burn injury only partially restores the membrane potential and intracellular sodium concentrations to normal levels, demonstrating that hypovolemia alone is not totally responsible for the cellular swelling seen in burn shock.[69] A circulating shock factor(s) is likely to be responsible for the membrane depolarization.[70–72] When plasma from a burn-injured animal is superfused to an isolated muscle preparation, membrane depolarization occurs. Furthermore, the depolarization can be reversed by changing the superfusate to normal plasma or saline.[69] Surprisingly the molecular characterization of such circulating factors has not been elucidated, suggesting that they have a complex and perhaps dynamic structure. Data suggest a large molecular weight, greater than 80 kDa.[73] Membrane depolarization may be caused by different factors in different states of shock. Very little is known about the time course of the changes in membrane potential in clinical burns. Furthermore, we do not know the extent to which the altered membrane potentials affect total volume requirements and organ function in burn injury.

Inflammatory Mediators of Burn Injury

Many local and circulating mediators are produced in the blood or released by cells after thermal injury. These mediators play important but complex roles in the pathogenesis of edema and the cardiovascular abnormalities of burn injury. For example, mediators alter vascular permeability and transvascular fluid flux, either directly or indirectly, by increasing the microvascular hydrostatic pressure and surface area via the arteriolar vasodilation superimposed on an already injured endothelial barrier. The exact mechanism(s) of mediator-induced injury are of considerable clinical interest because this understanding would allow for the development of pharmacologic modulation of burn edema and shock by mediator inhibition. Unfortunately most strategies directed at mediator blockage have only been effective in small localized burn wounds in patients or in animal studies and have had no clinical impact on the care of patients with major burns.

HISTAMINE

Histamine is a key mediator of very early increases in microvascular permeability following thermal injury. Histamine is released from mast cells in thermally injured skin; however the increase in histamine levels and its actions are only transient. Histamine causes large endothelial gaps to transiently form as a result of the contraction of venular endothelial cells.[74,75] Histamine is released from mast cells in thermally injured skin; however the increase in histamine levels and its actions are only transient. Histamine also can cause the rise in capillary pressure (P_c) by arteriolar dilation and venular contraction. Reductions in localized edema have been achieved with histamine blockers and mast cell stabilizers when tested in animal models.[74] Friedl et al.[42] demonstrated that the pathogenesis of burn edema in the skin of rats appears to be related to the interaction of histamine with xanthine oxidase and oxygen radicals. Histamine and its metabolic derivatives increased the catalytic activity of xanthine oxidase in rat plasma and in rat pulmonary artery endothelial cells.[76] In thermally injured rats, levels of plasma histamine and xanthine oxidase rose in parallel, in association with the increase in uric acid. Burn edema was greatly attenuated by treating rats with the mast cell stabilizer cromolyn, complement depletion, or the H_2 receptor antagonist cimetidine but was unaffected by neutrophil depletion.[76–78] Despite encouraging results in animals, beneficial antihistamine treatment of human burn injury has not been demonstrated.

PROSTAGLANDINS

Prostaglandins are potent vasoactive autocoids synthesized from the arachidonic acid released from burned tissue and inflammatory cells, and they contribute to the inflammatory response following burn injury.[79,80] Activated macrophages and neutrophils infiltrate the wound and release prostaglandin as well as thromboxanes, leukotrienes, and interleukin-1 (IL-1). These wound mediators have both local and systemic effects. Prostaglandin E_2 (PGE_2) and leukotrienes LB_4 and LD_4 increase microvascular permeability both directly and indirectly.[81] Prostacyclin (PGI_2) is produced in burn injury and is also a vasodilator, and it may cause direct increases in capillary permeability. PGE_2 appears to be one of the more potent inflammatory prostaglandins, causing postburn vasodilation and increased microvascular surface area in wounds that, when coupled with the increased microvascular permeability, amplifies edema formation.[82,83] Prostacyclin (PGI_2) is a vasodilator and may cause increases in capillary permeability.

THROMBOXANE

Thromboxane A_2 (TXA_2) and its metabolite, thromboxane B_2 (TXB_2) are produced locally in burn wounds by platelets.[74] Vasoconstrictor thromboxanes may be less important in edema formation; however by reducing blood flow they can contribute to a growing zone of ischemia under the burn wound and may be responsible in part for the conversion of a partial-thickness wound to a deeper, full-thickness wound. The serum level of TXA and TXA_2/PGI_2 ratios are significantly increased in burn patients.[84] Heggers showed that TXB_2 is released at the burn wound and is associated with local tissue ischemia, while thromboxane inhibitors prevented the progressive dermal ischemia associated with thermal injury and thromboxane release.[85,86] The TXA_2 synthesis inhibitor anisodamine also showed beneficial microcirculatory effects by restoring the hemodynamic and rheological disturbances toward normal. LaLonde[83] showed that topically applied ibuprofen (which inhibits the synthesis of prostaglandins and thromboxanes) reduces both local edema and prostanoid production in burned tissue without altering systemic production. On the other hand, systemic administration of ibuprofen did not modify early edema, but did attenuate the postburn vasoconstriction that impaired adequate oxygen delivery to tissue in burned

sheep.[87] Although cyclooxygenase inhibitors have been used after burn injury, they have not entered into routine clinical use.

KININS

Bradykinin is a local mediator of inflammation that increases venular permeability. It is likely that bradykinin production is increased after burn injury, but its detection in blood or lymph can be difficult because of the simultaneous increase in kininase activity and the rapid inactivation of free kinins. The generalized inflammatory response after burn injury favors the release of bradykinin.[88] Pretreatment of burn-injured animals with aprotinin, a general protease inhibitor, should have decreased the release of free kinin, but no effect on edema was noted.[89] On the other hand, pretreatment with a specific bradykinin receptor antagonist was reported to reduce edema in burn wounds in rabbits (Table 8.2).[90] Tao et al. demonstrated that blocking neurokinin-1 decreased the vascular permeability tissue around the wound and remotely in the jejunum of burned rats and that treated rats recovered more quickly than controls.[91]

SEROTONIN

Serotonin is released early after burn injury.[92] This agent is a smooth-muscle constrictor of large blood vessels. Antiserotonin agents such as ketanserin have been found to reduce peripheral vascular resistance after burn injury but not to reduce edema.[92] On the other hand, pretreatment with methysergide, a serotonin antagonist, reduces hyperemic or increased blood flow response in the burn wounds of rabbits and reduces burn edema.[90] Ferrara et al.[93] found a dose-dependent reduction in burn edema when methysergide was given to dogs prior to burn injury but claimed that this was not attributable to blunting of the regional vasodilation response. Zhang et al. reported a reduction in skin blood flow after methysergide administration to burned rabbits.[94]

CATECHOLAMINES

Circulating catecholamines epinephrine and norepinephrine are increased several fold after burn injury.[6,95,96] On the arteriolar side of the microvessels these agents cause

Table 8.2 Cardiovascular and Inflammatory Mediators of Burn Shock

Mediators	Central Cardiovascular Effects (at High Concentrations)	Load Tissue Effects	References
Histamine	↓ Blood pressure; hypovolemia	Arteriolar dilation; Venular constriction ↑ Blood flow ↑ Permeability	42, 74, 76, 77, 92, 160
Prostaglandin E_2 (PGE_2)	↓ Systemic arterial and pulmonary arterial blood pressure	Vasodilation ↑ Blood flow ↑ Permeability	74, 79, 85
Prostacyclin ($PG1_2$)	↓ Blood pressure	↑ Permeability	81, 83
Leukotrienes LB_4 LD_4	Pulmonary hypertension		74
Thromboxane A_2 (TXA_2) Thromboxane B_2 (TXB_2)	GI ischemia Pulmonary hypertension	Vasodilation ↑ Blood flow ↑ Permeability	84–87
Bradykinin	↓ Blood pressure Hypovolemia	Vasodilation, ↑ Permeability	74, 160
Serotonin		↑ Permeability	92–94
Catecholamines Epinephrine Norepinephrine	↑ Heart rate ↑ Blood pressure ↑ Metabolism	Vasoconstriction (receptors); Vasodilation (β_2 receptors in muscle); block ↑ permeability due to histamine & bradykinin via β receptors	74, 161
Oxygen radicals: Superoxide Anion (O_2^-) Hydrogen peroxide (H_2O_2) Hydroxyl Ion (OH^-) Peroxynitrite ($ONOO^-$)	Cardiac dysfunction	Tissue damage ↑ Permeability	42, 74, 76, 97, 99, 100
Platelet aggregation factor	↑ Blood pressure	Vasoconstriction	89, 113
Angiotensin II	GI ischemia ↑ Blood pressure	Vasoconstriction	114, 115, 117
Vasopressin	GI ischemia ↑ Blood pressure	Vasoconstriction	117

Enhanced microvascular blood flow typically opens recruits capillaries and increases surface area of exchange vessels.
Permeability refers to protein permeability of the microvascular barrier, which is often linked to hydraulic conductivity.

vasoconstriction via α_1-receptor activation, which tends to reduce capillary pressure, particularly when combined with the hypovolemia and reduced venous pressure of burn shock.[74] Reduced capillary pressure may limit edema and may induce transvascular refill of protein-poor interstitial fluid reabsorbed from unburned skin, skeletal muscle, and visceral organs, especially in under-resuscitated burn shock. Even in nonresuscitated animals, plasma protein concentration falls. Furthermore, catecholamines, via β-agonist activity, may also partially inhibit increased microvascular permeability induced by histamine and bradykinin.[74] These potentially beneficial effects of catecholamines may not be operative in directly injured tissue and may also be offset in unburned tissue by the deleterious vasoconstrictor and ischemic effects. The hemodynamic effects of catecholamines will be discussed later in the chapter.

REACTIVE OXYGEN SPECIES

Reactive oxygen species (ROS), also know as oxygen radicals, play an important inflammatory role in all types of shock, including burn shock. These short-lived elements are highly unstable reactive metabolites of oxygen; each one has an unpaired electron, making all of them strong oxidizing agents.[97] Superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl ion (OH^-) are produced and released by activated neutrophils after any inflammatory reaction or reperfusion of ischemic tissue. The hydroxyl ion is believed to be the most potent and damaging of the three. Evidence that these agents are formed after burn injury is the increased lipid peroxidation found in circulating red blood cells and biopsied tissue.[76,97,98]

Antioxidants, namely agents that either bind directly to the oxygen radicals (scavengers) or cause their further metabolism, have been evaluated in several experimental studies.[99,100] Catalase removes H_2O_2 and superoxide dismutase (SOD), lessens radical O_2^-, and is reported to reduce plasma loss after burn injury in dogs and rats.[76,99]

The plasma of thermally injured rats showed dramatic increases in levels of xanthine oxidase activity, with peak values appearing as early as 15 minutes after thermal injury. Excision of the burned skin immediately after the injury significantly diminished the increase in plasma xanthine oxidase activity.[42,76] The skin permeability changes were attenuated by treating the animals with antioxidants (catalase, SOD, dimethyl sulfoxide, dimethylthiourea) or an iron chelator (DFO), thereby supporting the role of oxygen radicals in the development of vascular injury as defined by increased vascular permeability.[76] Allopurinol, a xanthine oxidase inhibitor, markedly reduced both burn lymph flow and levels of circulating lipid peroxides and further prevented all pulmonary lipid peroxidation and inflammation. This suggests that the release of oxidants from burned tissue was in part responsible for local burn edema, as well as for systemic inflammation and oxidant release.[98] The failure of neutrophil depletion to protect against the vascular permeability changes and the protective effects of the xanthine oxidase inhibitors (allopurinol and lodoxamide tromethamine) suggests that plasma xanthine oxidase is the more likely source of the oxygen radicals involved in the formation of burn edema. These oxygen radicals can increase vascular permeability by damaging microvascular endothelial cells.[42,76] The use of antioxidants has been extensively investigated in animals, and some clinical trials suggest benefit.

Antioxidants (vitamin C and E) are routinely administered to patients at many burn centers. High doses of antioxidant ascorbic acid (vitamin C) have been found to be efficacious in reducing fluid needs in burn-injured experimental animals when administered postburn.[101–104] Beyond the action of vitamin concentrations are the use of high doses (e.g., 66 mg/kg per hour) of vitamin C, which was shown to, effectively reduce volume requirements in one clinical trial but was ineffective, in others, albeit with somewhat different doses.[102,105] High-dose vitamin C has been receiving wider clinical use, but the burn community awaits more definitive trials.

NITRIC OXIDE

Nitric oxide (NO) is a significant inhibitor of vascular smooth muscle tone and thus is a proximate cause of vasoplegia and distributive shock following burn injury. Blockade of guanylate cyclase with methylene blue as a treatment for vasoplegia has been described in several small case series.[106] NO has also been shown to be a significant driver of pulmonary dysfunction in inhalation injury. In an ovine model, blockade of inducible nitric oxide synthase (iNOS) and neuronal nitric oxide synthase (nNOS) fully prevented increases in pulmonary shunt, peak inspiratory pressure, and lung lymph flow and attenuated the decline in the PaO_2–FiO_2 ratio.[107]

Both beneficial and deleterious effects of NO have been described during the acute phase of burn shock. NO generated simultaneously with the superoxide anion can lead to the formation of peroxynitrite ($ONOO^-$). The presence of nitrotyrosine in burned skin found in the first few hours after injury suggests that peroxynitrite may play a deleterious role in burn edema.[108] Blockade of NOS did not reduce burn edema, whereas treatment with the NO precursor arginine reduced burn edema.[109] NO may be important for maintaining perfusion and limiting the zone of stasis in burn skin.[110] An $ONOO^-$ decomposition catalyst administered following smoke inhalation injury and burn was able to significantly reduce pulmonary microvascular hyperpermeability and improved pulmonary function in an ovine model.[111] A further study showed that low-dose arginine vasopressin given from 1 hour for up to 24 hours post smoke inhalation and burn injury in sheep significantly reduced NO plasma levels and edema formation.[112] Both the beneficial and deleterious effects of NO have been described to occur during the acute phase of burn shock and thus the long-term benefits of an acute NO reduction remain controversial. In brief, the value of acute NO reduction in burns remains controversial.

PLATELET AGGREGATION FACTOR

Platelet aggregation (or activating) factor (PAF) can increase capillary permeability and is released after burn injury.[89,113] Ono et al.[113] showed in scald-injured rabbits that TCV-309 (Takeda Pharmaceutical Co Ltd., Japan), a PAF antagonist, infused soon after burn injury, blocked edema formation in the wound and significantly inhibited PAF increase in

the damaged tissue in a dose-dependent manner. In contrast, the SOD content in the group treated with TCV-309 was significantly higher than that of the control group. These findings suggest that the administration of large doses of a PAF antagonist immediately after injury may reduce burn wound edema and the subsequent degree of burn shock by suppressing PAF and superoxide radical formation.

ANGIOTENSIN II AND VASOPRESSIN

Angiotensin II and vasopressin or antidiuretic hormone (ADH) are two hormones that participate in the normal regulation of extracellular fluid volume by controlling sodium balance and osmolality through renal function and thirst.[74] During burn shock, sympathetic tone is high and volume receptors sense hypovolemia, both of which elevate angiotensin II and ADH to supranormal levels in the blood. Both are potent vasoconstrictors of terminal arterioles with less effect on the venules. Angiotensin II may be responsible for the selective gut and mucosal ischemia, which can cause translocation of endotoxins and bacteria and the development of sepsis and even multiorgan failure.[114,115] In severely burn-injured patients angiotensin II levels were elevated two to eight times normal in the first 1–5 days after injury, with peak levels occurring on day 3.[116] Vasopressin had peak levels of 50 times normal upon admission and declined toward normal over the first 5 days after burn injury. Along with catecholamines, vasopressin may be largely responsible for increased SVR and increased left heart afterload, which can occur in resuscitated burn shock. Sun et al.[117] used vasopressin-receptor antagonists to improve hemodynamics and survival time in rats with burn shock, whereas vasopressin infusion exacerbated burn shock.

OTHER MEDIATORS

Hydrogen sulfide (H_2S) is a small-molecule mediator receiving increased attention in inflammatory shock. It is capable of both inducing and inhibiting inflammation. Murine data support H_2S as being an endogenous inflammatory mediator increasing both pro-inflammatory cytokine levels and NF-κB signaling. Studies are similarly being carried out to define concentrations and clinical utility for its anti-inflammatory characteristics.[57] Hu et al. used a 50% TBSA burn-injured dog model and reported that use of a *nicotinic agonist* with resuscitation increased survival, improved hemodynamics, increased plasma volume and urine output, and decreased TN-α, IL-1, and lactic acid.[118] Wiggins et al. elucidated a role of *metalloproteinases* (MMP) in lung edema and endothelial damage when a culture of lung endothelial cells had increased MMP activity and decreased tissue inhibitor of metalloproteinases (TIMP-2) after burn serum exposure. These cells had increased monolayer permeability, damaged adhesion junction proteins, and incited actin stress fiber formation. This damage was inhibited effectively by exogenous TIMP-2.[119] *Endothelin-1* has been shown to play a role in alveolar fluid clearance and pulmonary edema. ET-1 inhibits alveolar fluid clearance by inhibition of amiloride-sensitive epithelial sodium channels and increases capillary pressure.[120]

Hemodynamic Consequences

The cause of reduced cardiac output (CO) during the resuscitative phase of burn injury has been the subject of considerable debate. There is an immediate depression of cardiac output before any detectable reduction in plasma volume. The rapidity of this response may result from impaired neurotransmission of cardiac signaling and increased afterload due to vasoconstriction. Soon after injury a developing hypovolemia and reduced venous return undeniably contribute to the reduced cardiac output. The subsequent persistence of reduced CO after apparently adequate fluid therapy, as evidenced by restoration of arterial blood pressure and urinary output, has been attributed to circulating myocardial depressant factor(s), which possibly originates from the burn wound.[10,11] Demling et al.[16] showed a 15% reduction in CO despite aggressive volume replacement protocol after a 40% scald burn in sheep. However there are also sustained increases in catecholamine secretion and elevated systemic vascular resistance for up to 5 days after burn injury.[95,116] Michie et al.[121] measured CO and SVR in anesthetized dogs resuscitated after burn injury. They found that CO fell shortly after injury and then returned toward normal; however reduced CO did not parallel the blood volume deficit. They concluded that the depression of CO resulted not only from decreased blood volume and venous return, but also from an increased SVR and from the presence of a circulating myocardial depressant substance. After the resuscitation phase of burn shock, patients need a supranormal CO. This is associated with a hypermetabolic state and systemic inflammatory response syndrome (SIRS).

MYOCARDIAL DYSFUNCTION

Increases in the afterload of both the left and the right heart occur due to elevated SVR and PVR. Stroke volume and CO can be maintained despite contractile depression by augmented adrenergic stimulation, albeit at a cost of increased myocardial oxygen demands. The right ventricle has a minimal capacity to compensate for increased afterload. Myocardial function can be compromised after burn injury due to direct depression of contractility shown in isolated heart studies.[122,123] In severe cases, desynchronization of the right and left ventricles is deleteriously superimposed on a depressed myocardium.[124] Howard et al.[125] demonstrated both systolic and diastolic dysfunction in burn-injured children during the first few weeks post injury. Burn injury of greater than 45% TBSA can produce intrinsic contractile defects. Several investigators reported that aggressive early and sustained fluid resuscitation failed to correct left ventricular contractile and compliance defects.[123,124,126] These data suggest that hypovolemia is not the sole mechanism underlying the myocardial defects observed with burn shock. Serum from patients failing to sustain a normal CO after thermal injury have exhibited a markedly negative inotropic effect on in vitro heart preparations, which may be due to the circulating shock factor described earlier.[69,127] In other patients with large burn injuries and normal cardiac indices, little or no depressant activity was detected.

Traber and colleagues studied intact, chronically instrumented sheep after a 40% TBSA flame burn injury and smoke inhalation injury, and after smoke inhalation injury alone. They found that contractile force was reduced after either burn injury or inhalation injury alone.[128,129] Horton et al.[130] demonstrated decreased left ventricular contractility in isolated, coronary-perfused guinea pig hearts harvested 24 hours after burn injury. This dysfunction was more pronounced in hearts from aged animals and was not reversed by resuscitation with isotonic fluid. It was largely reversed by treatment with 4 mL/kg of hypertonic saline dextran (HSD) but only if administered during the initial 4–6 hours of resuscitation.[131,132] These authors also effectively ameliorated the cardiac dysfunction of thermal injury with infusions of antioxidants, arginine, and calcium channel blockers.[132–134] Cioffi and colleagues,[135] using an ex vivo myocardial preparation, observed persistent myocardial depression after burn when the animals received no resuscitation after injury. As opposed to most studies, Cioffi reported that immediate and full resuscitation totally reversed abnormalities of contraction and relaxation after burn injury. Murphy et al.[136] showed elevations of a serum marker for cardiac injury, troponin I, for patients with a TBSA burn of greater than 18%, despite good cardiac indices. Resuscitation and cardiac function studies emphasize the importance of early and adequate fluid therapy and suggest that functional myocardial depression after burn injury may be minimized in patients receiving prompt and adequate volume therapy.

The primary mechanisms by which burn shock alters myocardial cell membrane integrity and impairs mechanical function remain unclear. Oxygen-derived free radicals may play a key causative role in the cell membrane dysfunction that is characteristic of several low-flow states. Horton et al. showed that a combination therapy of free radical scavengers SOD and catalase significantly improved burn-mediated defects in left ventricular contractility and relaxation when administered along with adequate fluid resuscitation. Antioxidant therapy did not alter the volume of fluid resuscitation required after burn injury.[137]

Increased Systemic Vascular Resistance and Organ Ischemia

CO may remain below normal after adequate volume replacement in burn patients and experimental animals. Increased afterload after burn injury is the result of release of catecholamines, vasopressin, angiotensin II, and neuropeptide-Y.[116,117] These agents cause contraction of the arteriolar smooth muscle, which is systemically manifested by increased afterload and SVR. The increased SVR after burn injury is also, in part, the result of increased blood viscosity secondary to the hemoconcentration.

Hilton and others performed experiments in anesthetized dogs in which infusion of various peripheral vasodilators improved CO after burn injury.[121,138] They demonstrated a reduction in the SVR and augmented CO after verapamil, but the myocardial force of contraction remained depressed. Pruitt et al. demonstrated the utility of a vasodilator, hydralazine, to reduce SVR and augment CO (with the caveat that hypovolemia should first be corrected).[139]

There are several organs particularly susceptible to ischemia, organ dysfunction, and organ failure when burn resuscitation is delayed or inadequate. These include the kidney and the gastrointestinal tract. Renal ischemia can result directly from hypovolemia and increased sympathetic tone, but elevations in plasma hemoglobin, and particularly myoglobin, correlate with increased renal failure.[140,141] Renal failure rates have declined dramatically because of standardized regimens of adequate fluid therapy, but when therapy is delayed or associated with hypotension acute renal failure is not uncommon.[140–142]

Mesenteric vasoconstriction can occur despite apparently "adequate" resuscitation.[115,143] Bacterial and endotoxin translocation that can contribute to the development of sepsis is one consequence of visceral ischemia.

Encephalopathy is not uncommon after large cutaneous burns, particularly in children, but the exact cause remains unclear. Studies in anesthetized sheep subjected to a 70% TBSA scald show that cerebral autoregulation is well maintained in the immediate postburn period, but 6 hours after resuscitation increased cerebral vascular resistance reduced cerebral blood flow by 50%.[144]

PULMONARY CIRCULATION AND LUNG EDEMA

In large burns there is a pronounced increase in PVR that corresponds with the increased SVR.[7,54] In contrast to the systemic circulation, however, pulmonary edema is unusual and typically does not occur until after the fluid resuscitation phase is complete. Pulmonary wedge pressure is increased more than left atrial pressure after experimental burn injury due to postcapillary venular constriction.[54,145] By increasing capillary pressure, venular constriction may contribute to pulmonary edema. It is likely that some degree of left heart failure also contributes to the increased capillary pressure. However hypoproteinemia may be the greatest contributing factor to postburn pulmonary edema.[146] Analysis of lung lymph sampled in large animal models after 40% TBSA burn injury showed no evidence of increased microvascular permeability. Furthermore, lung lymph flow may increase considerably to counteract interstitial fluid accumulation. As a result, clinical studies of burn-injured patients suggest that, in the absence of inhalation injury, the lungs do not typically develop edema.[147,148] Pulmonary dysfunction associated with inhalation injury is discussed in a separate chapter.

FLUID OVERLOAD AND ABDOMINAL COMPARTMENT SYNDROME

Prompt and adequate fluid resuscitation has undoubtedly improved the outcome of burn-injured patients, and Chapter 9 describes resuscitation strategies in detail. Despite the advances in burn shock resuscitation, massive edema of both burned and unburned tissues continues to be a repercussion of large-volume fluid resuscitation.

It is now clear that there is a trend toward providing fluid in excess of the published formula, which has been termed "fluid creep."[149] Over-resuscitation and the resulting edema are fraught with complications. The problems of the over-resuscitated burn patient may include optic neuropathy due to intraocular hypertension,[150] pulmonary edema,[151,152]

the need for prolonged mechanical ventilation or tracheostomy,[153] graft failure, or the need for fasciotomy of uninjured extremities[154] due to massive edema.

The most life-threatening complication of edema, with a mortality rate of 75%, is abdominal compartment syndrome (ACS).[155] Intra-abdominal hypertension (IAH) is defined as an intra-abdominal pressure of more than 12 cm H_2O and is most often seen during the acute resuscitation phase up to 48 hours postburn.[156] ACS is sustained IAH of greater than 20 mmHg combined with new organ failure (e.g., elevated peak inspiratory pressures or oliguria despite aggressive fluid resuscitation). The syndrome typically leads to multiple organ dysfunction, characterized by impaired renal and hepatic blood flow, bowel ischemia, pulmonary dysfunction, depressed cardiac output, elevated intracranial pressures, and death.[157,158] ACS can occur after major abdominal trauma or surgery; the condition in the absence of abdominal injury is known as secondary ACS.[159] A review showed that the prevalence of ACS is between 4% and 17% in the severely burned.[155] The use of albumin during resuscitation may reduce the risk of ACS.[41] Massive edema of burned and unburned tissues continues to be a problem in burn-shock resuscitation.

Conclusion

Thermal injury results in massive fluid shifts from the circulating plasma into the interstitial space of both burned tissue and (in burns >20–30% TBSA) unburned tissue, causing hypovolemia and edema. Changes in the variables comprising the Starling equation favor fluid extravasation from blood to tissue. In burned tissue rapid edema formation is predominantly due to the development of strongly negative interstitial fluid pressure and, to a lesser degree, by an increase in microvascular pressure and permeability. In uninjured soft tissues, increased microvascular permeability is mainly the result of glycocalyx loss and endothelial activation. The type, volume, and timing of fluid used to resuscitate affect the magnitude of these fluid shifts.

Secondary to the thermal injury there is release of inflammatory mediators and stress hormones. These circulating mediators deleteriously increase microvascular permeability and alter cellular membrane function by which water and sodium enter cells. Circulating mediators also favor renal conservation of water and salt, impair cardiac contractility, and cause vasoconstriction. The end result of this complex chain of events is decreased cardiac output, end-organ ischemia, and metabolic acidosis. Without early and effective resuscitation these derangements can result in organ dysfunction, cardiovascular collapse, and death.

Resuscitation is a double-edged sword in that it increases edema in both burned and unburned tissue. Edema likely contributes to decreased tissue oxygen diffusion and further ischemic injury to already damaged cells. Research should continue to define better treatments that ameliorate burn shock and burn edema. The success of this research will require the identification of key circulatory factors that alter microvascular permeability, cause vasoconstriction, depolarize cellular membranes, and depress myocardial function. Cellular or systemic methods to prevent the release or block the activity of specific mediators are needed.

9 Burn Resuscitation

LEOPOLDO C. CANCIO, FREDRICK J. BOHANON, and GEORGE C. KRAMER

Introduction

Burns in excess of about 20% of the total body surface area (TBSA) cause shock, manifested by decreased circulating blood volume, decreased cardiac output (CO), and inadequate end-organ perfusion. Fluid resuscitation to address burn shock is one of the key lifesaving interventions in the early care of burn patients. Inadequate or delayed fluid resuscitation causes organ failure and death.[1] On the other hand, provision of excessive amounts of fluid (overresuscitation), by augmenting edema formation and engendering complications such as compartment syndromes, also increases morbidity and mortality.[2] Thus the overarching goal of fluid resuscitation is to achieve a careful balance between the two extremes of over- and underresuscitation; in other words, "to maintain vital organ function at the least immediate or delayed physiologic cost."[3]

The primary cause of burn shock is a reduction in the circulating blood volume due to loss of fluid similar in composition to plasma across the microvasculature. Thus burn shock is hypovolemic shock. Such fluid loss occurs primarily in burned tissues but also, for larger burns, in unburned tissues as well.[4] The term "leaky capillaries" is often used to describe this complex process (for details, see Chapter 8, Pathophysiology of Burn Shock and Burn Edema). Other factors that contribute to burn shock include intense vasoconstriction during the immediate postburn hours, causing increased afterload,[5] and a decrease in intrinsic myocardial contractility.[6,7] These three factors—hypovolemia, vasoconstriction, and decreased myocardial contractility—contribute to decreased CO. The aims of fluid resuscitation are simultaneously (1) to counteract the loss of circulating blood volume with intravenous fluids; (2) to monitor the physiologic response frequently and diligently; (3) to alter treatment strategy based on physiologic response (e.g., by titrating the fluid infusion rate hourly); and (4) to anticipate, guard against, and correct the effects of edema formation. This could be summarized as follows: burn shock mandates *simultaneous fluid resuscitation and edema management strategies*.

Early Approaches to Fluid Resuscitation

A wide variety of resuscitation formulas dominates much of the discussion on the treatment of burn shock (Table 9.1). Knowledge of how these formulas came about is helpful to understanding their advantages and limitations. Intravenous fluid resuscitation for the treatment of burns owes much to early investigations of the pathophysiology and treatment of cholera. In 1831, O'Shaughnessy, an Irish physician, performed studies of the chemical and microscopic features of the blood in cholera patients. Based on these studies, he proposed "the injection into the veins of tepid water holding a solution of the normal salts of the blood." He did canine experiments of this novel therapy but did not apply it to humans. One year later, Thomas Latta, a Scottish physician, read about O'Shaughnessy's work and treated patients with cholera using rectal, oral, and then intravenous saline solutions.[8] In 1906, Dr. Haldor Sneve of St. Paul, Minnesota, described the use of saline solutions, including enemas, for the treatment of burns.[9] His commonsense recommendations were not followed for years because the prevailing point of view at the time was that the main cause of death in patients with extensive burns was not hypovolemia but the absorption of toxic substances from the burned skin ("toxemia").[10] This belief led to the widespread adoption of tanning agents such as tannic acid,[11] the purpose of which was to "fix" the toxins and prevent them from entering the bloodstream.

Subsequent mass-casualty disasters and armed conflict both contributed to resuscitation advances. On November 27, 1921, the Rialto Theatre in New Haven, Connecticut, caught fire, killing 6 and injuring 80. Dr. Frank Underhill examined 21 survivors who were admitted following the fire. Underhill was a veteran of World War I and had previously reported on the effects of chemical warfare agents on the lungs. He drew a parallel between the process whereby the lungs are flooded with fluid following inhalation of toxic gases and that by which edema forms in wounds following thermal injury. He reported that the more severe the burn, the more severe the hemoconcentration (increased hemoglobin), and that fluid replacement must be rapid and is of paramount importance in survival. Additionally he reported that blister fluid was similar in composition to plasma and that the fluid lost could be replaced with an intravenous physiologic salt solution, supplemented rectally, orally, and subdermally.[12] Oral and rectal infusions were de-emphasized until recently, when their utility in austere and combat-casualty-care scenarios was revisited.[13]

In 1931, Alfred Blalock built on Underhill's reports by performing experiments in which anesthetized dogs sustained burns of approximately one-third of the TBSA, localized to one-half of the body (right or left). The animals were not resuscitated. After a period of observation (6–26 hours), the animals were euthanized, bisected, and the carcasses weighed. Thus he quantified the amount of fluid lost across the burn wounds, which averaged 3.34% of the total body weight. This fluid loss was accompanied by a mean increase in the hemoglobin level of 48%. Blalock speculated that this

Table 9.1 Common Burn Resuscitation Formulas

Formula	First 24 Hours Post Burn	Next 24 Hours Post Burn
Evans Formula	NS: 1 mL/kg/%TBSA burn	NS: 0.5 mL/kg/%TBSA burn
	Colloid: 1 mL/kg/%TBSA burn	Colloid: 0.5 mL/kg/%TBSA burn
	D5W: 2000 mL	D5W: 2000 mL
Brooke Formula	NS: 1.5 mL/kg/%TBSA burn	NS: 0.5 mL/kg/%TBSA burn
	Colloid: 0.5 mL/kg/%TBSA burn	Colloid: 0.25 mL/kg/%TBSA burn
	D5W: 2000 mL	D5W: 2000 mL
Modified Brooke Formula	LR: 2 mL/kg/%TBSA burn	LR: None
	Colloid: None	Colloid: 0.3–0.5 mL/kg/%TBSA burn
Parkland Formula	LR: 4 mL/kg/%TBSA burn	LR: None
	Colloid: None	Colloid: 5% albumin given at 0.3–1 mL/kg/%TBSA burn/16 per hour
Shriner's Cincinnati (For Children)	LR: 4 mL/kg/%TBSA burn + 1500 mL/m^2, ½ given over first 8 h and the remaining over the next 16 h (older children)	
	LR: 4 mL/kg/%TBSA burn + 1500 mL/m^2 + 50 mEq sodium bicarbonate for the first 8 h, followed by LR alone in second 8 h, followed by 5% albumin in LR in third 8 h (younger children)	
Galveston Formula (For Children)	LR: 5000 mL/m^2 burn + 2000 mL/m^2 total, ½ volume in first 8 h, followed by remainder in 16 h.

D5W, 5% Dextrose in water; *LR,* lactated Ringer's solution; *NS,* normal saline; *UO,* urinary output; *TBSA,* total body surface area.

process, rather than toxemia, was sufficient to explain the resultant postburn hypotension.[10] Further experiments involving excision of the burn wound as well as cross-transfusion (of burned to unburned dogs) supported his hypothesis.[10]

With World War II on the horizon, and following battles such as the Battle of Britain in 1940 and the attack on Pearl Harbor in 1941, there was great urgency to develop effective methods to care for wartime burn casualties. Meanwhile plasma now became available for intravenous administration. Several formulas were developed for burn-shock resuscitation using plasma. One recommended enough plasma to maintain the peripheral circulation, evidenced by the ease with which blood could be drawn by a needle prick. Others were based on calculations that incorporated the hematocrit and/or the protein levels in the blood.[14] The burn-size-based formulas we use today originated from a conference on January 7, 1942, of the National Research Council (NRC). This committee stated that a burn patient should receive 500 mL of plasma initially, followed by 100 mL of plasma per TBSA burned during the first 24 h post burn. Other fluids (normal saline or dextrose) should not normally exceed the plasma dose.[15] Interestingly, Harkins (who participated in the NRC meeting) described a First Aid Formula at the same time that recommended half this amount, or 50 mL/TBSA of plasma. In addition, patients should receive about 1000 mL of normal saline solution and "large amounts" of dextrose, preferably by mouth.[14,16]

These preparations were tested when, on November 28, 1942, the Cocoanut Grove nightclub in Boston caught fire, killing 492 people and injuring hundreds more in the deadliest nightclub fire in U.S. history. Patients were resuscitated with plasma, which, however, was provided by the blood bank diluted with equal volumes of normal saline.[17] Dr. Cope at the Massachusetts General Hospital provided in the first 24 hours 50 mL of plasma plus 50 mL saline for every 1% TBSA burned, followed by adjustments based on hemoconcentration.[18] Dr. Lund at the Boston City Hospital did not use a formula to guide resuscitation, but rather clinical parameters such as heart rate, blood pressure, and hematocrit.[19]

Later, Cope and Moore reported the first burn formula based on burn surface area for fluid therapy, recommending that 75 mL plasma and 75 mL noncolloid isotonic fluid be administered for every 1% TBSA burned in the first 24 hours, with one-half being given in the first 8 hours and the remaining being given in the next 16 hours. This practice of providing half of the fluid needs within the first 8 hours remains a feature of nearly all modern burn resuscitation formulas. Additionally, 2000 mL fluid was to be given on each day to maintain urine flow, preferably by mouth.[16]

These formulas were based on a normal-sized adult and could be unfavorable at the extremes of weight. Thus formulas based on both weight and TBSA were developed.

Dr. Everett Evans developed one such formula. This formula predicts infusion of 1 mL/kg per TBSA of normal saline and an equal part colloid, plus 2000 mL of 5% dextrose in water (D5W), in the first 24 hours. This is followed by 0.5 mL/kg per TBSA of saline and an equal part colloid and of D5W in the second 24 hours.[20]

BROOKE AND PARKLAND FORMULAS

The original Brooke formula of 1953 represents the beginning of a transition away from colloid use during the first 24 hours. In that formula, fluid needs for the first 24 hours are estimated as 2 mL/kg per TBSA: 0.5 mL/kg per TBSA is given as colloid, and 1.5 mL/kg per TBSA as crystalloid.[21]

Moyer eschewed the use of colloids for burn shock resuscitation, stating that crystalloid solutions alone, such as lactated Ringer's (LR), were sufficient to correct what he termed "sodium deficit shock."[22] G. Tom Shires and colleagues reported that hemorrhagic shock involved a loss not just of blood, but also of functional extracellular fluid (ECF) volume. This led to the use of large volumes of LR in the Emergency Department for the treatment of trauma patients.[23] Further studies showed that this depletion of ECF was accompanied by a decrease in the transmembrane potential difference and by intracellular sodium influx.[24]

In 1968, Baxter and Shires extended these findings to thermal injury. They measured the ECF in animals and humans, demonstrating that restoration of the functional ECF with LR could be performed, required infusion of a greater volume (4 mL/kg per TBSA) than recommended by the extant burn formulas, and led to a more rapid correction of both CO and metabolic acidosis.[6] This occurred despite a plasma volume deficit that persisted at the end of the first 24 hours post burn. During the second 24 hours post burn, plasma became effective as a volume expander and was indicated to correct this deficit. This was the origin of the widely used Parkland formula.[25]

Soon after Baxter's work, Pruitt and colleagues at the U.S. Army Institute of Surgical Research (USAISR) reported that varying the dose of colloid infused during the first 24 hours postburn did not further increase the plasma volume, meaning that colloid was no more effective than crystalloid during this period. During the second 24 h post burn, colloid did become more effective.[5] Estimation of fluid needs as 2 mL/kg per TBSA and elimination of colloid during the first 24 hours, became known as the modified Brooke formula. Also at the USAISR, Goodwin et al. conducted a randomized controlled trial comparing resuscitation with and without albumin from the time of admission. The colloid group received 2.5% albumin in LR from the start of resuscitation, whereas the crystalloid group received LR alone. They found that patients who received early albumin (1) had more rapid restoration of CO, (2) received a lower fluid volume during the first 24 hours, (3) had increased extravascular lung water on days 3–7 postburn, and (4) had increased in-hospital mortality.[26] These data, combined with the earlier study by Pruitt et al., bolstered the argument against albumin use during the first 24 hours.

Both the Parkland and modified Brooke formulas recommend crystalloids during the first 24 h; administration of colloids (i.e., 5% albumin) is reserved until the second 24 hours. This point should be underscored: these are not colloid-free, but delayed-colloid formulas. The modified Brooke formula provides a sliding scale for albumin dosing during the second 24 hours, as follows: 0.3 mL/kg per TBSA for 30–49% TBSA, 0.4 mL/kg per TBSA for 50–69% TBSA, and 0.5 mL/kg per TBSA for 70–100% TBSA.[27]

Today, crystalloid solution, mainly in the form of LR (see later discussion), is predominately used for burn resuscitation in the United States. Most burn centers use some colloid according to physician discretion or other rule.[28] The Parkland and modified Brooke formulas are the two most commonly used formulas to start fluid infusion rates. The 2012 American Burn Association consensus statement on quality improvement in fluid resuscitation concluded that evidence is lacking to recommend a standard of care.[29] On the other hand, the current Advanced Burn Life Support Guidelines recommend starting with the modified Brooke formula at 2 mL/kg per TBSA.[30] For both formulas, half of the volume is programmed for delivery during the first 8 hours post burn and half during the second 16 h post burn. Subsequent adjustment of the fluid infusion rate is made based on clinical status (see later discussion), and no abrupt change is normally made at the postburn hour 8.

To simplify fluid calculation in adults, Chung and colleagues at the USAISR recently described a "Rule of Tens": initial fluid rate (in mL/h) = TBSA × 10. Thus a patient with a 30% burn would be started at 300 mL/h. In addition, patients weighing more than 80 kg receive an additional 100 mL/h for each additional 10 kg. This estimate provides an initial infusion rate that lies between the Parkland and Brooke estimations for 88% of patients.[31] We emphasize that this formula is appropriate only for adults (weight ≥40 kg).

Children

Formulas have been developed specifically for resuscitation of children. Graves et al. at the USAISR performed a retrospective review of children weighing less than 25 kg who were resuscitated with the pediatric modified Brooke formula. This formula estimates 3 mL/kg per TBSA of LR for the first 24 hours, with half given over the first 8 hours;[32] LR is then titrated based on urine output (UO; target UO, 0.5–1.5 mL/kg per hour). Children are also given 5% dextrose in one-half normal saline (D5W½NS) at a maintenance rate, which is not titrated. The actual volume of LR infused was, on average, 3.91 mL/kg per TBSA (3.78 in those whose UO was within the target range). Maintenance fluids added an additional 2.39 mL/kg per TBSA to the total.[33] The 2011 Advanced Burn Life Support manual recommends the use of this 3 mL/kg per TBSA burned formula for children, with the addition of maintenance fluid of D5WLR.[30]

The Shriner's Cincinnati and Galveston pediatric formulas account for the larger body surface area-to-weight ratio of children. For the first 24 hours post burn, the Cincinnati formula provides 4 mL/kg per TBSA (with half given in the first 8 hours), plus maintenance needs (MN), plus evaporative losses (EL). Here, MN = (1500 mL) × (body surface area in m^2), and EL = 35 + (TBSA burned in %) × (body surface area in m^2).[34]

For the first 24 h post burn, the Galveston formula provides 5000 mL × (TBSA burned in m^2) + 2000 mL × (body surface area in m^2), with half given in the first 8 hours post burn.[35,36]

Choice of Fluid

LR is the most frequently used crystalloid solution for burn shock resuscitation. Normal saline (NS) was used in the past, but has been criticized primarily because (1) it may decrease renal blood flow and glomerular filtration rate, thus increasing the risk of acute kidney injury; and (2) in large volumes, it may cause hyperchloremic metabolic acidosis. Clinical trials of NS versus balanced crystalloid solutions such as LR or Plasma-Lyte in nonburn patients are contradictory,[37] and there are no studies in burn patients. Because LR is slightly hypotonic, it may increase brain water content and intracranial pressure (ICP).[38] This may explain, in part, the concerning finding of increased ICP in some burn studies (see later discussion). LR contains a racemic mixture of D- and L-lactate isomers. Ayuste and coauthors reported that resuscitation with standard (i.e., racemic) LR was associated with lung and liver apoptosis, which was prevented by removal of the D-lactate isomer from the LR.[39] Plasma-Lyte has an electrolyte composition and an osmolality that is closer to that of plasma, and it contains gluconate and acetate instead of lactate.[37] However there are no studies comparing Plasma-Lyte to LR in burn patients.

Although crystalloid is the mainstay of burn shock resuscitation, the debate concerning if, when, and how much colloid is needed has continued. There are several systematic approaches to colloid use, including (1) *immediate* (use colloids during all hours of burn resuscitation), (2) *early/rescue* (use colloids when resuscitation is becoming excessive, typically starting at 8–12 hours post injury), and (3) *late* (do not use any colloids for resuscitation during the first 24 hours).[28,40] Increasingly a rational approach to identifying those patients who may benefit from early colloid use is followed at many burn centers.

Demling and colleagues developed an ovine model with chronic lymph fistulas and described the dynamics of edema formation in burned and unburned tissues. Measurement of lymph flow rates (Q_L) and the lymph-to-plasma protein ratio (C_L/C_P) revealed that the ability of the microvasculature to retain plasma proteins began to recover between 8 and 12 hours post burn in unburned but not in burned tissue.[41] This provides evidence that a colloid-containing solution may be more effective than a crystalloid solution beginning about 8–12 hours post burn.

In a prospective randomized trial, O'Mara and colleagues compared fresh frozen plasma (FFP) resuscitation and crystalloid resuscitation.[42] In this trial, the FFP group received a mixture of 75 mL/kg FFP (titrated to maintain a UO of 0.5–1.0 mL/kg per hour) plus 2000 mL LR (83 mL/h), while the crystalloid group received LR according to the Parkland formula (titrated to maintain a UO of 0.5–1.0 mL/kg per hour). The crystalloid group required significantly more fluid than the FFP group (260 vs. 140 mL/kg). FFP resuscitation was associated with a lower peak intra-abdominal pressure (16 vs. 32 mm Hg). Furthermore the crystalloid group developed elevated creatinine, blood urea nitrogen (BUN), and peak airway pressure, whereas the FFP group developed only elevated peak airway pressure.

This and similar studies suggest that, particularly in patients who are at risk for complications like abdominal compartment syndrome (ACS)—e.g., patients with large burns whose early resuscitation hours feature rapid escalation in the infusion rate—early colloid use is reasonable. Consistent with this idea, an approach taken at the University of Utah burn center involves use of "albumin rescue" when the fluid infused-to-UO ratio increases above expected levels.[40,43]

Five percent albumin in NS is the most commonly used colloid for burn resuscitation today. In a previous era in which albumin was not widely available and donor screening was rudimentary, infusion of plasma was associated with a high risk of hepatitis transmission. Today the availability of safe FFP should cause us to raise the question of whether FFP offers advantages over albumin or LR. Pati et al. found that FFP or Kcentra (a factor concentrate) may be superior to albumin in protecting against increases in endothelial permeability induced by vascular endothelial growth factor-A (VEGF-A) or by trauma/hemorrhage.[44] Also in hemorrhagic shock models, Peng and colleagues observed that FFP compared to LR decreases pulmonary shedding of syndecan-1 from the endothelium, reduces endothelial permeability, and decreases neutrophil infiltration.[45] These findings in hemorrhagic shock indicate that more work on the microvascular effects of FFP during burn resuscitation is needed.

Compared with albumin and FFP, there is currently less enthusiasm for the use of hetastarch solutions such as 6% hydroxyethyl starch (HES) for burn shock resuscitation. Vlachou et al. in the United Kingdom resuscitated 26 adults with Hartmann's solution or with a combination of two-thirds Hartmann's solution and one-third HES. They found that the HES group received less fluid (263 mL vs. 307 mL/kg).[46] On the other hand, a Swiss trial in 48 patients compared LR versus 6% HES for the first 72 hours post burn. They found no difference in volume requirements, renal function, acute respiratory distress syndrome (ARDS), length of stay, or mortality.[47] A Cochrane review concluded that HES solutions increase the risk of acute kidney injury and the need for renal replacement therapy.[48] As a consequence of these and other studies, the European Medicines Agency stated in 2013 that HES should not be used in critically ill, septic, or burns patients.[49]

Another approach to reducing the infused volume during burn resuscitation is the use of hypertonic saline. While Shires, Baxter, and colleagues were advocating the rapid correction of the extracellular sodium deficit with large volumes of LR by means of the Parkland formula, Monafo argued that hypertonic lactated saline solution, given intravenously and orally, could just as easily correct the sodium deficit while avoiding the administration of excessive volumes. His fluid contained 300 mEq/L of sodium, 200 mEq/L of lactate, and 100 mEq/L of chloride.[50] Several burn centers have routinely used hypertonic saline during resuscitation. For example, Warden at the Cincinnati Shrine used LR plus 50 mEq of sodium bicarbonate per liter, which results in a mildly hypertonic solution, for the first 8 hours postburn.[51]

During fluid resuscitation using hypertonic solutions, the extracellular fluid volume deficit is partially corrected by means of water flux from the intracellular to the extracellular space, in response to the increased extracellular sodium concentration.[32] The serum sodium should be

monitored during hypertonic resuscitation, since a level of greater than 160 mEq/L has been associated with adverse renal and cerebral effects.[52]

Huang and colleagues described a study in which a first cohort of patients was treated with LR, a subsequent cohort was treated with hypertonic saline (290 mEq/L), and a third cohort was treated with LR. The hypertonic patients had a fourfold increase in the risk of renal failure and twice the mortality.[53] This experience dampened enthusiasm for hypertonic saline. However Oda et al. reported a prospective study of burn patients resuscitated either with hypertonic lactated saline (HLS) or with LR. The concentration of sodium decreased from 300 to 150 mEq/L with each subsequent liter or two administered. Patients who received HLS had a lower prevalence of intra-abdominal hypertension and received less fluid (3.1 vs. 5.2 mL/kg per TBSA).[54] Thus there may be a role for hypertonic saline resuscitation in those patients who are particularly volume sensitive or at risk of overresuscitation.[52]

A different approach to hypertonic therapy in burn shock is to use the much more concentrated fluid, hypertonic saline dextran (HSD), which consists of 7.5% normal saline and 6% dextran-70 and whose sodium concentration is 1280 mEq/L. Elgjo and colleagues in an ovine model demonstrated that 4 mL/kg of HSD given 1 hour postburn rapidly restored CO and reduced early, but not late, fluid requirements.[55] In a follow-up study, this group showed that the fluid-sparing effect of HSD could be sustained to 48 hours by use of a second dose given when net fluid accumulation reached 20 mL/kg.[56] We do not have clinical trials of HSD use in burn shock resuscitation.

Route of Administration

A survey of burn specialists performed by Greenhalgh revealed that the peripheral intravenous route (70%) is preferred for burn resuscitation. However, central venous access is often used (48%).[57] In cases of severe injury with widespread deep burns and edema, use of peripheral veins may not be possible. As a temporary option, intraosseous access may be lifesaving, but flow rates are limited due to the hydraulic resistance of the bone marrow. Later, central venous access can be established in the intensive care setting.

Early initiation of fluid resuscitation (within the first hours of burn injury) is essential for the prevention of organ failure,[1,58] but may be difficult to achieve in austere environments, combat casualty care, and mass-casualty events. Here enteral or oral resuscitation should be considered and may be effective for burns between 10% and 40% TBSA.[59,60] Clinical use of enteral resuscitation of burns was described by several early authors, including Fox in 1944.[61] Its utility might be limited by ileus and reduced gastric function. The effectiveness and safety of enteral resuscitation merit further investigation.[13]

There are no burn-specific oral/enteral fluid resuscitation solutions. World Health Organization (WHO) oral rehydration solution is available as a dry powder that is reconstituted with clean water. It was originally developed for treatment of dehydration secondary to cholera. These, and commercially available solutions, contain sodium, other electrolytes, and sugars. The sugar component is important because it increases the uptake of sodium across the intestinal mucosa. If enteral resuscitation is performed via a nasogastric tube, frequent (e.g., hourly) monitoring of gastric residual fluid volumes is recommended, especially during the initial hours post burn.

Patients at Increased Risk During Resuscitation

Patients with significant comorbidities (e.g., heart failure, cirrhosis, preexisting renal insufficiency, morbid obesity[62]) often do not respond in the usual way to fluid resuscitation and may benefit from closer monitoring, as described later.[63] Patients at the extremes of age—the very young and the very old—are less tolerant of "swings" in volume status; that is, their ability to compensate for hypovolemia or hypervolemia is limited, and they are particularly "volume sensitive." Again, closer attention to detailed monitoring is warranted in these patient populations.

Baxter reported that patients with inhalation injuries and large burns have the greatest fluid requirements in the burn population.[64] Most studies have reported increased fluid requirements of 20%–30% when compared to equal-size burns without inhalation injury.[65] However, this response is unpredictable, such that a modification of the burn resuscitation formulas because of inhalation injury is not commonly recommended.

Patients whose resuscitation is delayed may require more fluids than suggested by the formulas and may have increased complications because of the deleterious effects of prolonged ischemia followed by reperfusion.[58] Again, no modification of practice is commonly recommended in this scenario. Patients with a mechanism of injury suggesting risk of mechanical trauma and who do not respond to resuscitation in the usual fashion, may have a missed injury and ongoing bleeding. Patients with clinically evident myoglobinuria, as may occur following high-voltage electric injury, are typically given fluids at an increased rate in order to decrease pigment deposition in the renal tubules, with a target urine output of 75–100 mL/h in adults.[66]

Monitoring Resuscitation

Optimizing resuscitation—that is, ensuring administration of sufficient volume to achieve organ perfusion at the lowest physiologic cost—requires hourly monitoring (UO, hemodynamics, and clinical signs of adequate perfusion) and titration of fluid based on these endpoints. The most commonly used assessments are vital signs, laboratory assays, and UO. The primary index of the adequacy of resuscitation is most often the UO, with the rationale that it is a surrogate metric for glomerular filtration rate, renal blood flow, and CO. Recommended UO is 30–50 mL/h in adults, 0.5 to 1.0 mL/kg per hour in children of less than 30 kg, and 1.0 to 2.0 mL/kg per hour in infants. Recent trends have many burn caregivers targeting the lower values of these ranges. UO is usually recorded hourly; however studies validating this frequency are lacking. UO may fail as an index of resuscitation adequacy in patients with renal failure and in those

whose UO is elevated by the use of a diuretic, alcohol intoxication, or glycosuria. In these patients, alternate methods of monitoring are recommended.

UO is only one metric of adequate perfusion. Heart rate, blood pressure, central venous pressure, and echocardiography can serve as indices of cardiovascular status, particularly in patients with large burns and complex comorbidities. These variables must be considered in the context of burn shock physiology, however. For example, a well-resuscitated adult with extensive burns should have a heart rate in the 100–130/min range. This is because of the massive release of catecholamines caused by injury and because of the relative hypovolemia that characterizes a prudent resuscitation. A mean arterial pressure (MAP) of 60 mm Hg is a reasonable target for most patients, but some patients will tolerate a MAP as low as 50–55 mm Hg and still achieve adequate UO, cerebral perfusion, and decreasing lactic acidosis.

Laboratory values are an important assessment tool. Complete blood count, electrolytes, glucose, and acid–base status should be monitored frequently, although evidence regarding the optimal frequency of measurement is lacking. Lactate and base deficit (BD) are often used as indices of the adequacy of global perfusion. Elevated BD and serum lactate correlate with larger burn size, inhalation injury, greater fluid requirements, and mortality.[1,67,68] In a prospective study of BD and outcomes in burn patients, Cartotto et al. reported that patients with worse BD had greater fluid requirements as well as higher rates of sepsis, ARDS, and multiple organ dysfunction syndrome.[69] Kamolz et al. showed that lactate levels and the rate of lactate clearance are useful markers of shock and resuscitation status.[70] Additionally, they demonstrated that if the lactate levels were normalized within 24 hours the survival rate was 68%, compared to 32% if lactate normalization did not occur within 24 hours.

The pulmonary artery catheter (PAC) was used for decades during resuscitation to measure pulmonary capillary wedge pressure, systemic and pulmonary vascular resistances, CO, and oxygen consumption, a practice now largely limited to research applications. Transpulmonary thermodilution (TPTD) is a less invasive option that requires one access point via a central venous line as well as one access point via a peripheral artery. Commercial TPTD monitors also provide beat-to-beat estimates of CO (based on arterial waveform contour analysis). In addition, one can measure global end-diastolic volume (GEDV), a marker of cardiac preload, as well as extravascular lung water, a marker of pulmonary edema. Sánchez et al. showed that TPTD, but not MAP or UO, accurately detected hypovolemia during acute resuscitation (within 24 hours of burn).[71] A recent study in burned children by Kraft et al. confirmed these findings.[72]

How best to use TPTD or PAC data during resuscitation is not obvious. Attempts to "normalize" the CO or the GEDV during the first 24 hours postburn are often ill-advised because they may lead to overresuscitation with no net improvement in outcome.[73] Rather, an understanding of the expected dynamics of the successfully resuscitated average patient may allow a determination of whether a given patient is "on course" or "off course" with respect to his progress.[74] Information from Pruitt et al.[5] is helpful in this regard. In that study of successful resuscitations, the plasma volume deficit persisted until after 48 hours post burn, and CO remained below baseline levels until 36 hours post burn.

Echocardiography has largely replaced the PAC for the cardiac evaluation of selected burn patients.[75] Transthoracic echocardiography (TTE) provides information on volume status and cardiac function. TTE can be performed easily without the need for preassessment sedation. Nevertheless, TTE should be performed by well-trained clinicians to minimize user-dependent errors.[76] A further advantage of echocardiography, in comparison to PAC and TPTD, is that it can help diagnose heart failure and determine the response to inotropes. Further prospective randomized controlled trials comparing different echocardiography techniques are warranted.[75]

An increase in the hematocrit (or hemoglobin) during burn shock likely indicates a worsening plasma volume deficit. For this reason, early treatises on burn resuscitation recommended following this value as an index of volume status.[21] Certainly it can provide supportive information, bearing in mind that a decrease in hematocrit below normal levels is frequently seen as resuscitation continues, reflecting red blood cell damage.[5]

Fluid Creep and Edema Management

During resuscitation, the desire to maintain adequate perfusion of vital organs and the failure to titrate fluid input appropriately can lead to overresuscitation.[40] "Fluid creep" was first described by Pruitt as a recent trend toward infusing greater volumes of fluid than those predicted by the burn formulas, leading to organ dysfunction or even life-threatening complications.[2] Overresuscitation may lead to ACS,[77] airway and pulmonary edema,[78] extremity compartment syndrome (ECS),[79] orbital compartment syndrome,[80] and cerebral edema. The risk of cerebral edema is particularly underappreciated. Gueugniaud et al. observed elevated ICP in patients with a TBSA of greater than 60% and no history of head injury, peaking on day 2 postburn.[81] Shin et al. in an ovine 70% TBSA model showed an increase in ICP and a decrease in cerebral blood flow at the end of 6 hours postburn, with increased brain water content at autopsy.[82] Ding and colleagues conducted studies in a rat model and demonstrated increased blood–brain barrier permeability post burn that could be prevented by tumor necrosis factor-α (TNF-α) or matrix metalloproteinase-2 blockade.[83] Gatson et al. demonstrated increased brain cytokine levels in burned rats and their blockade with 17-β-estradiol.[84]

To this list of early complications, we should add the effect of wound edema on the progression of injury depth and on the success of wound healing,[50] the importance of which to survival cannot be overstated.[85]

These complications are highly morbid, and strenuous efforts to forestall them are a critical aspect of burn shock resuscitation in the modern era. For example, ACS in burn patients, when treated by laparotomy, carries a near 100% mortality in many series. ECS (in burned or unburned limbs) may be detected late, leading to muscle necrosis,

nerve injury, and possibly limb loss.[79] Ivy observed that risk of ACS increases when the infused volume exceeds 250 mL/kg during the first 24 hours postburn.[77] For this reason, that volume is often referred to as the "Ivy Index." Early identification of patients who are on course for a resuscitation in which the Ivy Index will be exceeded may permit corrective actions to decrease the infusion rate and preclude or promptly address these complications. Such corrective actions include (1) strategies to reduce the fluid infusion rate and (2) strategies to address edema.

A reduction in fluid infusion rate may be possible by (a) initiation of colloids, (b) tolerance of a subtarget UO, (c) initiation of continuous renal replacement therapy to address acidosis or renal insufficiency, (d) initiation of high-dose ascorbic acid, and/or (e) a diagnostic work up for non–volume-related causes of shock, such as echocardiography to assess cardiac function and the need for inotropes.

Strategies to reduce edema formation or to address its effects include (a) aggressive elevation of burned extremities; (b) monitoring of extremity compartment pressures and/or physical exam, with escharotomies or fasciotomies as needed;[86] (c) monitoring of the bladder pressure to diagnose intra-abdominal hypertension (IAH); (d) use of sedation/paralysis/positioning to reduce IAH; (e) placement of a diagnostic peritoneal lavage (DPL) catheter connected to intravenous tubing to permit evacuation of ascites and reduction in IAH; and (f) measurement of intraocular pressures and lateral canthotomy for orbital compartment syndrome.[80]

Fig. 9.1 shows a plot of actual 24-h volumes infused for burn resuscitation when LR was used and hourly rates were adjusted based on UO. Data are from all studies that were identified between 1980 and 2015. Clearly most studies report volumes that exceed Parkland estimations. While these data suggest a trend toward increased fluid volumes, more striking are the wide variations reported for mean values and the large standard deviations reported for most individual studies. These data stand in sharp contrast to Baxter's original publications that suggest most patients can be resuscitated with 4 mL/kg per %TBSA burned,[25] and

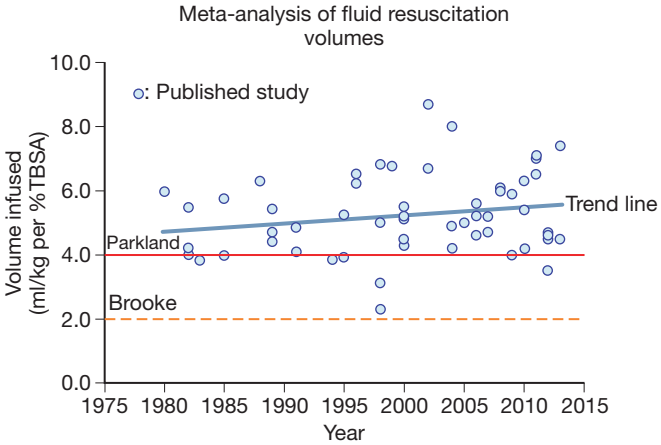

Fig. 9.1 Scatter plot and regression of published studies showing actual fluid infused over 24 hours compared to fluid requirements estimated using the Parkland and Brooke formulae. Studies were from 1980 to 2014 and the mean fluid infused was 5.3 ± 1.2 (SD) mL/kg per %TBSA burned. (Unpublished data, Kramer GC et al.)

Pruitt's, which suggest that most can be resuscitated with slightly less than 3 mL/kg per TBSA.[87]

While there are no randomized controlled trials to suggest the superiority of one burn formula over another, Chung et al. retrospectively analyzed data from combat casualties treated in Iraq. Clinical practice guidelines in place during the war recommended that burn patients be resuscitated using 2–4 mL/kg per TBSA. In practice, the resuscitation of most of these patients was initiated at either 2 or 4 mL/kg per TBSA. This permitted comparison of the modified Brooke and the Parkland formulas. Patients in both groups received more than predicted by the formulas: those started at 2 mL/kg per TBSA received 3.8 mL/kg per TBSA, whereas those started at 4 mL/kg per TBSA received 5.9 mL/kg per TBSA. Patients started at 2 mL/kg per TBSA were less likely to exceed the Ivy Index than were those started at 4 mL/kg per TBSA (29% vs. 57%).[88] This suggests that one answer to fluid creep is to initiate resuscitation using the more conservative modified Brooke formula.

Faraklas et al. and Cancio et al. suggested that clinicians may be more aggressive at increasing fluid infusion rates initially than they are at decreasing fluid infusion rates later.[89,90] Furthermore Faraklas et al. concluded that seriously injured patients, pediatric patients, and patients with combinations of burns and inhalation injuries are more prone to fluid creep. Greater fluid volumes were associated with significantly more escharotomies and complications as well as longer hospital stays.

In 2004, Sullivan et al. suggested that fluid creep might be associated with increased administration of opioids during burn shock resuscitation, a phenomenon termed "opioid creep."[80] They compared fluid requirements in a cohort of burn patients who received low doses of opioids (treated in 1975) to those in a group of patients (treated in 2000) who received four times higher doses of opioids. A significant correlation was noted between opioid dose and fluid requirements within the first 24 hours of acute hospitalization. Nevertheless opioids remain a crucial part of pain management in severely burned patients.[91] The cardiovascular effects of opioids and benzodiazepines need to be considered, and the amount given must be strictly monitored.

Lawrence et al. described a "colloid rescue" in which they provided 5% albumin to patients who were requiring excessive amounts of crystalloids; this approach permitted a subsequent reduction in crystalloid infusion rates.[43] The use of colloids should be considered in patients heading toward fluid needs in excess of Parkland volume estimates (see earlier discussion), particularly after the first 8–12 hours postburn have passed.[41]

Pharmacologic and Extracorporeal Adjuncts

There is a limited role for vasoactive medications during burn shock resuscitation. Traditionally we have been reluctant to use vasoconstrictors such as norepinephrine or vasopressin during burn shock, recognizing that many of these patients respond to injury and hypovolemia with intense catecholamine release and vasoconstriction. However, on a case-by-case basis, such agents may be useful to support

a minimally acceptable mean arterial blood pressure while volume resuscitation proceeds.[92] Likewise, cardiac inotropes such as dobutamine (or agents which reduce afterload, such as hydralazine) should be used with caution in hypovolemic burn patients since afterload reduction in this population may precipitate overt hypotension.[5] However, in volume-replete patients whose CO remains low, inotropes may be appropriate. The choice of vasoactive medication may be facilitated by echocardiography.

High-dose ascorbic acid (vitamin C) has been used as a pharmacologic adjunct during burn resuscitation. Its proposed mechanism of action is that it is a free-radical scavenger capable of reducing post-burn lipid peroxidation and microvascular leakage. At a dose of 66 mg/kg per hour (begun as soon as possible after admission), it was evaluated in a prospective randomized controlled trial by Tanaka and colleagues. They showed that high-dose ascorbic acid significantly reduced 24-hour fluid requirements (from 5.5 to 3.0 mL/kg per TBSA), weight gain, and edema. Additionally, treated patients had fewer ventilator days, less lung water, lower rates of acute lung injury, and lower levels of serum malondialdehyde, a marker of oxidative stress. The ascorbic acid group, although given significantly less fluid than the control group, had comparable hemodynamics and hourly UO.[93] Dubick and coworkers reported that, in an ovine model of burns, high-dose isotonic ascorbic acid reduced total volume infused over the 48-hour study. Furthermore the treatment group had markedly elevated plasma antioxidant potential and reduced lipid peroxidation.[94] A small retrospective study yielded similar findings.[95] Specifically ascorbic acid-treated patients had significantly lower resuscitation volumes and reduced vasopressor use. These studies suggest that high-dose ascorbic acid holds promise in resuscitation, but a multicenter trial is yet to be performed. Ascorbic acid may act as an osmotic diuretic, which may affect the use of UO as an index of resuscitation adequacy. Also, institution of this drug upon admission, rather than at some later time point when a patient appears to be failing resuscitation, makes sense considering its antioxidant mechanism of action.

Extracorporeal adjuncts to burn resuscitation include therapeutic plasma exchange (TPE), continuous renal replacement therapy (CRRT), and extracorporeal blood purification. TPE has been used at a small number of burn centers for the treatment of patients who are not responding to resuscitation appropriately. In TPE, the patient's plasma volume is replaced with FFP. The basis for this intervention is the concept that burn shock is mediated, in part, by circulating cytokines and other factors that can be removed by TPE. Neff et al. reported on experience with 21 patients who underwent TPE when the volume received exceeded 1.2 times the goal of 3 mL/kg per TBSA at any given point during the first 24 hours, along with other evidence of failure such as oliguria or hypotension. TPE was associated with increases in blood pressure and in UO, and decreases in the intravenous fluid rate and lactate. There was no difference in mortality with a control group.[96] Klein et al. applied TPE to 37 patients who typically were receiving twice the volume predicted by the Parkland formula. Findings were similar to those of Neff et al.[97]

There are no data on the utility of CRRT for the treatment of burn shock. Chung et al. reported on burn patients with acute kidney injury (Acute Kidney Injury Network [AKIN] level 3, or level 2 with shock). These patients were initiated on CRRT on mean hospital day 17 ± 24. Compared to historical controls, they had better mortality; fewer of the patients with shock required vasopressors at 24 hours. The authors speculated that the mechanism of action for this improvement could be nonspecific removal of cytokines.[98] Application of these findings to patients with refractory burn shock and who do not meet AKIN criteria for CRRT would be based on this hypothesis.

Extracorporeal blood purification aims to remove inflammatory mediators and/or other molecules from the circulation by means other than CRRT. Linden and colleagues evaluated a novel extracorporeal cytokine-adsorbing column, CytoSorb (CytoSorbents Corporation, Monmouth Junction, NJ), in a porcine model of smoke inhalation injury and 40% TBSA burns. This column removed interleukin-1b (IL-1b), IL-6, IL-10, and myoglobin from the extracorporeal circuit but did not reduce systemic levels. Thus more work would be needed to optimize factors such as therapy duration, blood flow rate, and possibly device size.[99]

Protocol-Driven and Computerized Resuscitation

Nurse-driven burn resuscitation using hourly flow charts is an approach to achieving tighter control of fluid therapy. Nurse-implemented protocols allow nurses to make timely and effective changes to the resuscitation rates without having to wait for physicians' orders, which can delay needed adjustments in therapy. Additionally these protocols diminish the effects that experience and/or comfort level have on titration (a new nurse or intern may be reluctant to make significant changes). Faraklas and colleagues instituted a nurse-driven resuscitation protocol (Fig. 9.2) as a performance-improvement project and showed excellent protocol adherence. However, large-volume fluid resuscitation still occurred in patients with the largest burns or with inhalation injury.[90]

A logical next step to paper protocols is a computerized decision-support system (CDSS). A CDSS is an open-loop system that provides recommendations to the clinical team using data obtained from the patient. Salinas et al. developed an algorithm that calculates, on an hourly basis, the infusion rate most likely to achieve a UO within the target range during the next hour. The inputs used by the algorithm include the linear trend in the past three urine outputs, the burn size, the time post burn, and the current fluid infusion rate. The algorithm was implemented in software and was shown to decrease the total volume delivered while increasing the percentage of time during which UO rates achieved the target range. Ventilator days and ICU length of stay were also decreased.[100] Although encouraging, the study was small and awaits validation in larger trials.

Hourly adjustments in the fluid infusion rate are based on a convenient but arbitrary time interval, whereas the kidneys respond to changes in volume status more rapidly. Thus there may be value in developing a closed-loop system that continuously measures UO and automatically makes corrections to the infusion rate on a more frequent basis. Closed-loop fluid resuscitation systems have been shown to

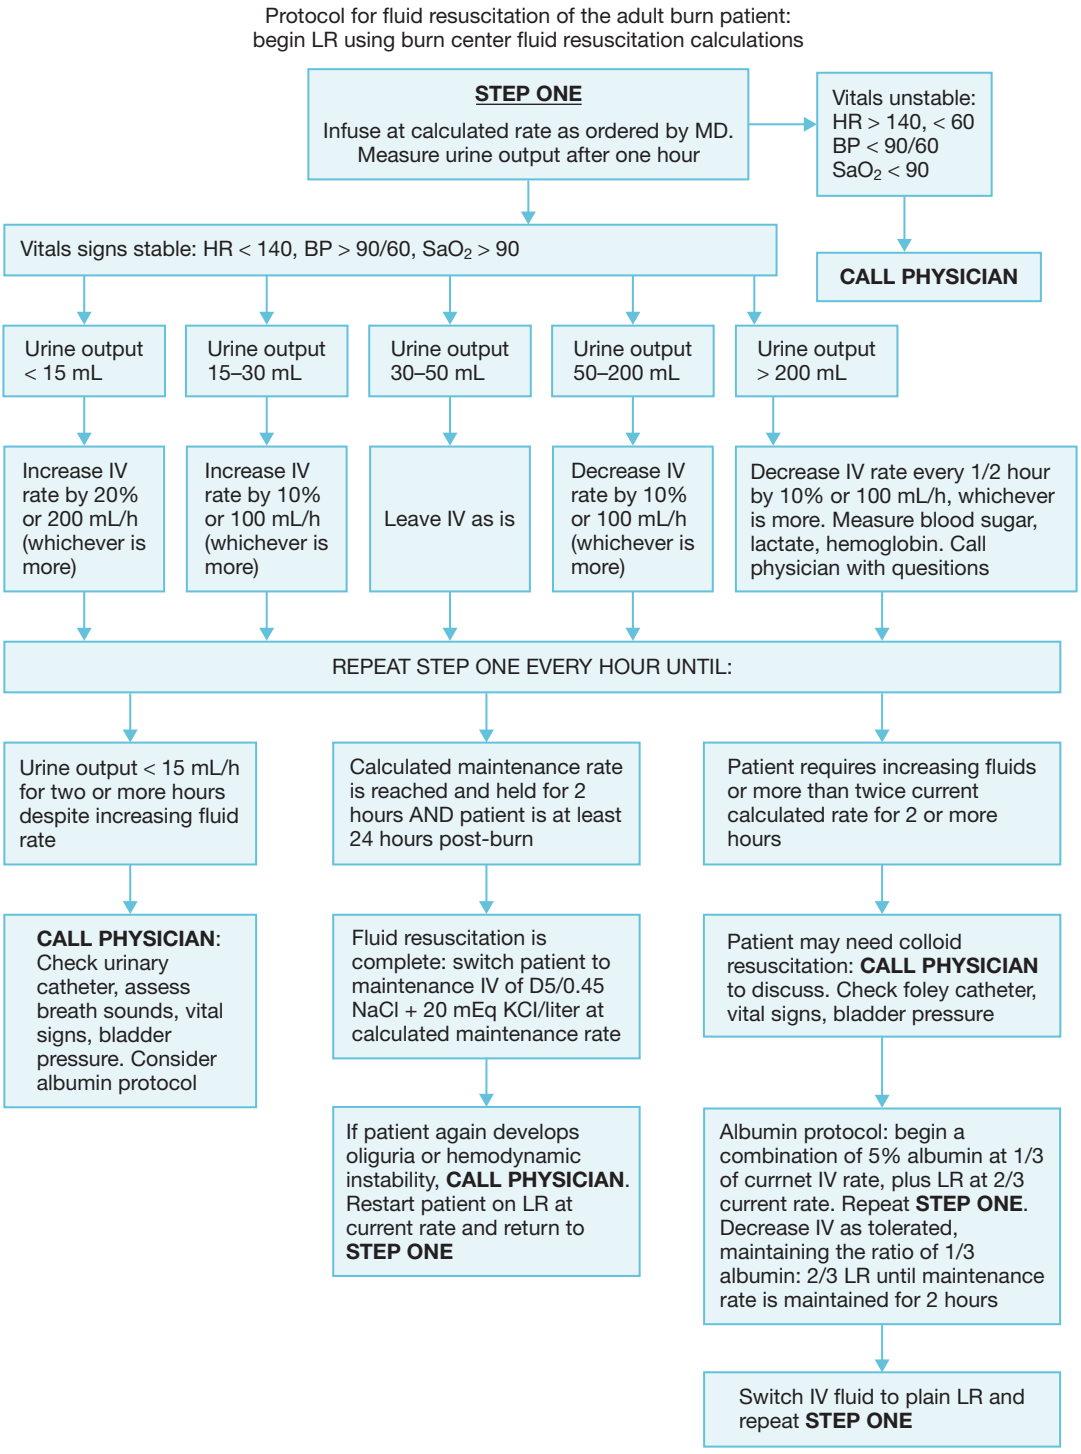

Fig. 9.2 Adult Fluid Resuscitation Protocol used at University of Utah. The pediatric protocol differs from the adult protocol in that urine output is targeted to 1.0–1.9 mL/kg per hour, and patients younger than 2 years receive 25 mL/h of 5% dextrose in lactated Ringer's (LR) throughout resuscitation. (From Faraklas I, Cochran A, Saffle J. Review of a fluid resuscitation protocol: "fluid creep" is not due to nursing error. *J Burn Care Res.* 2012;33(1):74–83.)

be effective (in maintaining resuscitation targets) and efficient (in reducing volume delivered) in large-animal models of both burn injury and hemorrhage.[101] Closed-loop systems could reduce much of the bedside caregiver's time in measuring and transcribing UO and making manual adjustments in infusion rates, allowing more time for other tasks. A closed-loop system may be particularly valuable in non-burn-center settings or mass-casualty scenarios, where burn expertise is lacking, diluted, or degraded. However a closed-loop system should not replace careful patient monitoring and should enhance, rather than reduce, a provider's situational awareness. Such systems must allow the

caregiver to override the computer and regain manual control.[102]

Conclusion

Fluid resuscitation is the important first step in the critical care of burn patients. There is still great controversy surrounding optimal resuscitation of patients: there are a multitude of strategies designed to improve resuscitation, with no single approach having universal acceptance. More important than any formula or technology is a diligent burn team of physicians and nurses assessing the overall adequacy of hemodynamics and end-organ perfusion and making adjustments as needed.

10 Evaluation of the Burn Wound: Management Decisions

ELISHA G. BROWNSON and NICOLE S. GIBRAN

Introduction

Advances in the resuscitation of burn patients have greatly improved survival so that death from burn shock has become uncommon. In the 21st century, prompt functional recovery for the burn patient hinges on proper early management of the burn wound. The greatest advance in burn care to date has been the institution of early surgical burn wound excision with an immediate or delayed wound closure strategy individualized to each patient.[1-4] For years, burns were treated by daily washing, removal of loose dead tissue, and application of some sort of topical nostrum until wounds healed or granulated. Superficial dermal burns healed within 2 weeks, and deep dermal burns healed over many weeks if infection could be prevented. Full-thickness burns lost their eschar in 2–6 weeks by bacterial enzyme production and daily bedside debridement; split-thickness skin grafts were applied usually 3–8 weeks after injury. A 50% graft survival rate was acceptable, and repeated grafting eventually closed the wound. The prolonged and intense inflammatory response led to hypertrophic scars, contractures, and considerable physical and psychological disability.

Burns that heal within 3 weeks generally do so without significant hypertrophic scarring or functional impairment, although long-term pigmentation is unpredictable. Burns needing longer than 3 weeks to heal often result in unsightly hypertrophic scars and functional impairment. State-of-the-art burn care now involves early excision and grafting. The challenge is to define "early." Knowing which burn wounds benefit from early excision and grafting requires understanding of skin biology and pathophysiological changes caused by thermal injury. In spite of ongoing efforts to objectively assess wound depth, the standard technique for determining burn depth in the 21st century remains clinical assessment of the wound by a burn specialist.

Pathophysiology of the Burn Wound

SKIN BIOLOGY

Skin protects against fluid and electrolyte loss, infection, and radiation and provides thermal regulation. Skin contact provides clues to the surrounding environment through touch, perception of temperature, and pain. In addition, skin appearance is a major determinant of identity and body image and affects interpersonal interactions. The largest organ in the human body, skin is comprised of two layers: the epidermis and the dermis. Epidermal thickness varies among different body parts: from 0.05 mm on the eyelids to over 1 mm on the soles.[5] Most skin thickness comes from the dermis, which varies with age, gender, and body location.

Epidermis derives from ectoderm; the principal cell is the keratinocyte, but epidermis also contains melanocytes, Langerhans cells, Merkel cells, and inflammatory cells. Keratinocytes begin their division and differentiation at the stratum basale and migrate progressively outward over 2–4 weeks[6] through the stratum spinosum, the stratum granulosum, the stratum lucidum, and the stratum corneum, at which point they are flattened anuclear cornified structures. In a wound with a sloughed epidermal basal layer, keratinocytes proliferate and migrate from the wound edges and epidermal appendages (hair follicles, sweat glands, and sebaceous glands) to achieve epithelialization. Melanocytes produce melanin pigment essential for protection against ultraviolet radiation, and Langerhans cells and other inflammatory cells perform phagocytosis and antigen presentation. After injury, melanocytes regenerate more slowly and less predictably, leading to potential permanent pigment changes.[7,8]

Epidermal projections (rete ridges) interdigitate with dermal projections (papillae) at the basement membrane zone, which connects the epidermis and dermis via keratinocyte-derived collagen VII anchoring fibrils, critical structures that stabilize the epidermal–dermal junction.[9,10] Since anchoring fibrils take several months to mature during wound healing, minor shearing forces cause shearing, blistering, and epidermal loss.

The dermis is comprised of the superficial papillary and deeper reticular dermis, separated by a capillary plexus that delivers necessary nutrients to dermal cellular structures. The abundant extracellular matrix, comprised primarily of collagen and elastin fibers, provides the dermal structure; organized collagen fiber orientation provides tensile strength[11] and elastin fibers impart cutaneous elastic recoil properties. Glycosaminoglycans and proteoglycans, such as hyaluronic acid and chondroitin sulfate, attract water to maintain matrix hydration, provide absorption, and regulate cellular cross-talk by binding and releasing inflammatory mediators.[12,13] Protein turnover, accounting for the high plasticity of skin, increases with mechanical stress and responses to injury.[14] After wounding, microvascular endothelial cells mediate local and systemic inflammatory responses and eventually proliferate and migrate to form

new vessels during angiogenesis.[15] Sensory nerves, which traverse into the epidermis, also play a significant role after injury, as they mediate pain and itching, modulate inflammation, and influence the remodeling phase of wound healing.[16,17] The dermis, like other mesoderm-derived structures, heals not by regeneration but by fibrosis and scarring.

Pathophysiological Changes of Thermal Injury

Applied heat at the cellular level causes denaturation of proteins and loss of plasma membrane integrity. Temperature and duration of contact have a synergistic effect; cell necrosis occurs after 1s of exposure at 156°F (69°C), or after 1h at 113°F (45°C).[18] Following a burn, necrosis occurs at the center of the injury and becomes progressively less severe at the periphery. Jackson's description in 1953 of the three zones of injury remains our conceptual understanding of the burn wound (Fig. 10.1).[19] The zone of coagulation at the center of the wound has no remaining viable cells. A mix of viable and nonviable cells, capillary vasoconstriction, and ischemia characterizes the surrounding zone of stasis; this "at-risk" zone may convert to necrosis in the presence of hypoperfusion, desiccation, edema, or infection. Approximately half of the cells in the zone of stasis undergo apoptosis or necrosis as a result of oxidative stress, ongoing inflammation, and decreased blood flow due to microthrombosis.[20] Systemic factors such as advanced age, diabetes, and other chronic illnesses increase risk for "conversion." Efforts to enhance wound healing have focused on prevention of necrosis in the zone of stasis since medical care has little impact on the outcome of the zone of coagulation. Protection of this sensitive area is achieved with adequate fluid resuscitation, avoidance of vasoconstriction and edema, and prevention of infection.[21,22] Optimal wound care consists of nondesiccating dressings, topical antimicrobials, and regular monitoring of the wound.[23–25] At the periphery of the burn wound, the zone of hyperemia contains viable cells with vasodilation mediated by local inflammatory mediators. Tissue in this zone usually recovers unless complicated by infection or hypoperfusion.

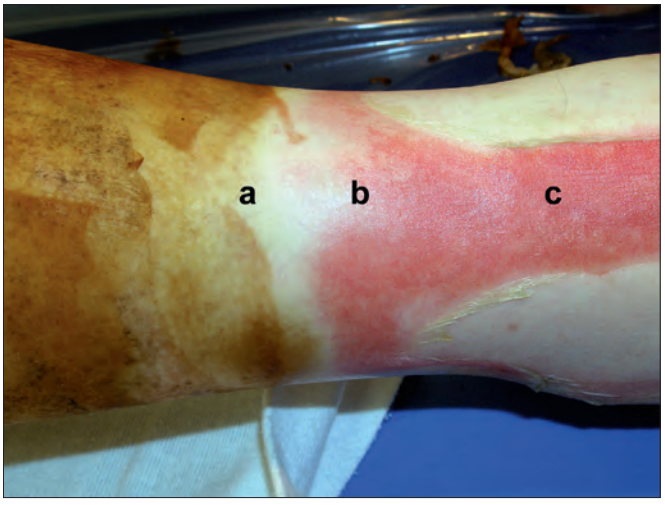

Fig. 10.1 Jackson's three zones of injury on an ankle burn: **(A)** the zone of coagulation; **(B)** the zone of stasis, and **(C)** the zone of hyperemia.

Interest in cooling of the wound to minimize the extent of injury can be traced to antiquity[26] but, firm evidence of its efficacy is lacking. Cooling immediately after injury should not supersede other priorities in the evaluation of the injured patient. The optimal temperature and duration of cooling is unknown[27–29] but excessive or prolonged cooling may be harmful in that it promotes vasoconstriction and systemic hypothermia.[30,31] Current guidelines of the American Burn Association recommend limiting cooling to 30 min in the management of minor burns.[32] Modalities to improve dermal perfusion and block injury from released inflammatory mediators have also garnered much interest. Whereas beneficial effects of many pharmacologic agents such as heparin, steroidal and nonsteroidal anti-inflammatory agents, thromboxane inhibitors, and epidermal growth factor have been reported,[20,33] all remain investigational since none has demonstrated clinical validity.

Assessment of Burn Depth

CLINICAL OBSERVATION

Burn injury may involve one or both layers of the skin and may extend into the subcutaneous fat, muscle, and even bony structures.[34] Burns involving only the outer layers of the epidermis (first-degree burns) are erythematous and very painful, but do not form blisters. Most sunburns fit this category of superficial, epidermal injury. Within 3–4 days, the dead epidermis sloughs and is replaced by regenerating keratinocytes. These burns are not included in burn size calculations for estimates of injury severity and resuscitation fluid estimations.

Superficial dermal burns (superficial second-degree burns) extend into the papillary dermis and characteristically form blisters. Blistering may not occur immediately after injury, and burns initially perceived to be superficial might subsequently be diagnosed as dermal burns. The wound bed underlying a blister on a superficial partial thickness burn is pink, wet, and hypersensitive to touch. Debriding the blister may be painful due to the currents of air passing over the wound. These wounds blanch with pressure because of vasodilation and increased blood flow in the dermis compared to normal skin. With appropriate wound care, superficial dermal burns usually heal within 2 weeks without risk of scarring and therefore do not require operation.

Deep dermal burns (deep second-degree burns) extend into the reticular dermis and generally take 3 or more weeks to heal. They blister, but the underlying wound surface appears mottled pink and white immediately following the injury (Fig. 10.2A). When pressure is applied to the burn, capillaries refill slowly or not at all. The wound is often less sensitive to pinprick than the surrounding normal skin. By postburn day 2, the wound may be white and dry (Fig. 10.2B). As a rule, most partial-thickness

Fig. 10.2 Lower extremity deep dermal burn: **(A)** on day of presentation wound has a wet, pink and moist appearance; **(B)** on day 3 post-injury wound has a mottled appearance with both moist pink and dry white areas.

burns that have not healed by 3 weeks should be excised and grafted.

The most difficult management decision involves intermediate partial-thickness burns. The determining factor as to whether these burns heal in 3 weeks may be less than a millimeter. These burns are aptly called "indeterminate" burns because their healing potential becomes evident with serial assessments over several days after injury. Histologic studies suggest that burn injury is a dynamic process that peaks around 3 days after injury.[35–37] Initial evaluation by an experienced surgeon as to whether an indeterminate dermal burn will heal in 3 weeks is only 50%–70% accurate.[38–40]

Partial thickness scald burns usually should be managed nonoperatively for 10–14 days, unless they are obviously full thickness. However, these burns should be excised and grafted once it is clear that they will not heal by 3 weeks.[41] Serial clinical exams for partial thickness burns for 2 weeks after injury have been associated with excision of significantly smaller areas or avoidance of surgery entirely.

Full-thickness burns (third-degree burns) involve the entire cutaneous layer and may extend into the superficial subcutaneous tissue. Their appearance may be charred, leathery, dry, firm, and depressed when compared to adjoining normal skin. Noncharred full-thickness burns can be deceptive. Like deep dermal burns, they may be mottled in appearance. They rarely blanch on pressure and may have a dry, white appearance. In some cases, the burn may appear translucent with clotted vessels visible. These wounds are insensate to light touch and pinprick. Some full-thickness burns, particularly immersion scalds or "bake" injuries (caused by convective heat), may have a red appearance and can be confused with a superficial dermal burn by an inexperienced observer; these burns do not blanch with pressure. Most full-thickness burns should undergo early excision and grafting to minimize infection and hypertrophic scarring and to expedite patient recovery. Deeper burns that involve adipose tissue (fourth-degree burns), muscle (fifth-degree burns), and bone (sixth-degree burns) also require surgical management.[42]

ADJUNCTS TO CLINICAL EVALUATION

The search for technologies to obtain a more precise method to diagnose burn depth surged when the benefits of early operation were recognized. Multiple modalities have been trialed, including thermography, photometry, nuclear imaging, pulse-echo ultrasound, and, more invasive than the aforementioned, serial tissue biopsy.[43–45] These techniques take advantage of the ability to detect dead cells or denatured collagen (biopsy, ultrasound, vital dyes)[19,46–49]; wound color (light reflectance)[50]; physical changes, such as edema (magnetic resonance imaging)[51]; and altered blood flow (fluorescein, laser Doppler imaging, and thermography).[52–54] Unfortunately, none of these techniques has proved superior to serial clinical assessment by an experienced burn provider. Several groups have recently reported clinical benefit with the use of noncontact laser Doppler imaging in indeterminate thickness burns.[37,43,55] This technique provides a color perfusion map of the burn that can be assessed without direct contact with the skin surface, making this test well tolerated; furthermore, serial exams can track dynamic changes in wound bed perfusion. Although identified as an accurate measurement tool, noncontact laser Doppler imaging remains an adjunct, rather than a substitute, for clinical assessment.[56]

Mechanisms of Thermal Injury

FLASH AND FLAME BURNS

Flash and flame burn injuries represent approximately 40% of the admissions to American regional burn centers.[57] Explosions of natural gas, propane, gasoline, and other flammable liquids cause intense heat for a very brief time, causing flash burns. Flash burns often result from an inappropriate use of a flammable liquid as a fire accelerant on camp, trash, and brush fires. For the most part, flash burns reach progressive layers of the dermis in proportion to the amount and kind of fuel involved. Gasoline, especially, has highly flammable vapors that are 3–4 times denser than air. At room temperature, gasoline vapors diffuse above ground and accumulate in enclosed spaces. Clothing, unless it ignites, is protective in flash burns. Thus, a flash burn injury distribution typically involves exposed skin, with the deepest areas facing the source of ignition. If a flash burn causes clothing or hair to catch on fire, the injury will be more typical of a flame burn. Whereas such flash burns generally heal without extensive skin grafting, they may cover large areas and may be associated with thermal injury to the upper airway.

Flame burns invariably involve deep dermal or full-thickness injury because of prolonged exposure to intense heat. Although the incidence of injuries from house fires has decreased with the advent of smoke detectors, careless smoking, improper use of flammable liquids, automobile accidents, and clothing ignited from stoves or space heaters still exact their toll. Patients whose bedding or clothes have been on fire usually sustain some full-thickness burns. Victims of house fires with prolonged exposure to flames or heat due to immobility, intoxication, or confusion caused by hypoxemia or carbon monoxide toxicity are also prone to

have deeper burns. In one study of several burn centers, 28% of flame burns occurred in patients with high blood ethanol level, and 51% of victims in fires behaved inappropriately when trying to escape.[58] Loss of consciousness exposes victims to convective heat inside a burning room. This type of "bake" injury may deceptively appear shallow with intact epithelium to the inexperienced observer but is really a full-thickness burn.

SCALDS

Hot water scalds are the next most common cause of burns in the United States, representing approximately one third of cases.[57] Despite educational programs, the epidemiology and incidence of scalds worldwide has changed very little. The depth of scald injury depends on the water temperature, skin thickness, and duration of contact. Water at 140°F (60°C) creates a deep dermal burn in 3 s but causes the same injury in 1 s at 156°F (69°C).(18) Freshly brewed coffee from an automatic percolator is generally about 180°F (82°C). Once in the pot, coffee temperature approximates 160°F (70°C). Boiling water often causes a deep dermal burn, unless the duration of contact is very short. Soups and sauces, which are thicker due to proteins and oil, remain in contact longer with the skin and invariably cause deep dermal burns. Exposed areas tend to incur shallower burns because clothing (such as diapers and socks) retains heat and keeps the liquid in contact with the skin longer. Consequently, scalds are often a mosaic of superficial and indeterminate dermal burns. A common example is a toddler who reaches above head level and spills hot water; his face bears a superficial burn, the trunk burn is of indeterminate thickness, and skin under his diaper has a deep dermal burn.

Immersion scalds are often deep because of prolonged skin exposure, although the water temperature may not be as high as with spill scalds.[59,60] They occur in individuals who do not perceive the discomfort of prolonged immersion (i.e., diabetic patients or spinal cord injury patients with peripheral neuropathy), or who are not able to escape from the hot water (i.e., young children, elderly, or people with physical and cognitive disabilities). This latter group of vulnerable individuals is susceptible to nonaccidental scald burns,[61,62] which account for about 2% of all children admitted to our burn center. Circumferential extremity injuries, symmetrical burns to a child's buttocks and perineum represent a few injury characteristics that should raise suspicion of nonaccidental trauma (Fig. 10.3). Allegations of abuse should include expert burn wound assessment by an experienced burn surgeon who is familiar with burn distribution and etiologies.

Grease and hot oils cause deep dermal or full-thickness injuries. During cooking, grease and hot oils are usually heated to a level below their smoke point to avoid unpleasant odors from their decomposition. The smoke point is 350°F (177°C) for butter, 400° F (204°C) for lard, and 450°F (232°C) for corn oil. Cooking oils reach their flash point at 600°F (316°C). Domestic grease burns occur in a

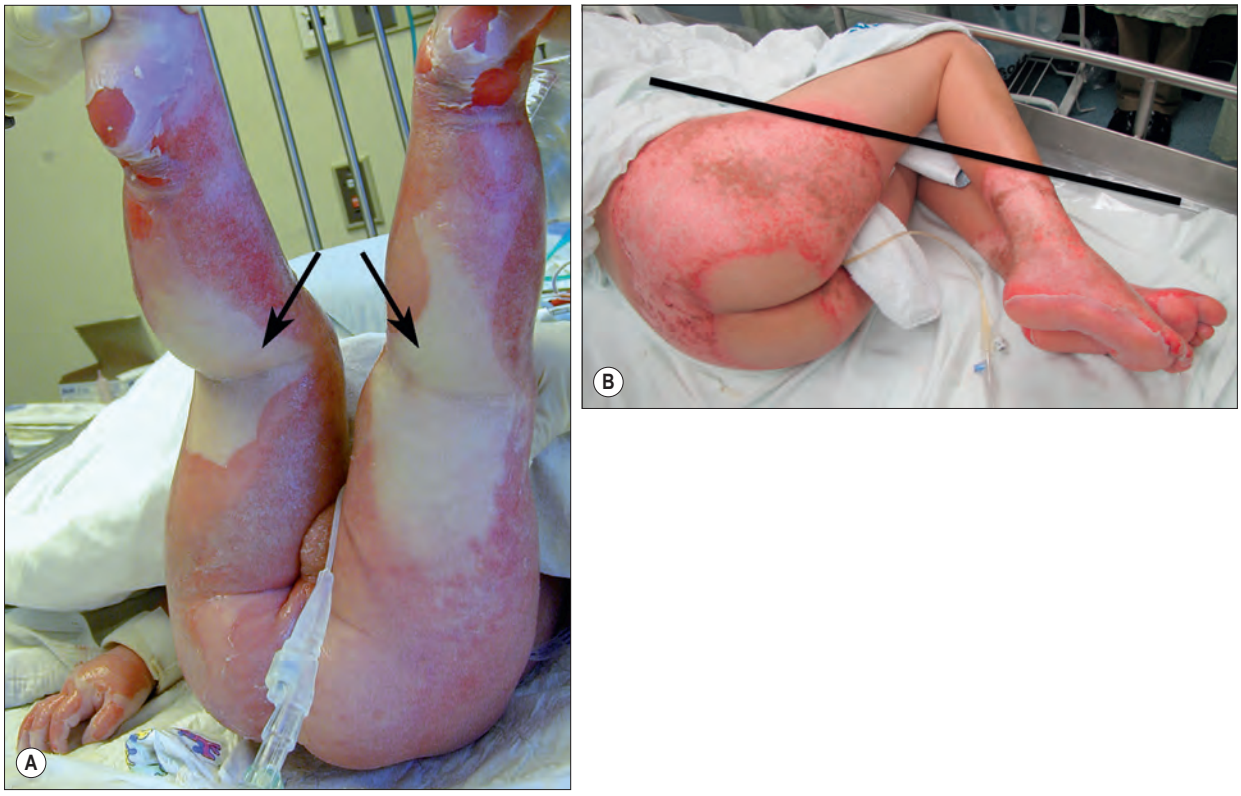

Fig. 10.3 Immersion scald burns: **(A)** on a child; arrows denote sparing of bilateral popliteal fossae: the child by reflex bent his knees to avoid contact with the hot water; **(B)** pattern of nonaccidental trauma: line denotes water level, note soles of feet and buttocks are spared as they were pressed against the bottom of the tub.

Fig. 10.4 Deep contact burn in an elderly patient who was unconscious next to a space heater. Arrows denote the imprints of the space heater grill on his lateral thigh.

predictable pattern, attributed to patients trying to carry the burning pan of grease outdoors instead of putting the lid on the pan and extinguishing the fire. The majority of patients sustain an isolated upper extremity burn, but injuries may involve the face, lower extremities, or trunk. Approximately 30%–40% of grease burns require excision and grafting.[63,64]

Tar and asphalt represent a special kind of scald. The "mother pot" at the back of the roofing truck maintains tar at a temperature of 400–500°F (204–260°C). Burns caused by tar directly from the "mother pot" are invariably full-thickness. By the time tar is spread on the roof, its temperature has diminished to the point where most of the burns are deep dermal in nature. Initial evaluation and injury depth assessment requires tar removal with application of a petroleum-based ointment that is reapplied every 2–4 hours until the tar has dissolved. Medi-Sol adhesive remover spray (Orange-Sol, Gilbert, AZ, USA) successfully removes tar without injury to the burn wound.

CONTACT BURNS

Contact burns resulting from hot metals, plastic, glass, or hot coals are generally small but are challenging in that the injury is often very deep (Fig. 10.4). The temperature of the material and the duration of contact determine burn depth. Molten materials in industrial accidents instantaneously cause a burn extending below the dermis. An unconscious victim with prolonged contact to a hot surface will often sustain a burn extending into fat and sometimes muscle. Industrial accidents involving presses or other hot, heavy objects may cause both contact burns and crush injuries. In these circumstances, the clinician must anticipate the possibility of extensive myonecrosis and myoglobinuria despite the relative small size of the wound. Contact burns with a hot muffler or engine block are usually full-thickness and often require serial surgeries to achieve wound closure.[65]

In toddlers, contact burns often involve palms and fingers when the child puts his hands on a wood-stove, fireplace insert, clothing iron, or oven door.[66] With aggressive wound care and hand stretching, most intermediate-depth palm burns heal in about 3–4 weeks. Beyond this time, careful consideration of management of the unhealed deep palm

Fig. 10.5 Chemical burn on lower extremity from cement. The discoloration of the skin is characteristic of a full-thickness chemical burn.

burn must be considered. Deep palm burns may epithelialize from the wound edges, allowing granulation tissue development to lead to palmar contracture and permanent disability. However, burn excision and grafting with either thick split-thickness or full-thickness grafts[67,68] results in loss of sensory nerve endings unique to glabrous skin (Pacinian and Meissner's corpuscles). Therefore, an observation period of 3–4 weeks with meticulous wound care and aggressive exercise provides a prudent compromise.

CHEMICAL BURNS

Chemical burns caused by strong acids or alkalis often result from industrial accidents, drain cleaners, assaults, and the improper use of harsh solvents. Chemical burns cause progressive tissue damage until the chemicals are inactivated by reaction with the tissue or by dilution by copious water. Although circumstances vary, acid burns are usually more self-limiting than alkali burns. Acid tends to "tan" the skin, creating an impermeable barrier that limits further penetration of the acid. Conversely, alkali combines with cutaneous lipids to create soap and thereby continues "dissolving" tissue until it the reagent is neutralized. A full-thickness chemical burn may appear deceptively superficial, clinically appearing as a mild brownish discoloration of the skin (Fig. 10.5). The skin may appear intact for the first few days postburn and later will slough spontaneously.

Initial management consists of diluting the agent with copious water for at least 15–20 min, preferably at the site of the accident; to this end, many industrial workplaces are now equipped with showers and eye wash stations. An important exception to immediate irrigation is exposure to a chemical powder, such as dry concrete, cement, and sodium hydroxide; in this instance, it is critical to brush the

agent off before irrigation since moisture activates the chemical. A paper pH test applied to the burn surface can verify that the agent has been neutralized. Attempts to neutralize alkalis with acids (and vice-versa) are contraindicated because the ensuing exothermic reaction leads to a thermal injury superimposed on the chemical burn.

Hydrofluoric acid represents a unique and very destructive chemical, one that is widely used in the circuit board etching process, cleaning solvents, and paint removers. Fluoride ions penetrate the skin, binding with cellular calcium and magnesium and causing progressive deep tissue destruction as sequential cells undergo necrosis.[69,70] Fluoride is also a metabolic poison that inhibits key enzymes of cellular metabolism. A 10% TBSA hydrofluoric acid burn may be life-threatening due to systemic hypocalcemia[71] and may indicate urgent surgical wound excision. A patient may not become symptomatic for several hours after exposure, when severe pain develops in the involved fingers; unfortunately, delayed or inadequate treatment may lead to amputation. Older recommendations of calcium-containing topical gels and direct injection of calcium gluconate into the involved tissue[72,73] have largely been replaced by intra-arterial infusion of calcium gluconate[74–77] which results in immediate cessation of pain and minimal tissue destruction and may be discontinued when acute symptoms resolve.

ELECTRICAL BURNS

Electrical burns are thermal burns from very high-intensity heat generated as the patient's body becomes an accidental resistor. Many electrical burns are work-related (i.e., construction workers, field workers, linemen, utility and electrical workers). Evaluation of the injured patient in these settings must account for associated trauma because these injuries may have occurred in association with associated myoclonic contractions or a fall.

Low-voltage injuries (<440 volts) rarely cause significant damage beyond deep thermal burns at contact points. An exception is the child who chews on an active electrical connection[78]; the child's saliva completes the circuit between the positive and neutral leads, causing a severe burn inside the mouth and lip. Eschar separation at the oral commissure 7–10 days after injury may be associated with brisk labial artery bleeding that requires hemostasis by digital pressure to the corner of the mouth.[79] Burns involving the oral commissure are at high risk for late contracture and warrant an aggressive splinting and exercise regimen.[80,81]

High-voltage injuries (>1000 volts) are more apt to cause deep tissue destruction. In this setting, extensive deep tissue destruction may take place underneath a relatively small, innocuous-appearing wound (Fig. 10.6). High resistance at skin contact points is partially protective because a dry calloused hand may provide twice the resistance of normal skin and five times the resistance of wet skin. High resistance within the body causes more harm due to conversion of electrical energy to heat in proportion to current and electrical resistance. Hence even when superficial muscle appears uninjured, deep muscle necrosis may occur adjacent to bone, which has high resistance.[82,83] Smaller body parts including fingers, hands, forearms, and feet also generate more intense heat with less dissipation and subsequently sustain more injury than the trunk, which may dissipate enough current to prevent extensive damage to internal viscera (unless the contact wound is on the abdomen or chest).[84–86] Arc electrical burns that result because current takes the most direct path occur at joints in close apposition at the time of injury, such as the popliteal fossa with a bent knee, the antecubital fossa with a flexed elbow, and the axilla with the shoulder adducted.

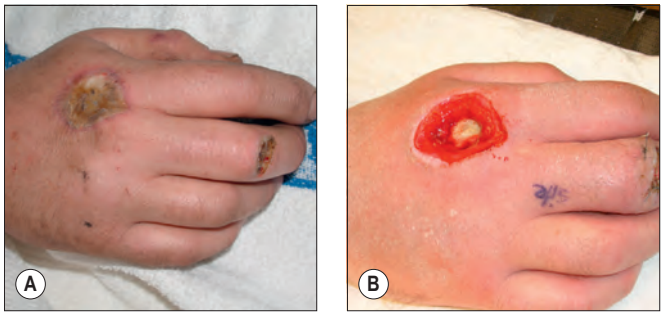

Fig. 10.6 High-voltage contact point on a hand: **(A)** prior to, and **(B)** after débridement. Once wound is debrided, much deeper injury to tendon and bone is revealed.

There are two indications for early operation in a patient with electrical burns: acidosis or myoglobinuria that will not clear with standard resuscitation techniques or the development of compartment syndrome. In these circumstances, urgent fasciotomy, major debridement, and amputation may be needed. If immediate decompression or debridement is not required, definitive operations can be performed 3–5 days after injury, before bacterial contamination occurs and after the tissue necrosis is delineated.[87,88] Extraordinary measures, such as vascular grafting for clotted arteries or free tissue transfer may sometimes be indicated,[89,90] but the zone of injury should be defined before assuming that vascular anastomoses will remain patent. Extensive operative salvage in lieu of a well-fitting prosthesis may increase morbidity and prolong the patient's recovery.

11 Treatment of Infection in Burn Patients

JANOS CAMBIASO-DANIEL, JAMES J. GALLAGHER, WILLIAM B. NORBURY, CELESTE C. FINNERTY, DAVID N. HERNDON, and DEREK M. CULNAN

Introduction

Skin is the first immune defense mechanism and functions as a barrier against microorganisms. Infections are a significant problem once open wounds compromise this barrier. According to the U.S. National Burn Repository, the four leading causes of burn morbidity are (1) pneumonia, (2) cellulitis, (3) urinary tract infections, and (4) burn wound infections. Infections are a primary factor contributing to mortality, accounting for 51% of deaths in burn patients, as discussed in both Chapters 30 and 32, on multisystem organ failure and critical care, respectively.[1–3]

A cutaneous burn is initially sterile as commensal skin flora are killed with the skin in the thermal event. Unfortunately the burn wound provides optimal bacterial growth conditions due to a reduced blood supply and a nutrient-rich environment, leading to rapid wound colonization. The 2007 American Burn Association Consensus Conference defined wound colonization as follows: (1) low concentrations of bacteria on the wound surface, (2) absence of invasive infection, and (3) less than 10^5 organisms per gram tissue.[3] In a superficial burn, skin flora can survive in hair follicles and sebaceous glands in the same manner as keratinocytes to repopulate a physiological microbiome.[4-6] However, burns are customarily colonized by pathogens from the environment, the patient's gut, or the nasooropharyngeal tract.

A race thus exists between the patient and the pathogen to dominate the wound surface. In the log phase growth, bacteria double 2–3 times per hour; consequently a single bacterium can become 10 million in 1 day, far faster than any human cell can multiply.[7] Therefore colonization can quickly become an infection capable of converting partial-thickness into full-thickness burns by causing vessel thrombosis and necrosis in viable tissues in the wound penumbra. Gram-positive bacteria tend to colonize an affected area first, with subsequent colonization by gram-negative bacteria. Delayed treatment risks colonization by extended-spectrum pathogens, bloodstream invasion, and the development of sepsis, all of which increase the likelihood of death.[2]

The model of burn care advocated throughout this text is to rig this race for wound dominance in favor of the patient. Early wound excision eliminates the devitalized tissue that is the main reservoir for pathogen nourishment and habitat. Prompt autografting reestablishes skin barrier function and denies pathogens access to the host. Topical antimicrobials suppress bacterial growth and colony counts while allowing host fibroblasts and keratinocytes to proliferate and cover the wound. Assiduous washing technique allows 2-log reduction in colony counts, breaks down and removes biofilms, and purges the devitalized tissue that pathogens thrive upon.[8] Systemic antimicrobials kill and suppress the invading pathogens accessing perfused areas of tissue. Quantitative wound culturing enables effective diagnosis and directed application of the most efficacious antimicrobial with the lowest toxicity. Coordinated critical care, therapy, and nutrition ensure that the wounds have a sufficient supply of nutrients and immune-cell–laden blood to clear pathogens, expand skin grafts, and reepithelialize wounds.

Prevention of Infection

Prevention is the optimal way to minimize infection.[9] Pathogens can be carried into or transmitted around the unit by staff, by visitors, or on equipment. Patients should have single rooms separated from other rooms by a door. Positive pressure in the rooms further aids in minimizing bacterial contamination. Patient rooms should undergo a daily cleaning in addition to deep cleaning upon patient discharge. This terminal cleaning should include washing the walls and ceiling and should be done 72 hours prior to admitting another patient to avoid the transfer of more virulent strains.[10] Another important prevention measure is the use of contact precautions with all patients, including gowns and gloves. These items should be donned before entering and doffed prior to exiting the room, regardless of the bacteriological status of the particular patient. Routine hand hygiene before and after patient interaction is also mandatory to prevent infection. Dressing materials, supplies, devices, and equipment must not be shared between patients. Bathing, showering, tubbing, mobile diagnostic equipment, and operating facilities should be decontaminated between each patient use. Furthermore, fomites, such as ties, rings, watches, and cell phones, should be prohibited since these are possible pathogen vectors.[11,12] Water and air filters ought to screen particles down to 0.2 and 0.3 μm, respectively, be changed monthly, and be cultured routinely as part of infection control monitoring. By maintaining these strict measures, transmission of infectious organisms between patients can be limited.[13]

Diagnosis of Burn Wound Infection

Diagnosis of burn infection in burn wounds can be complicated. The typical cytokine and immune cascades that

create the typical presentations of infection known to all doctors are often initiated in the burn patient via the elaboration of damage-associated molecular patterns (DAMPS) and pathogen-associated molecular patterns (PAMPS) from burn wounds. This complicates diagnoses of infection and sepsis in the burn patient where clinical signs, such as elevated temperature or tachycardia, are normal components of burn pathophysiology, as discussed in Chapter 29 on hypermetabolism.

Wound culturing is a critical tool to guide the treatment of burn wounds and to determine what bacteria are colonizing the burn wound. In patients with major burns, the wound usually becomes colonized 5–7 days after injury.[6] Since most initial infections in burn patients derive from endogenous bacteria flora, it is good clinical practice to perform initial wound cultures upon patient admission. This screening should include swabs of both sides of the groin and axilla, as well as of the nose and throat.[14] In addition, at each burn excision, and whenever suspicion of invasive infection warrants, quantitative tissue cultures may be helpful.

Wound appearance and odor changes can help to diagnose wound colonization versus wound infection (Fig. 11.1). Kwei et al. described three main methods that exist for culturing a wound: qualitative (presence or absence of growth), semi-quantitative (grading of the bacterial presence as scanty, few, moderate, or numerous), and quantitative (an absolute quantity is determined).[15,16] Swabs are useful but limited since they cannot distinguish between infection and colonization and are only accurate for the region sampled. These problems are mitigated by performing multiple tissue biopsies, which can reveal significant quantitative differences in different areas.[17] Although quantitative cultures are more expensive, bacterial counts have been shown to correlate with histological evidence of wound infection in approximately 80% of cases after biopsies are taken or after sterilization of the surface with antimicrobials.[6,18] Histological examinations can be used to confirm invasive bacterial infection when counts exceed 10^5 organisms per gram of tissue. If histological evidence of invasion is present, systemic antibiotics should be administered and the wound excised.[6,19,20]

Fig. 11.1 Burn wound colonization. Flame burn to the left medial arm depicted post-burn day 7. The eschar has degraded but is still present. However, the surrounding tissue is not cellulitic.

Studies by Robson demonstrated that if burn wound colony counts from biopsies or after cleaning of the surface of the wound are greater than 10^5/g tissue, the graft survival rate is only 19%, whereas colony counts of less than 10^5/g tissue are associated with a 94% chance of graft survival.[21] Sensitivities to available antibiotics, both systemic and topical, should instruct therapy. In the setting of resistant organisms, antibiotic synergy testing is advised. Thus the ultimate diagnosis of burn wound infection and the guidance of antimicrobials are directed by culture data.

Physical examination of the patient also provides valuable insight into the infectious nature of the burn wound. *Burn wound erythema* is a physiologic phenomenon produced sterilely by the liberation of inflammatory mediators from tissues surrounding the burn area and must not be confused with cellulitis. Normally this erythema presents within 2–3 days of the burn injury and resolves by 1 week post burn (Fig. 11.2). The best differential diagnosis comes from clinical palpation: erythema lacks significant induration or tenderness compared to an infectious process like cellulitis.[8]

Cellulitis is a noninvasive infection of the tissues surrounding the burn wound.[3] Cellulitis can be caused by a variety of pathogens.[6] This infection is characterized by edema, hyperesthesia, erythema, induration, and tenderness detectable upon examination (Fig. 11.3). The color of the wound contour and the odor from the wound may also raise suspicion of cellulitis. Furthermore it can have a lymphangitic component. Particular attention should be given to elderly patients and diabetic patients due to the ease and speed with which infections progress in these populations. Cellulitic burn wounds benefit from systemic antimicrobials to cover likely causative agents in addition to standard burn treatments, such as topical antimicrobials or surgical excision and grafting. Progression of cellulitis despite antibiotics must always trigger suspicions of resistant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), and these organisms should be covered empirically.[6]

Graft ghosting (impetigo) is a wound infection that can cause late graft loss (Fig. 11.4). This phenomenon can occur after spontaneous closure of a partial-thickness wound, following loss of previously adherent graft sites, and in skin donor sites. Characterized by multiple small abscesses, graft ghosting can lead to the complete destruction of the healed wound.[6] The culprit typically responsible for this condition is *S. aureus*, particularly MRSA. The diagnosis is essentially clinical and can be confirmed by culturing. Treatment requires regular dressing changes, débridement of abscesses, local disinfection, and application of topical antimicrobials, such as mupirocin.

Toxic shock syndrome (TSS) is a complication of severe soft tissue infections (SSTI), which occurs predominately in small burns. This syndrome results from colonization with TSS toxin-1–producing *S. aureus*. This disease is primarily seen in young children with burns covering less than 10% of the total body surface area (TBSA) and that would otherwise be expected to heal without problems. The incidence is approximately 2.6% with a mean age of 2 years. TSS is clinically characterized by a prodromal period lasting 1–2 days with pyrexia, diarrhea, vomiting, and malaise. While

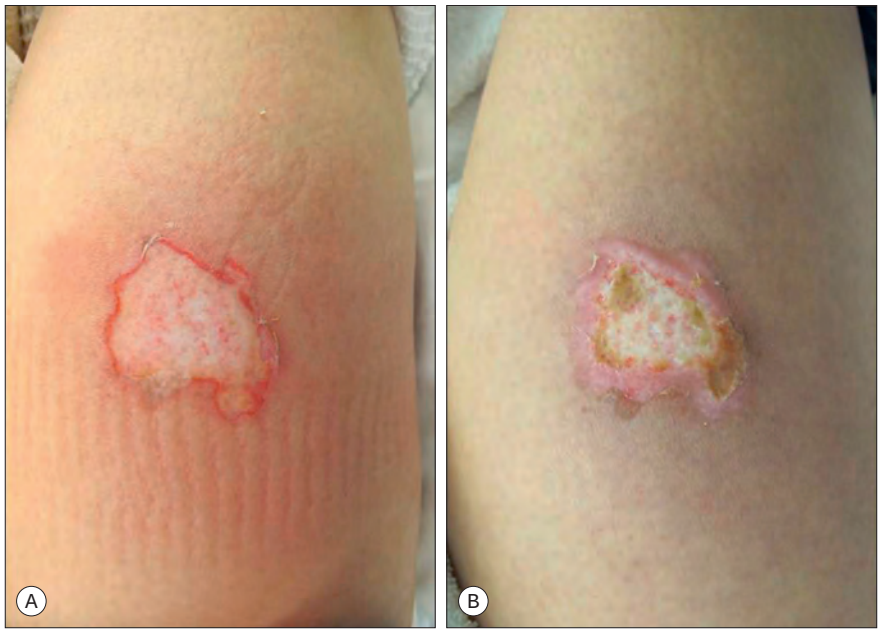

Fig. 11.2 Burn wound erythema. A hot oil scald burn on the lateral thigh is depicted with (A) surrounding erythema noted on post-burn day 2. (B) Resolution of redness and healing on post-burn day 12.

Fig. 11.3 Burn wound cellulitis. Cultures demonstrated *Staphylococcus aureus*. Clinical findings include increased pain, local inflammatory signs, and fever. Treatment includes systemic and topical antibiotics, excision, and autografting.

a rash is often present, at this stage, the burn appears clean (Fig. 11.5). Shock subsequently develops in untreated cases, but determining the cause of shock to be TSS can be complicated in this early phase of the patient's presentation when a litany of potential and more common etiologies of shock exist. Once shock has developed, mortality can be as high as 50%. Awareness and aggressive action are the principal safeguards against the development and progression of TSS. A possible diagnosis of TSS should be considered in small burns where the patient is unexpectedly in shock. Because MRSA has emerged as the most commonly identified cause of SSTI, initiation of empiric anti-MRSA antimicrobials is warranted in all cases of suspected TSS.[19,22]

Invasive wound infections manifest clinically with wound color changes, exudate, and odor. Within a short time, partial-thickness burns progress to full-thickness necrosis and begin expanding into unburned tissues. The 2007 American Burn Association Consensus Conference defined invasive infections as follows: "the presence of pathogens in a burn wound at concentrations sufficient in conjunction with depth, surface area involved, and age of patient, to cause suppurative separation of eschar or graft loss, invasion of adjacent unburned tissue or cause the systemic response of sepsis syndrome."[3] Goal-standard diagnosis is made with histologic examination; however, clinical exam and quantitative cultures usually suffice (Fig. 11.6). It should be noted that sepsis does not always develop during invasive infections (Fig. 11.7). Treatment must be immediate and include aggressive surgical intervention augmented by the administration of systemic and topical antimicrobials. If no culture results are initially available, a broad-spectrum empirical therapy against fungi, drug-resistant gram-positive and -negative organisms should be initiated until culture data become available. Surgical extirpation must be aggressive and encompass excision of all necrotic and infected tissue, including fascia and muscle when warranted. Definitive wound coverage is not always indicated in this extirpative operation as dressing changes and hydrotherapy may be needed to further decrease heavy bacterial loads. In cases where tissue has already been excised or there is a life-threatening infection, limb amputation may be indicated. Topical antimicrobials and assiduous washing technique are indicated after extirpation to suppress microbial growth. However, the optimal methodology is to prevent infection, with swift action being taken should an infection arise.[23]

Sepsis and *septic shock* are complicated diagnoses in burn patients because large burns create a systemic inflammatory response syndrome (SIRS) and hypermetabolism of their own, as discussed in Chapter 8 on the etiology of shock. This hypermetabolism is a natural part of the body's

Fig. 11.4 Burn wound impetigo. Right hand in a 13-year-old boy with 85% TBSA burn, third-degree to the hands shown (A) 4 months post-burn at hospital discharge. (B) Three weeks later the patient presented with reopening of the previously taken skin grafts to the hand and clinical impetigo. Cultures were positive for MRSA, and the patient was treated with vancomycin, mupirocin, and tub therapy.

compensatory mechanism to burn injury and can last for up to a year following the insult, making it difficult to fit shock in burn patients into the definitions of sepsis and septic shock established by the Society of Critical Care Medicine.[24–26] Patients with high concentrations of bacteria in the burn wounds in conjunction with delayed admission to a burn center or delayed removal of burned tissues are at the greatest risk of developing sepsis.[8] Rapid and complete closure of deep burns is the best defense against this condition. An additional factor influencing the development of sepsis and increasing mortality during hospitalization in patients with equal burn sizes is decreased lean body mass. The identification of parameters associated with sepsis in burn patients is extremely important and ongoing. The American Burn Association Consensus Conference in 2007 provided criteria (Box 11.1).[3] These criteria are useful markers and indicators for sepsis but are by no means gospel. A skilled physician must take these factors into account along with changes in the patient's clinical condition over time to make a presumptive diagnosis of sepsis. Aggressive treatment should be initiated and de-escalated based upon definitive diagnosis and patient response.

Treatment of Burn Wound Infections

Treatment of burn wound infections is multimodal. Surgical débridement and assiduous washing technique decrease the bacterial and nutritive burden. Aggressive grafting denies the pathogens wound surface area to colonize and infect. Topical antimicrobial compounds reduce pathogen burden in the wound and periwound areas while allowing skin grafts to proliferate and cover the wound. Systemic antimicrobials are administered to treat invasive pathogens and prevent or reduce the systemic spread of infection.

TOPICAL ANTIMICROBIAL COMPOUNDS

Topical antimicrobial compounds have significantly reduced burn mortality.[7,27] However, no single agent is entirely effective. Each possesses its own spectrum, advantages, and disadvantages. Some retard wound healing while others have systemic metabolic effects on the patient. Recent studies have demonstrated that some agents used in the past are now ineffective in inhibiting bacterial growth.[28,29] Wounds may be dressed with any topical agent when quantitative culture counts persist at less than 10^2/g tissue. However, higher colony counts warrant culture-directed topical antimicrobial selection. Topical antimicrobial agents fall into five major classes, each possessing different antimicrobial spectra, duration of action, penetration, and toxicities (Box 11.2).

Soaps are the first form of topical antimicrobial and are employed during washing. They are effective in disrupting biofilms and washing pathogens from the patient. *Biofilms* are coherent clusters of bacterial cells embedded in a biopolymer matrix that, compared with planktonic cells, resist host defenses and show increased tolerance to topically (antiseptics) and systemically (antibiotics) administered antimicrobials, thus creating the perfect environment for bacterial growth.[30] Biofilm bacteria are extremely difficult to remove, requiring surgical or sharp instruments and/or mechanical wound débridement and washing with soap and water. According to recent recommendations, burn

Fig. 11.5 Toxic shock syndrome (TSS) rash. Cutaneous rash commonly seen in patients with TSS. This rash does not universally appear in cases of TSS. Patients with small burns developing shock should be evaluated and treated for TSS with excision, grafting, and vancomycin. (A) A 13-year-old girl presenting TSS rash following a 10% TBSA burn. (B) The typical macular erythroderma lesions. (C) A hematoxylin and eosin 4× magnification micrograph of a TSS rash lesion showing an epidermal blister. Sangüeza, MD; Professor and Director of Dermatopathology, Wake Forest University School of Medicine, North Carolina.)

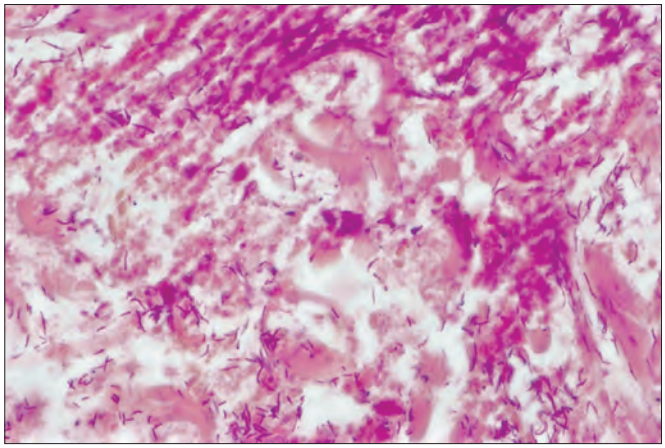

Fig. 11.6 Gram-negative bacilli invading deep viable tissue. Histopathologic confirmation is the gold standard test to diagnose burn wound infection by bacteria in viable tissue. Shown is a typical hematoxylin and eosin stained section at 1000× magnification.

Fig. 11.7 Invasive burn wound infection. Seventy-five percent TBSA full-thickness burns with wound sepsis due to *Enterococcus faecalis* and *Enterobacter cloacae*. Prompt excision, homografting, hemodynamic support, and systemic antibiotics controlled the infection. This patient was subsequently autografted and survived.

Box 11.1 The 2007 American Burn Association Consensus Conference Definition of Sepsis.[3]

"Sepsis is a change in the burn patient that triggers the concern for infection. It is a presumptive diagnosis where antibiotics are usually started and a search for a cause of infection should be initiated. While there is need for clinical interpretation, the diagnosis needs to be tied to the discovery of an infection (defined below). The definition is age-dependent with adjustments necessary for children.

The trigger includes at least three of the following of sepsis:

I. Temperature >39mpera<36.5er
II. Progressive tachycardia
  A. Adults >110 bpm
  B. Children >2 SD above age-specific norms (85% age-adjusted max heart rate)
III. Progressive tachypnea
  A. Adults >25 bpm not ventilated
    i. Minute ventilation >12 L/min ventilated
  B. Children >2 SD above age-specific norms (85% age-adjusted max respiratory rate)
IV. Thrombocytopenia (will not apply until 3 days after initial resuscitation)
  A. Adults <100,000/mcl
  B. Children <2 SD below age-specific norms
V. Hyperglycemia (in the absence of pre-existing diabetes mellitus)
  A. Untreated plasma glucose >200 mg/dL or equivalent mM/L
  B. Insulin resistance – examples include
    i. >7 units of insulin/h intravenous drip (adults)
    ii. Resistance to insulin (>25% increase in insulin requirements over 24 hours)
VI. Inability to continue enteral feedings >24 hours
  A. Abdominal distension
  B. Enteral feeding intolerance (residual >150 mL/h in children or 2ce (residual er 24 hours
  C. Uncontrollable diarrhea (>2,500 mL/d for adults or >400 mL/d in children)

In addition, it is required that a documented infection (defined below) is identified
  A. Culture positive infection, or
  B. Pathologic tissue source identified, or
  C. Clinical response to antimicrobials.

wounds not associated with clinical signs or symptoms of infection yet suspected of having biofilm should be treated with débridement, antimicrobial dressings, antiseptic soaks, and thorough cleansing with antiseptic products to prevent bacterial growth.[31] Findings from Kennedy and colleagues support the significant role played by biofilms in burn wound sepsis and the importance of early excision and closure of the wound.[32] Herndon et al. demonstrated that washing burn wounds with soap and water using assiduous washing techniques can cause a 2-log reduction in bacterial counts over 48 hours, improving autograft take by infected wounds.[8]

Many oxidative halides are used as topical antimicrobials. Classically sodium hypochlorite (Dakin's solution) has been employed due to its broad bactericidal range and effective dissolution of biofilms.[33–36] Commercially available Clorox bleach is 5.25% NaOCl; the original Carrel-Dakin's Solution used in World War I was diluted with water to 0.5% and is described as full-strength Dakin's Solution. Studies have demonstrated full-strength to be tissue toxic, as are the pharmacy-available half- and quarter-strength Dakin's solutions, though they are effective antimicrobials. Investigations by Heggers and coworkers established the efficacy of NaOCl at a concentration of 0.025%, or one-twentieth Dakin's.[23,37,38] Buffered one-twentieth Dakin's was formulated to mimic normal human physiologic parameters, with the added benefits that it is a broad-spectrum antiseptic, yet nontoxic to fibroblasts nor inhibiting of wound healing. It is bactericidal against *P. aeruginosa*, *S. aureus*, methicillin-resistant staphylococci, enterococci, and other gram-negative and gram-positive organisms, and it may be used separately or in combination with other agents.[23] Subsequently Carrel and Dakins developed oxychlorosene (Clorpactin) to allow longer tissue half-life, neutral pH, and lower tissue toxicity. It is used intravesicularly and intrarenally to control hemorrhage in genitourinary cancer cases and has been recently resurging as a topical antimicrobial.[39] It has been demonstrated to be nontoxic to skin grafts when tested as a wound irrigant.[40] Currently products are coming to market using hypochlorous acid as an active oxidizing agent in pH-neutral, isotonic formulations.[41,42] While of interest as topical antimicrobials for burn wounds, they lack the century-long experience of sodium hypochlorite solutions and so require further research.

Povidone-iodine (Betadine) is another halide used as a topical antimicrobial; it is available as a liquid or an ointment in varying concentrations. It has a broad-spectrum of activity, covering gram-positive and gram-negative bacteria, yeast, and fungi. Quantitative bacteriological assessments imply that iodine is most efficacious when administered every 6 hours. Topical application of this agent can be painful. The iodine component of this topical agent may be absorbed more extensively in burn wounds, resulting in iodine toxicity, renal failure, acidosis, and dermatitis (in intact skin). Furthermore povidone-iodine is cytotoxic to fibroblasts and keratinocytes. However, it remains a highly effective disinfectant when used on intact skin.[43,44]

Acetic acid, also called ethanoic acid or vinegar, is a colorless topical agent used as a disinfectant for skin and soft tissue infections. It is effective against gram-negative bacteria, especially *P. aeruginosa.* Its clinical antibacterial efficacy requires a minimum concentration of 0.5%.[45] Philips et al. reported the use of acetic acid as a topical agent for the treatment of superficial wounds infected by *Pseudomonas*[46]; later Sloss et al. investigated topical use of acetic acid at concentrations between 0.5% and 5%.[47] Sloss showed all strains of Pseudomonas exhibited a minimum inhibitory concentration (MIC) of 2% in vitro, yet other studies determined a concentration of 3% acetic acid to have bacteriostatic activity, including against multiple antibiotic-resistant strains of *Pseudomonas.*[45,48] The results of in vitro studies indicate that acetic acid is toxic to fibroblasts and substantially decreases cell viability, effects that increase with the concentration. Although these results are not considered decisive for the treatment of burn wounds, a surgeon should always consider the eventual cytotoxic interaction, especially on fresh skin grafts, while using acetic acid.[49]

Silver ions are a common topical heavy metal antimicrobial. Silver is delivered as solutions, creams, or bound to dressing materials. The silver ions bind to proteins and

Box 11.2 Topical Antimicrobial Agents.

CLASS	AGENTS	ANTIMICROBIAL SPECTRUM	GRAFT TOXICITY	SYSTEMIC TOXICITY
Soaps	Johnson's Baby Shampoo	Broad-spectrum + Biofilm	Low	None
Oxidative Halides	Full-Strength Dakin's Solution (0.5% NaOCl)	Broad-spectrum + Biofilm	High	Hyponatremia
	1/20th Buffered Dakin's Solution (0.025% NaOCl)	Broad-spectrum + Biofilm	Low	None
	Oxychlorosene (Clorpactin)	Broad-spectrum + Biofilm	Low	None
	Hypochlorous acid	Broad-spectrum + Biofilm	Unk.	Unk.
	Povidone-iodine (Betadine)	Broad-spectrum	High	High
Acids	Acetic Acid 0.5%	Bacteriostatic	Low	None
	Acetic Acid 2%	Bacteriostatic	Moderate	Moderate
	Acetic Acid 3%	Bacteriostatic	High	High
Heavy Metals	Silver Nitrate 0.5%	Broad-spectrum	None	Electrolyte imbalance
	Silver Sulfadiazine (Silvadene)	Broad-spectrum	None	Low
	Silver Releasing Dressings	Broad-spectrum	None	Low
	Xeroform - Bismuth tribromophenate	Limited Bacteriostatic	Low	None
	BIPPS - Bismuth subnitrate and iodoform	Bacteriostatic	High	High if >1% TBSA
Antibiotics	Mafenide acetate (Sulfamylon)	Broad-spectrum	Low	Metabolic acidosis
	Gentamicin sulfate (Gentamicin)	Broad-spectrum	Low	Low
	Bacitracin/polymyxin (Polysporin)	Broad-spectrum	Non-toxic	Low
	Nitrofurazone (Furacin)	Broad-spectrum, no *Pseudomonas*	Low	Low
	Mupirocin (Bactroban)	Broad-spectrum, no *Pseudomonas*	Moderate	Moderate
	Nystatin 100,000 U/g (Mycostatin)	Weak Antifungal	Low	Low
	Nystatin 6,000,000 U/g	Strong Antifungal	Low	Low

enzymes, damaging those systems, and to DNA, resulting in an antimicrobial effect via a heavy metal oxidative pathway.[50] In debrided wounds, a 0.5% silver nitrate ($AgNO_3$) solution is a potent disinfectant. It does not injure regenerating epithelium in the wound and is bacteriostatic against *S. aureus*, *E. coli*, and *P. aeruginosa*. $AgNO_3$ has limited wound penetration because the silver binds rapidly to the surface proteins.[27] Its hypotonic nature can cause osmolar dilution, resulting in hyponatremia and hypochloremia, so serum electrolytes must be monitored. $AgNO_3$ turns black when exposed to light or on contact with tissues or chlorine-containing compounds, but this is nontoxic. It can be combined with miconazole powder to yield an aqueous solution of 0.5% silver nitrate and 2% miconazole for greater efficacy in preventing bacterial and fungal overgrowth in burn wounds.[51] *Klebsiella* spp., *Providencia* spp., and other Enterobacteriaceae are less susceptible to 0.5% $AgNO_3$ than other bacteria. Rarely the combination of 0.5% $AgNO_3$ solution with *Enterobacter cloacae* or other nitrate-positive organisms can cause methemoglobinemia by converting nitrate to nitrite in the body.[52]

Silver sulfadiazine (Silvadene, Thermazine, Flamazine, SSD), a 1% water-soluble cream, is a combination of sulfadiazine and silver with antimicrobial efficacy lasting up to 24 hours. While most effective against *P. aeruginosa* and the enterics, silver sulfadiazine has great utility against some yeasts, such as *C. albicans.* However, recent reports of *P. aeruginosa* resistance and inadequacy against some strains of *Klebsiella* have emerged. More frequent dressing changes are required if a creamy exudate develops. Although this topical agent is facile in use and reduces pain, it retards wound healing.[53] Unlike mafenide acetate, tissue-penetration of silver sulfadiazine is limited to the surface epidermal layer, and it is not associated with acid–base disturbances or pulmonary fluid overload. It can be used separately or in combination with other antibacterials. An adverse drug reaction may be a reversible granulocyte reduction due to silver toxicity, although this is controversial and transient.[7,27] Over multiple applications a pseudoeschar of silver sulfadiazine cream builds up on the wound, making assessment of the wound depth difficult because it then bears a strong resemblance to burn eschar. This limits the utility of this topical agent in our center.

Over the past decades there has been a proliferation of silver-containing dressings formulated to remain in place over a prolonged period. On superficial burns, these dressings are utilized as functional skin substitutes to permit re-epithelialization in a bacterially suppressed, moist environment. Many centers employ silver-containing dressings rather than applying solutions of topical antimicrobials like silver nitrate because they are easier to manage, have more consistent antimicrobial levels, and are generally less messy.

The antimicrobial actions of the dressings derive from the silver ions, so their spectrum is thus defined. Each product's dressing substrate and particular silver formulation provide different dressing characteristics; however, the release and efficacy of silver against bacteria in wounds have not been largely studied or reported. Furthermore there are to date no large-scale studies defining the supremacy of any particular product, so preference of the practitioner and cost typically define use. It is important to remember that no dressing, no matter how well marketed, replaces the tenets of burn surgery: aggressive débridement of devitalized tissue, coverage of wounds with skin, assiduous wound cleansing to remove pathogens and contaminants, and physical examination.

Bismuth is another heavy metal commonly employed as a topical antimicrobial. It is bacteriostatic against enterics, but not cytotoxic to dermal fibroblasts and does not inhibit wound healing.[54] It is usually used on the commercially available dressing Xeroform, a gauze impregnated with bismuth tribromophenate and petroleum jelly. Bismuth is also delivered in conjunction with iodine in the compounded paste, BIPP (1 part bismuth subnitrate, 1 part liquid paraffin, and 2 parts iodoform). We have used BIPP effectively on thousands of patients treated in our hospital for more than 50 years. Coated liberally on cotton gauze, this paste is used to dress small, débrided areas of exposed bone and tendons.[55,56] BIPP should not be applied to areas greater than 1% TBSA, and the course of treatment should be as brief as possible to limit the risk of bismuth toxicity.[57,58] In our experience, this compound prevents the development of infection and promotes the prodigious formation of granulation tissue, thereby permitting split-thickness skin grafting over surfaces conventionally described to be ungraftable.

Antibiotic-based topical antimicrobials define the fourth major class, and their mechanism of action is determined by the specific biochemistry characteristic of each particular agent. Mafenide acetate (Sulfamylon), available both as an 8.5% water-soluble cream and a 5% aqueous solution, is among the most commonly employed topical agents. While broad-spectrum, mafenide is particularly effective against all strains of *Pseudomonas* and *Clostridium.*[59] The cream is applied twice a day and has the advantage that it does not require a dressing to adhere to wounds. Studies have reported that the use of 5% mafenide acetate solution in patients with major burns results in a 33% reduction in death.[6] When used as a solution, an eight-ply dressing should be resaturated with fresh solution every 8 hours to remain above MIC. Mafenide has excellent tissue penetration, including eschar. This penetration makes it the topical agent of choice for deep ear burns because it effectively prevents invasive chondritis. It can cause pain on application and, like other sulfa drugs, can lead to allergic reactions. Since mafenide can inhibit carbonic anhydrase, metabolic acidosis can develop. Furthermore protracted use may lead to the growth of *C. albicans.* While it can be used with other antimicrobials, mafenide acetate retards wound healing and reduces the breaking strength of healed wounds.[27]

Gentamicin sulfate (Gentamicin) is an aminoglycoside available as a 0.1% water-soluble cream or solution. It has broad-spectrum bactericidal activity against aerobes and is often deployed against *P. aeruginosa*. However, resistance can develop and sensitivities should be monitored.[60]

Bacitracin/polymyxin (Polysporin) ointment is commonly used to prevent mechanical shear and suppress bacterial growth on newly grafted tissue. Both drugs are cell wall lytic agents, and polymyxin is a topical analogue of colistin, discussed in the systemic antimicrobial section. Drug concentrations available in the ointment do not treat infection. However, many surgeons rely on this topical agent for skin graft coverage as it is nontoxic and maintains the moist wound environment needed for epithelial growth. Effectiveness in contaminated or infected burns post excision can be enhanced by use in combination with other agents, such as silver nitrate or mafenide. Prolonged use is associated with hypersensitivity development.

Nitrofurazone (Furacin), available as an ointment, solution, or cream, has been proved effective in the treatment of methicillin-resistant staphylococci. Furthermore, nitrofurantoin was demonstrated to be 75% effective against gram-negative bacterial isolates other than *P. aeruginosa*, whereas bacitracin/polymyxin was only 21% effective.[3]

Mupirocin (Bactroban, pseudomonic acid A) is an antibiotic derived from the *Pseudomonas fluorescens* capsule and inhibits isoleucyl t-RNA synthetase and thus bacterial protein synthesis.[61] It is the topical treatment of choice for MRSA infections, gram-positive microbes, and intranasal carriage.[62] Mupirocin inhibits wound healing by a half-life of 2 days compared to controls, but the breaking strength of the wound is significantly enhanced.[63] Due to rapid development of resistance, mupirocin should not be used for longer than 10 days.

Nystatin (Mycostatin, Nilstat) is an antifungal antibiotic produced by *Streptomyces noursei*. Nystatin is the highly potent topical equivalent of Amphotericin-B; both exert antifungal activity by binding to ergosterol and lysing fungal cell membranes. Low-dose applications of 100,000u/g as creams, lotions, or ointments are used as prophylaxis against fungal growth. Treatment with pure nystatin powder at a concentration of 6,000,000 U/g on burn wounds has proved effective in eradicating invasive fungal infections. This novel application is not only effective superficially but also eradicates invasive clusters of fungi in deep wound tissues, as documented by pathological examination.[64] The application of the powder is easy and does not produce pain, discomfort, or impair wound healing. All previously autografted areas heal uneventfully.[64] Liquid nystatin 'swish and swallow' is used prophylactically to prevent the oral or perineal overgrowth of yeast and fungi in patients receiving multiple systemic antibiotics.[64]

SYSTEMIC ANTIMICROBIALS IN BURN PATIENTS

Long maligned, routine prophylactic use of antibiotics is well indicated for select burn patients. Whereas prophylactic antibiotics may be warranted for patients arriving from endemic areas, with penetrating traumas, open fractures, or from highly contaminated scenes, no prophylactic antibiotic treatments are typically initiated at admission or for routine perioperative prophylaxis. This is principally to avoid creation of antibiotic resistances with more difficult subsequent treatment. Additionally thermal wounds are normally aseptic in the first hours following injury as the burn sterilizes the wound surfaces.[65,66]

Empiric antibiotics are indicated in the setting of clinically suspected invasive wound infections, suspected sepsis, or septic shock. These antibiotics should broadly cover

all likely infecting organisms and be instituted as a component of multimodal critical and surgical care of the burned patient. Clinical response should be followed to ensure adequate treatment and antibiotics de-escalated as soon as possible based on culture findings. After time and culture data allow definitive diagnosis of infection, culture-directed treatment antibiotics should be continued for a finite treatment course, until cultures return negative or the wounds close.[67]

Greatly altered in burn patients, pharmacokinetics and pharmacodynamics require regular evaluation by a skilled clinical pharmacologist to ensure safe and effective drug dosing.[68] During the resuscitative phase of burn injury, which occurs within the first 48 hours post-trauma, burn shock can decrease blood flow to organs and tissues.[68] Drug treatments during this phase result in a slower distribution rate, slower renal and hepatic elimination, and delayed absorption of enteral, subcutaneous, and intramuscular drugs. After 24–48 hours, the patient enters the hypermetabolic phase, discussed extensively in Chapters 29 and 32 covering the hypermetabolic response, endocrine function, and critical care. During this period, burn patients exhibit increased blood flow to organs and tissues, an increased internal core temperature, and hypoproteinemia and edema formation.[68] Intravenous drugs have a shorter half-life due to the enhanced glome rular filtration rate and elimination of renally excreted drugs. Antibiotic treatments in these patients must be administered at higher doses and/or frequency. Time-dependent, renally excreted antibiotics, such as vancomycin, must be carefully monitored to ensure they exceed the MIC of the bacteria. Oral drugs will also exhibit greater absorption from the gastrointestinal tract and a faster onset of action.[68] The hypermetabolic phase causes hypoalbuminemia and raises the levels of acute-phase proteins.[68] Albumin binds to acidic and neutral drugs, such as aminoglycosides, vancomycin, aztreonam, and cefotetan; consequently in hypoalbuminemia more free drugs are circulating so a lower dose will be required for therapeutic effect. Conversely acute-phase proteins bind tightly to basic drugs, such as penicillins and cephalosporins, resulting in less free drug and necessitating higher drug dosages to produce a therapeutic effect. The hepatic response occurring during the hypermetabolic phase will present as a decrease in phase 1 metabolism, such as oxidation, reduction, or hydroxylation of a drug by the cytochrome P450 system, affecting many antibiotics, such as the quinolones and the macrolides. The decreased activity of these hepatic drug–metabolizing enzymes, as well as their decreased hepatic clearance and prolonged half-life, may produce systemic toxicity. However, phase 2 metabolism in the liver, such as conjugation reactions between the drug and the endogenous substrate, will not be impaired.[68] In light of the myriad of changes, care in the modern burn unit is greatly enhanced by the active participation of a pharmacist familiar with systematic drug level monitoring in burn patients.

Selection of systemic antibiotics is based on the likely etiologic organism, local antibiogram, and systemic toxicity. In the setting of an outpatient with cellulitis around a burn wound, empiric gram-positive coverage to include MRSA is indicated. We routinely cover these outpatients with rifampin, a bactericidal antibiotic inhibiting RNA synthesis by binding to the β-subunit of the DNA-dependent RNA polymerase and blocking RNA transcription.[69] Due to its high resistance pattern when employed alone, rifampin must be used in conjunction with other antiinfectives, such as sulfamethoxazole-trimethoprim (Bactrim) or levofloxacin, in the treatment of MRSA. Linezolid is a bacteriostatic synthetic antibacterial agent of a newer class of antibiotics, the oxazolidinones, developed for MRSA, methicillin-resistant *S. epidermidis*, enterococci, and staphylococci. Linezolid inhibits bacterial protein synthesis by binding to the 50S ribosomal subunit to prevent translation.[69] Adverse effects of linezolid include myelosuppression (e.g., anemia, leukopenia, pancytopenia, and thrombocytopenia), which is generally reversible on discontinuation of the drug, and *Clostridium difficile* colitis. A weak, nonselective, and reversible inhibitor of monoamine oxidase, linezolid may cause increased serotonin serum levels and serotonin syndrome in patients on various serotonin reuptake inhibitors, such as fluoxetine and sertraline. Prolonged use also carries a risk of polyneuropathy.

Invasive wound infections, graft loss, sepsis, and septic shock from suspected gram-positive bacteria should be treated empirically with intravenous vancomycin until culture-directed de-escalation can occur. Vancomycin is bactericidal, preventing gram-positive bacterial cell wall glycopeptide polymerization thereby producing immediate inhibition of cell wall synthesis and lysing the cytoplasmic membrane.[69] As a time-dependent antimicrobial, serum levels of this drug must unceasingly exceed the MIC to provide sufficient bactericidal activity. Due to the wide variability in vancomycin elimination among burn patients, the dosage must be individualized to optimize serum concentrations by serially following trough levels, with a typical goal of 10–15 μg/mL for most burn wound infections. Due to poor penetration, certain compartments, such as the lungs and central nervous system, require higher trough concentrations to achieve therapeutic levels of vancomycin; in cases of pneumonia or meningitis, concentrations of 15–20 μg/mL are recommended.[70]

Alarmingly, gram-positive strains resistant to vancomycin, such as vancomycin-resistant *Enterococcus* (VRE) and vancomycin-intermediate *S. aureus* (VISA), have emerged. These bacteria are often susceptible to linezolid, as discussed earlier, as well as to tigecycline, daptomycin, quinupristin-dalfopristin, and dalbavancin, which have been developed specifically to tackle this problem. Working closely with a clinical pharmacist who can help establish an antibiotic and dosing regimen best fitting the specific resistance pattern in a given patient is critical.

Gram-negative infections more frequently require admission and intravenous antibiotics. While empiric therapy should be directed by local antibiogram, consideration must also be given to additive toxicity when combined with empiric gram-positive agents. In our hospital, we empirically use imipenem/cilastatin due to their low nephrotoxicity when used in conjunction with vancomycin.[71] De-escalation and discontinuation of antibiotics should occur as soon as cultures, wounds, and physiology warrant. Because gram-negative bacteria frequently become multidrug-resistant, testing for synergy between different classes of antibiotics is advisable.

Third- and fourth-generation cephalosporins and extended-spectrum penicillins are the antibiotics of choice

for many burn centers for empiric coverage of gram-negative infections due to their broad coverage and low toxicity. Fourth-generation cephalosporins (e.g., cefepime), extended-spectrum β-lactamase inhibitor penicillins (e.g., piperacillin-tazobactam and ticarcillin-clavulanate), and most importantly the carbapenems (e.g., imipenem/cilastatin, meropenem, and ertapenem) are important tools in eradicating gram-negative infections. Newer fifth-generation cephalosporins were developed to treat resistant *Pseudomonas*; unfortunately novel resistance patterns are already emerging.[72] These antibiotics are time-dependent and most efficacious when serum concentrations between dosing intervals are maintained at 1–2 times the MIC; thus extended infusions over 3–4 hours or continuous infusion may be necessary to keep concentrations above MIC, particularly when a pathogen is near the resistance threshold.[72] In perforating the cell wall, penicillins are often synergistic with intracellular antibiotics, such as aminoglycosides, and testing is warranted in the setting of highly or pan-resistant organisms.[73,74]

Aminoglycosides remain effective for significant susceptible gram-negative infections. Much of critical care has moved to once-daily dosing of these concentration-dependent antibiotics since it is as effective and less toxic than conventional dosage intervals. Pooled data from randomized controlled studies in adults showed that once-daily administration of aminoglycosides is associated with similar or greater efficacy (e.g., bacteriologic and/or clinical cure), less nephrotoxicity, and no greater risk of ototoxicity than administration of multiple daily doses.[69] Some clinicians remain concerned that traditional dosing intervals may be preferable in severe infections or in patients with unpredictable pharmacokinetics, as described in burn patients.[75] Therefore monitoring aminoglycoside serum concentrations and/or the peak serum concentration to MIC ratio in burn patients with life-threatening infections, suspected toxicity or nonresponse to treatment, decreased or varying renal function, and increased aminoglycoside clearance is well indicated.

Multidrug-resistant (MDRO) and pan-drug-resistant (PDRO) gram-negative organisms are increasingly prevalent. Many of these islets have sensitivities to polymyxins, a class of cell-wall intercalating antibiotics that includes the topical agent polymyxin-B and its intravenous analogue colistimethate sodium (colistin, polymyxin-E).[71] These antibiotics were largely abandoned in the 1970s due to concerns of toxicity when Kunin and Bugg showed polymyxin accumulation highest in the kidney and brain tissues, followed by liver, muscle, and lung. It was also reported that colistimethate appeared to increase the incidence of *C. difficile* colitis, renal dysfunction, and neuropathies proportionately to the duration of its use.[76,77] However, colistimethate use against MDRO has surged due to a lack of other systemic options. Branski et al. reported that, in 118 patients with life-threatening MDRO gram-negative infections, colistimethate provided an important salvage option for burn patients with otherwise incompletely treated infections. They further found that hepato-, neuro-, and nephrotoxicity were no different in matched patients treated with or without colistimethate, indicating concerns from 40 years ago might be unfounded with modern critical care.[71]

Antifungal treatment is complicated by the limited number of agents and their relative toxicities. The most commonly used antifungal agent, fluconazole, has excellent activity against *C. albicans* and low toxicity. However, non-albicans *Candida* spp. are increasingly frequent causes of invasive candidiasis, and these are resistant to fluconazole.[78] The Infectious Disease Society of America advocates echinocandins as the best empiric treatment for yeast infections, as most yeast are susceptible to them.[79] However, these are recommended only until cultures become available. Cultures should be performed frequently in these patients since resistance can develop quickly.[80,81] There is an increased prevalence of *Candida* spp. with greater antimicrobial resistance and higher mortality rates than *C. albicans*, such as *C. tropicalis* and *C. krusei*.[82,83] Ponziconazole and voriconazole, both azoles, are the treatment of choice for invasive *Aspergillus* and *Fusarium*. They are also effective against infections caused by *Candida* spp., including fluconazole-resistant ones. However, azoles have unpredictable, nonlinear pharmacokinetics with extensive interpatient and intrapatient variation in serum levels. Due to this and numerous drug–drug interactions, therapeutic drug monitoring is crucial.[84,85]

For decades Amphotericin B dexolate (AmBd), an intravenous polyene analogue of nystatin, has been the standard choice for intravenous treatment of life-threatening invasive molds. This drug is associated with significant toxicity, including infusion-related events and dose-limiting renal dysfunction.[86] Three new lipid formulations of amphotericin B (AmB lipid complex [ABLC], AmB colloidal dispersion, and liposomal AmB [AmB-L]) offer several advantages over AmBd, including increased daily doses of the parent drug (up to 10–15-fold), high tissue concentrations in reticuloendothelial organs, a decrease in infusion-related events (especially with ABLC and AmB-L), and a marked decrease in nephrotoxicity.[86] These lipid drugs are more expensive, but their enhanced safety profiles make them the new standard for treating invasive molds, particularly *Mucor*. The most successful treatment for fungal infection is prevention via swift removal of all burned tissue and closure of wounds with autografts. In the presence of active mold infections, voriconazole is the first-line treatment, followed by ABLC. An echinocandin, such as caspofungin, can be considered for combination treatment of *Aspergillus* and *Fusarium*.[71] *Fusarium* spp. have demonstrated innate resistance to Amphotericin.[87]

Pathogens will continue to evolve novel resistance mechanisms more rapidly than researchers can develop antibiotics. In the dire case where no antibiotic susceptibility exists for an infecting pathogen, it is important to remember excision of infected tissue, graft coverage of wounds, and topical care remain effective treatment plans. Barret and Herndon noted that aggressive, early surgical treatment reduced wound culture counts from greater than 10^5/g to less than 10^4/g and yielded excellent skin graft take. In contrast, poorer skin graft take occurred in patients with initial counts of greater than 10^6/g, but were reduced to 10^4/g only after delayed surgical excision, thus underscoring the correlation between early and aggressive wound excisions and better patient outcomes in the treatment of severe burns.[8,15] While infections can become overwhelming, there is no bacterial resistance mechanism to the surgeon's knife.

Specific Pathogens in Burn Wounds

Staphylococcus aureus, gram-positive cocci in clusters, remains the chief cause of burn wound infection and is a well-documented opportunistic pathogen in humans.[18,88] Colonization with these bacteria in an uninjured individual is usually asymptomatic, but they are a source of opportunistic infection that can lead to severe illness and death, especially in burn patients.[89] *Staphylococcus* produces virulence factors, such as proteinases, coagulases, and hyaluronidases, that enable it to invade local tissues and disseminate hematogenously, causing generalized systemic infection and sepsis.[90] The most common infections of *Staphylococcus* spp. are septicemia, cellulitis, impetigo, scalded skin syndrome, and postoperative wound infections. However, puerperal sepsis, pneumonia, osteomyelitis, endocarditis, and burn wound infection are the most grave. Exotoxins, which are produced by pathogenic strains of staphylococci, include a pyrogenic toxin, a dermonecrotizing toxin, and leukocidin. In addition to the exotoxin TSST-1, these organisms can produce enterotoxins A, B, and C, risk factors for TSS in susceptible patients.[91] *Staphylococcus* spp. generally produce penicillinases that make natural penicillins ineffective and thus require treatment with penicillinase-resistant penicillins, such as oxacillin. MRSA is now the predominant isolate, with rates of infection greater than 50% in burn units.[92,93] Empiric coverage should be vancomycin for intravenous therapy or Bactrim and rifampin orally, as detailed earlier, based on the local antibiogram and patient cultures.

Streptococci were once the leading cause of burn wound infection but are now less prevalent. Arranged in chains, these gram-positive cocci are particularly virulent when infecting a burn wound and quantitatively do not require less than 10^5 CFU/g tissue to prevent wound closure. A mere few β-hemolytic streptococci can cause wound infection, failure of a primary closure, and loss of a skin graft.[9] The major infecting species are *Streptococcus pyogenes* (also referred to as group A streptococci and the most problematic) and *S. agalactiae* (group B streptococci).[94] Natural penicillins, such as penicillin G and penicillin V, and first-generation cephalosporins are bactericidal to these species. While resistance to these penicillins or cephalosporins has not yet emerged, culture and antibiotic sensitivity data should be followed.

Enterococci are important inciters of gram-positive burn wound infection. Encouragingly a recent review comparing sepsis mortality between consecutive decades (1989–1999 and 1999–2009) found a steep decline in the rate of infection with enterococci (25% to 2%, respectively), perhaps stemming from the more liberal use of vancomycin of recent years.[2] However, with the increasing prevalence of vancomycin-resistant enterococci, VRE mortality rates are now greater than those of MRSA (58% and 33%, respectively).[95] While most *Enterococcus* spp. respond to vancomycin, VRE is treated with linezolid, a combination of ampicillin and aminoglycosides, or quinupristin/dalfopristin (Synercid). De-escalation is advised as soon as indicated by culture data.

Pseudomonas is not just the most ubiquitous gram-negative burn wound pathogen, but also the most likely to be responsible for sepsis leading to burn-related death.[2,18] Both local environments and gastrointestinal tracts (via translocation of endogenous gastrointestinal flora) are believed to be the primary sources of this bacterium. This species has a predilection for moist environments, and human burn wound exudates have been shown to stimulate the expression of virulence factors of *P. aeruginosa*, the pathogen chiefly responsible for nosocomial respiratory tract infections.[96] Additionally it breeds invasive and troublesome wound infections in burn patients. A superficial wound infection caused by *P. aeruginosa* typically will have a yellow-green color and noxious fruity smell.[97] This may become an invasive infection, ecthyma gangrenosum, causing purplish-blue ''punched-out'' lesions in the skin, and, if local thrombosis of vessels is present, the wound requires immediate dif local t to remove newly necrotic tissues (Fig. 11.8). Empiric treatment for *P. aeruginosa* infection has evolved from aminoglycosides to antipseudomonal β-lactams, such as piperacillin/tazobactam, cefepime, and carbapenems.[98] The increasing prevalence of MDRO *P. aeruginosa* requires the expanding use of antibiotics based on culture data, employment of fifth-generation cephalosporins, use of synergistic antibiotic coverage, and use of colistimethate, as discussed in the systemic antimicrobial section. This rapidly evolving and virulent pathogen is best eradicated by rapidly closing wounds to deny the bacterium access to any susceptible wound surface.

Acinetobacter spp. are gram-negative rods used commercially to convert wine to vinegar and are native flora of the respiratory tract, skin, gastrointestinal tract, and genitourinary tract. This organism may lead to numerous opportunistic infections, including pneumonia and infections of the surgical site and urinary tract.[99] Second only to *P. aeruginosa* in prevalence, this pathogen has an enhanced capacity for transfer between patients due to its ability to survive in both dry and wet conditions and equally on animate and inanimate objects, whether metal or plastic, making nosocomial transmission a major concern.[100,101] *Acinetobacter* spp. have been isolated from diverse clinical sources, including the upper and lower respiratory tracts, the urinary tract, and surgical and burn wounds, as well as in bacteremias secondary to intravenous catheterization. An agent of low virulence, it has a predilection for infecting patients with dysfunctional host defense mechanisms. Although traditionally susceptible to ceftazidime and ciprofloxacin, *Acinetobacter* has developed resistance to such an extent that only carbapenems (e.g., imipenem and meropenem) can now be relied on to treat these infections. In cases of MDRO *Acinetobacter*, colistin has become the rescue treatment, as with *Pseudomonas* infections.[71,102]

Stenotrophomonas maltophilia (also known as *P. maltophilia* or *Xanthomonas maltophilia*) is an aerobic gram-negative bacillus responsible for nosocomial infections in immunocompromised patients.[103] Increasingly reported in burn patients, this pathogen causes life-threatening infections which are very difficult to clear due to the particularly obturant biofilm *Stenotrophomonas* produces.[104] Additionally *S. maltophilia* is inherently resistant to a variety of antimicrobial agents, such as aminoglycosides, β-lactam agents, and carbapenems. The most common types of infections caused by *S. maltophilia* are wound and bacteremia; pneumonia and generalized infections associated with this

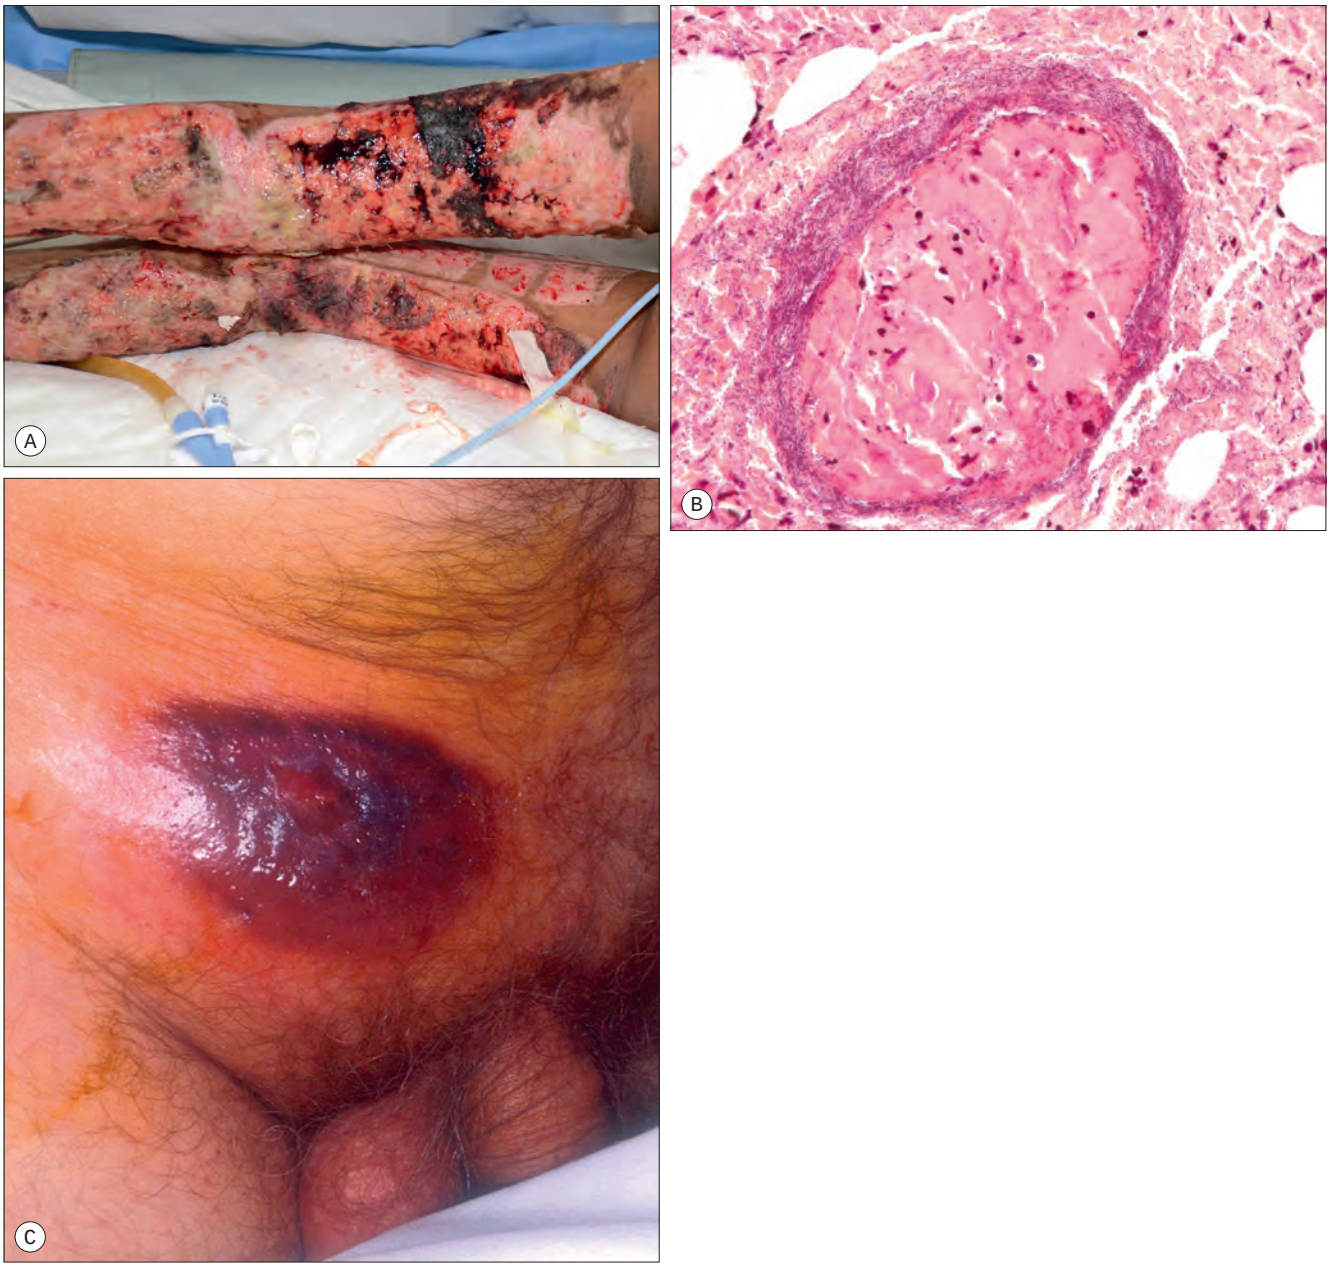

Fig. 11.8 Ecthyma gangrenosa. A tissue-invasive burn wound infection here seen in a 7-year-old girl transferred to our hospital after a 6-week treatment at another hospital. Note the (A) extensive greenish and slime-coated wound consistent with an invasive wound infection. The patient died subsequently from an overwhelming hematogenously spread pneumonia. (B) The vessel wall at 40× magnification micrograph shows a clear bacterial infiltration. (C) A typical purplish ecthyma gangrenosa lesion in a 35-year-old man. (C courtesy of Omar P. Sangüeza, MD; Professor and Director of Dermatopathology, Wake Forest University School of Medicine, North Carolina.)

pathogen are less common.[105,106] Infections are sensitive to trimethoprim-sulfamethoxazole alone or used with levofloxacin, and sensitivities should be monitored. Aggressive surgical dulfamethox and assiduous washing technique with soap and water are vital to combat the resultant biofilm.

Enterobacteriaceae, such as *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., *Serratia marcescens*, and *Proteus* spp., are often revealed as the cause of burn wound infections and other nosocomial infections in burn patients.[107] Although these pathogens have greater sensitivity to antibiotics than other gram-negative bacteria, emerging resistance patterns to carbapenems and fourth-generation cephalosporins led to a larger array of MDRO and PDRO.[108] Carbapenem-resistant Enterobacteriaceae (CRE) are increasing in incidence and in many cases require treatment with colistin.

Anaerobic bacteria, such as *Bacteroides* spp. and *Fusobacterium* spp., are rarely a cause of invasive burn infection. These bacteria are normal flora from the oropharyngeal cavity to the gastrointestinal tracts. Anaerobic flora are responsible for 2%–5% of surgical wound infections in the oropharyngeal area[109,110] and 10%–15% of wound infections in the gastrointestinal and urogenital tracts.[111] In burn patients, anaerobic infections are usually associated with avascular myonecrosis secondary to electrical injuries,

frostbite, or cutaneous flame burns with concomitant crush-type injuries.[112] With the advent of early excision and grafting, the incidence of anaerobic infections in thermal injury has been reduced significantly. If anaerobic infection is suspected, it is vital that collected specimens be placed in appropriate transport tubes void of oxygen. In these cases, broad-spectrum antibiotics covering anaerobes should be given until sensitivities are available to ensure the administration of the appropriate drug.[113,114]

Fungal wound infection and colonization have become increasingly prevalent following the introduction of topical antibacterials and liberal use of broad-spectrum antibiotics.[115] This has resulted in a surge in invasive fungal infection linked to higher death rates, regardless of the extent of the burn, coincident inhalation injury, or patient age.[116] In a recent review of 15 burn units, fungi were isolated at least once from 6.3% (435/6,918) of patients,[117] with positive cultures being most commonly obtained from the wound itself followed by (in order of decreasing frequency) respiratory, urine, and blood specimens.[118] Yeasts are identified primarily on the basis of specific biochemical tests, but both macroscopic and microscopic morphologies are also used to make final identification (Fig. 11.9). Mold identification is based on growth rate, colony structure, microscopic/microscopic appearance, dimorphism at different incubation temperatures, and inhibition of growth by cycloheximide, as well as various biochemical tests (Fig. 11.10).[119]

Early diagnosis of fungal infection can be difficult because clinical symptoms frequently mimic low-grade bacterial infections. Routine culture techniques may require 7–14 days to identify fungal contaminants, delaying initiation of treatment.[118] In contrast to bacterial sepsis, venous blood cultures might not reflect the causative fungal organism.[120] For this reason, arterial blood cultures and retinal examination for characteristic candidal lesions can be useful. *Candida* spp. are the most common fungal colonizers of the burn wound, although fungi like *Aspergillus* spp., *Penicillium* spp., *Rhizopus* spp., *Mucor* spp., *Rhizomucor* spp., *Fusarium* spp., and *Curvularia* spp. can also be present, and they have a vastly greater invasive potential than yeasts.[110,115] *Candida albicans* is the fourth most frequently identified pathogen in blood cultures from ICU patients; however, invasive infection with molds such as *Aspergillus* is correlated more closely with death.[121] Candidemia warrants retinal examination for retinal plaques, as further discussed in Chapter 43 on burn injuries of the eye (Fig. 11.11)

Fig. 11.9 *Candida* Infection in a healing second-degree burn wound. Pain and itch is usually present in this kind of infection. Treatment with silver sulfadiazine mixed with Mycostatin was effective in controlling *Candida* in this patient.

Most patients infected with molds are exposed to spores in the environment at the time of injury, from either rolling on the ground or extinguishing flames in contaminated surface water. Other environmental foci have been cited as the source of nosocomial mold infection, including bandaging supplies left open to the air, heating and air-conditioning ducts, and floor drains.[110,115] Once colonized, hyphae extend into subcutaneous tissue, stimulating an inflammatory response. This phenomenon is diagnostic of mold wound infection. Vascular invasion and systemic dissemination are common and often accompanied by thrombosis and avascular necrosis, clinically observed as rapidly advancing dark discolorations of the wound margins or well-described lesions[120] (Fig. 11.10). Treatments for yeasts and molds vary greatly due to the vastly different pathogenicities of these organisms. Yeasts found in burn wounds are more often associated with colonization and do not represent infection. Treatment is usually considered when the same yeast is identified at multiple sites, and topical treatment is applied liberally; if invasive infection is considered systemic, antifungals are administered. In contrast, the identification of mold in a burn wound is a very serious condition. Often invasive, infection with mold requires radical débridement including amputation and high-dose topical and systemic antifungals, such as 6,000,000 U/g nystatin powder.[64] Hyphae invading live tissues and blood vessels should be considered a surgical emergency and treated aggressively. It is essential to work closely with a pathologist to make rapid diagnosis of invasive mold and ensure complete surgical resection at the margin, as one would resect a malignant cancer.

Viral infections, particularly Herpesviridae, have become more significant causes of morbidity. Prospective and retrospective assays of sera have documented a large incidence of subclinical viral infections. In one of the first large retrospective studies from the 1980s, Linnemann et al. found a fourfold increase in anti-cytomegalovirus (CMV) antibodies in 22% of patients, increased herpes simplex virus (HSV) in 8%, and a rise in varicella-zoster (VZV) titers in 5%.[122] The study continued in a prospective manner, with 33% of the children developing CMV infection, 25% developing herpetic infection, and 17% developing adenovirus infection.[122] The most common cause of viral infection is reactivation of latent infection due to the debilitated, immunosuppressed state of the patient after a substantial injury. Herpes viruses, especially HSV and VZV, have by far the greatest occurrence, but CMV is not unusual.

CMV infection frequently occurs concurrently with bacterial and fungal infections but rarely alters the patient's clinical course. Kealey and coworkers showed that, in addition to blood transfusions, cadaver skin is a principal source of CMV infections in burn patients.[123] Overall seroprevalence in burn patients ranges between 37% and 73%.[124,125] Gong and coworkers studied the reactivation rate and found 108 of 180 patients to be positive at admission.[126] Linnemann and colleagues determined that primary infection or reactivation of CMV was reported with an overall

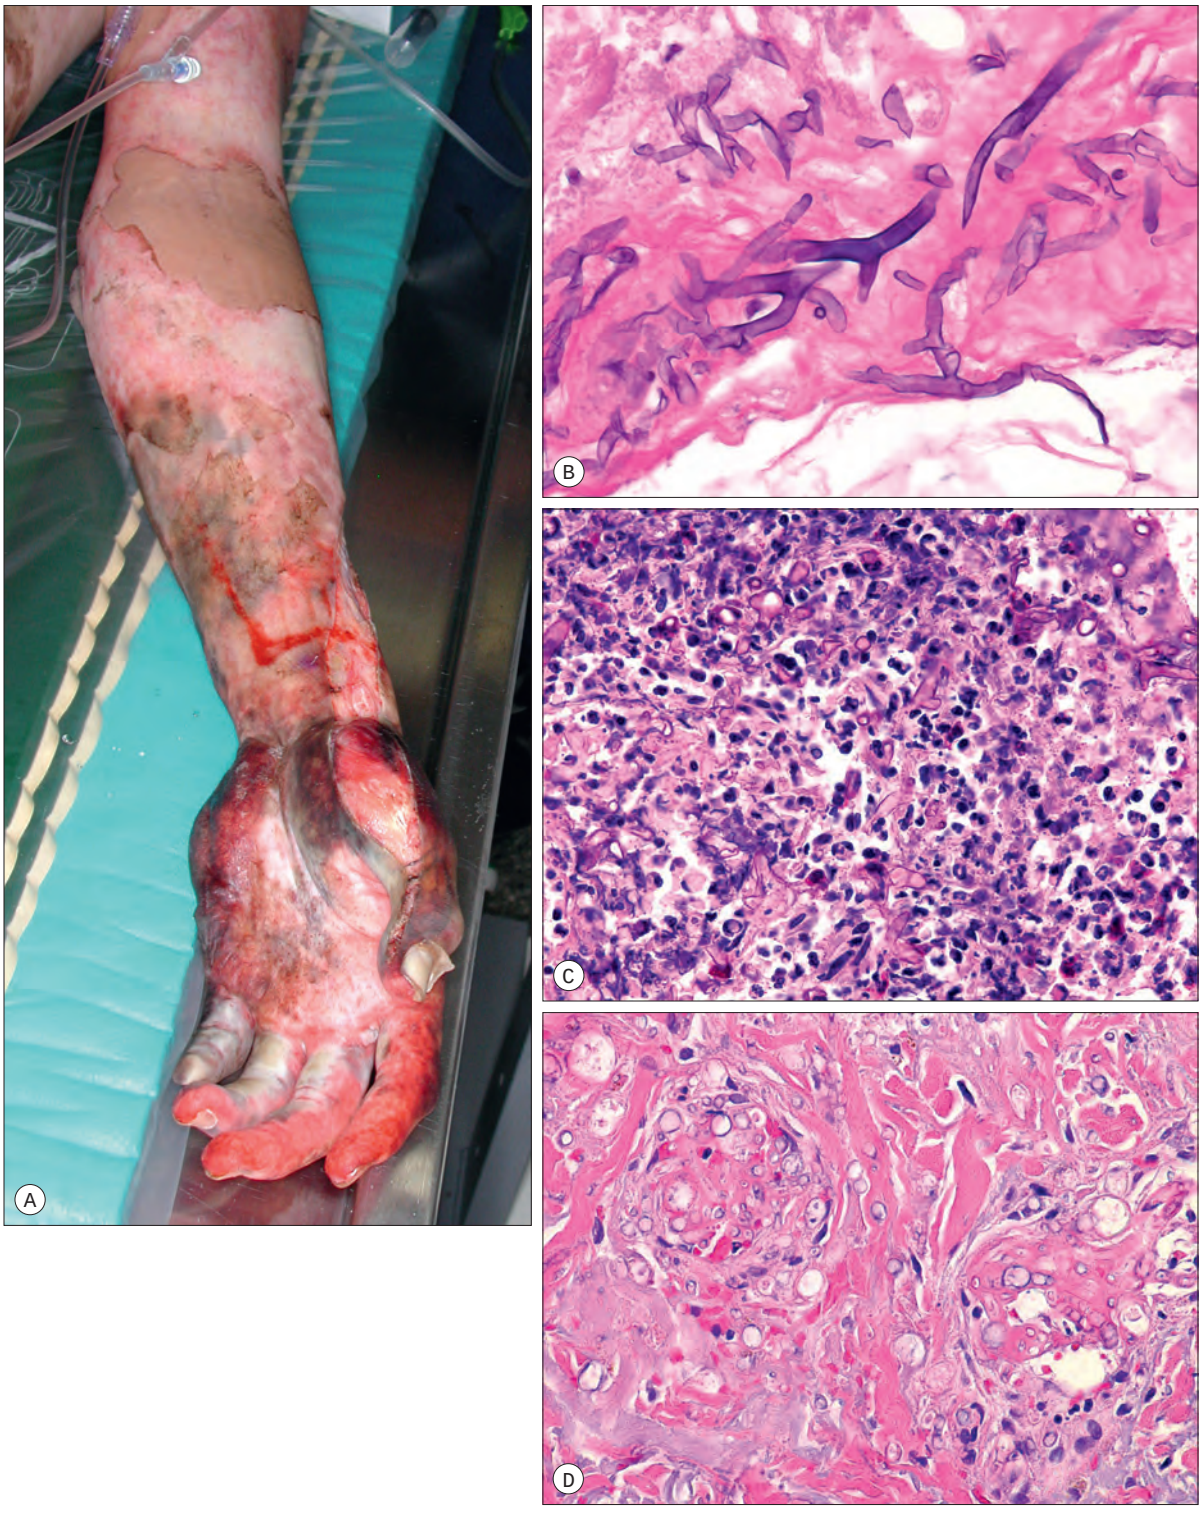

Fig. 11.10 Diagnosis of invasive mold infection. Invasive mold infection carries a significant increase in morbidity and mortality. Physical examination reveals (A) a left forearm and hand wound with macroscopical fungal growth (a white, fluffy appearance) and necrotic borders before repeated surgical débridement. Diagnosis on histological examination is critical to guide both surgical treatment as well as selection of antifungal therapy. Below are 40× magnification micrographs of (B) *Aspergillus*, (C) *Mucor*, and (D) *Fusarium* findings. (B, C, D courtesy of Omar P. Sangüeza, MD; Professor and Director of Dermatopathology, Wake Forest University School of Medicine, North Carolina.)

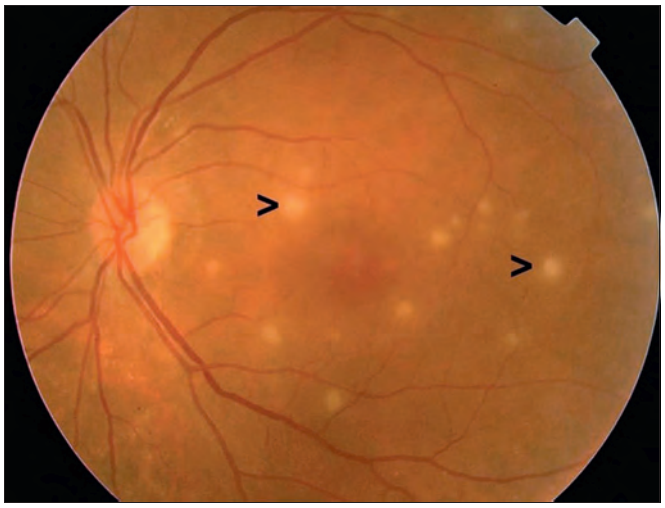

Fig. 11.11 Candidal retinopathy. Yeasts are an increasingly common infectious agent in burn patients. Funduscopic examination is critical to diagnose candidal retinal implants and determine the length and success of antifungal treatment. The picture reveals the typical multiple creamy white intra retinal lesions with hemorrhage.

frequency of 33%.[122] In this study, prospective analyses "directly correlated CMV infection with more severe burns, more skin grafts, and subsequent higher numbers of blood transfusions." In contrast Rennekapff and coworkers found in 2007 a seroconversion rate between 18% and 22% for burn patients seronegative for CMV prior to burn injury.[127] CMV inclusions may be identified in the cells of multiple organs but have not been reported in the burn wound.[128] Immunocompromised patients have a higher frequency of CMV infection, resulting in a broad range of adverse conditions from febrile illness to systemic infections with organ involvement.[129] CMV infection has also been associated with unexplained fever and lymphocytosis, as seen by a concomitant rise in specific antibodies.[122,128] Systemic CMV disease is an unusual occurrence; the majority of patients who demonstrate increased CMV-specific antibody sustain more limited CMV infections. The absence of reports of severely burned patients with increased CMV antibodies suggests that most of these infections are subtle and have been overlooked by past studies. Nevertheless a higher number of CMV copies per milliliter of blood is associated with a higher rate of major infections, more ventilator days, and longer hospitalizations.[130,131]

Generalized, nonhealing burn wounds have been associated with CMV-related pathological changes in endothelial and periendothelial cells.[124] Inclusion bodies consistent with CMV infection, as well as CMV antigens, have been detected by immunohistochemical staining of a skin biopsy from a transplanted cadaver allograft (from a CMV-positive donor) on a severely burned adult male; however, the relationship of the CMV infection to necrosis, inflammation, and increased vascularity evident in infected skin is unknown.[132] Severe burn injury has been shown to predispose experimental animals to murine CMV infection, which is associated with greater susceptibility to sepsis.[133,134]

Tennenhaus and colleagues surveyed and evaluated U.S. and German burn centers for awareness, perception, diagnosis, and treatment of CMV in patients with burn injury.[135] CMV infection incidence was reported at 1 : 280 and 1 : 870 in German and U.S. burn centers, respectively. When testing, 70% of German and 19% of U.S. burn centers used serology, 52% German and 25% U.S. centers used body fluid viral isolation, and 43% German and 6% U.S. centers used leukocyte CMV-DNA analysis. Two-thirds of the German and half of the U.S. centers distinguished infection from disease. A total of 43% German and 19% U.S. centers would subsequently treat the established disease; however, no differences were observed in mortality.[136] CMV infection is an undesirable outcome and should always be considered in cases of unexpected fever and hepatitis, especially in burned children.[122]

Treatment of CMV infection is commonly initiated with intravenous acyclovir or its longer-acting oral prodrug valacyclovir, despite both demonstrating only moderate anti-CMV activity. This is because they are inexpensive and readily available in most hospitals. Less obtainable intravenous ganciclovir, a medication designed for CMV, is the agent of choice for treatment of patients with symptoms of significant CMV infection.[137] Valganciclovir, the longer acting oral prodrug of ganciclovir, has similar efficacy to intravenous ganciclovir but does not require a chemotherapy hood for preparation by the pharmacy. Thus valganciclovir has emerged as the drug of choice whenever oral therapy is possible.[138–140] Prophylactic therapy against CMV is not recommended in burned patients.

Viral infections arising in healing burn wounds are often attributed to HSV, particularly on the face and genitals. These infections most commonly manifest as vesicles in healing partial-thickness burns or split-thickness donor sites (Fig. 11.12). Partial-thickness burns and donor sites infected with herpes may convert to full-thickness injuries requiring skin grafting for ultimate closure. Skin graft donor sites can convert to full-thickness injury, also requiring grafting to close.[8] In the immunocompromised burn patient, the infection usually starts with the formation of vesicles at the edge of the wound, with these vesicles then coalescing into a confluent raw area. A near-total loss of epidermal coverage can occur (Fig. 11.13). Other epithelial surfaces, such as oral or intestinal mucosa, can also be involved, potentially causing erosion and perforation.

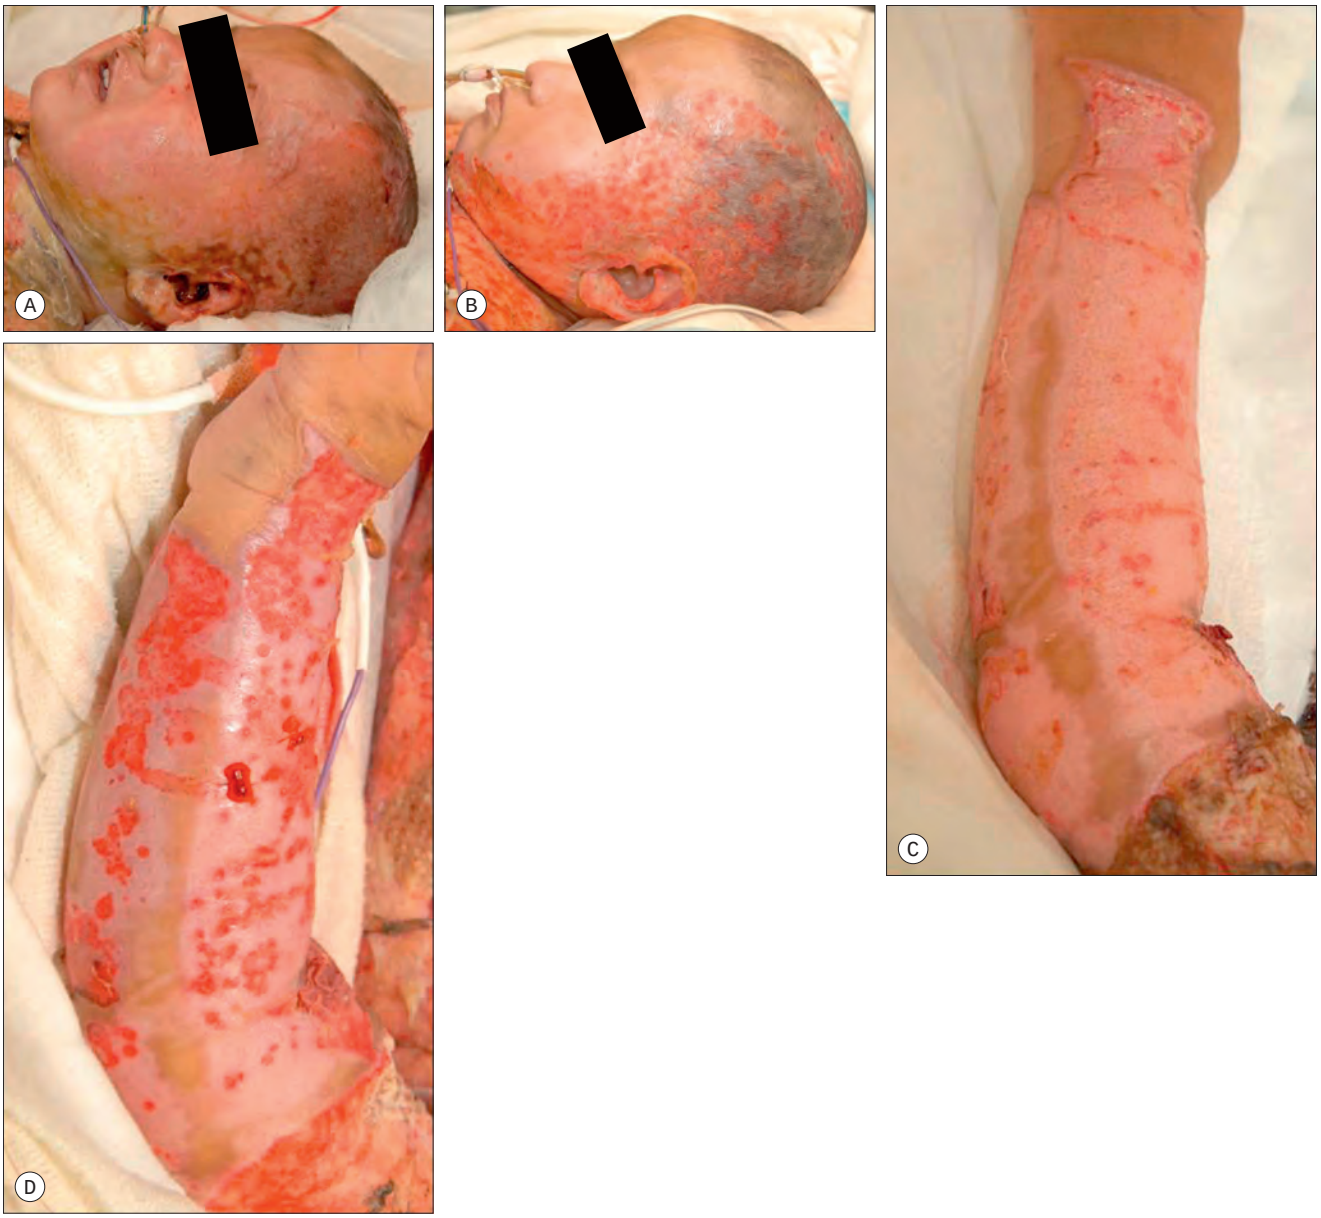

Fig. 11.13 Fulminant herpetic infection. A 13-month-old girl with 80% TBSA scald burn who developed a fulminant herpes simplex II infection 2 weeks after admission. (A) Ten days post-burn, prior to clinical manifestation of infection. (B) Post-burn day 18. Full manifestation of herpetic lesions that affect the entire body surface area and convert previously healed areas into open wounds. (C) The left arm, which was used twice as a donor site for split-thickness skin graft (days 4 and 11) prior to herpetic infection. The image is from day 17, with initial manifestation of herpetic infection with red macules. (D) Day 18 post burn; 30 hours later, conversion to confluent defects with near total loss of epidermis.

The clinical manifestations of lesions may be preceded by unexplained fever unresponsive to routine antibiotic coverage.[141]

Tzanck smears, viral cultures, and polymerase chain reaction (PCR) are the methods of choice to diagnose herpetic infections. Tzanck smears are a rapid, inexpensive, and minimally invasive tool used to detect infections by cytology over the course of the past last century (Fig. 11.14). While they lack the diagnostic precision necessary to discriminate between different types of Herpesviridae or even primary versus recurrent infections, they can reveal active infections that warrant treatment.[142] Viral cultures are effective means of diagnosis, but they take several days and are expensive. More sensitive than smears and quicker than cultures, PCR has thus become the standard in our burn center.

Increased mortality, extensive visceral involvement, and necrotizing tracheobronchitis have become associated with herpetic infections post-burn in recent years. Fidler and colleagues performed a retrospective study characterizing the incidence, presentation, and outcome of 14 patients with facial herpes rashes out of 95 severely burned intubated adults. Rashes attributed to herpetic infections were found to be present in at least 15% of patients, but no difference in mortality or length of stay between patients with or without the infection was detected.[143] Necrotizing hepatic and adrenal lesions may lead to multisystem organ failure. Mortality in patients with disseminated infection is

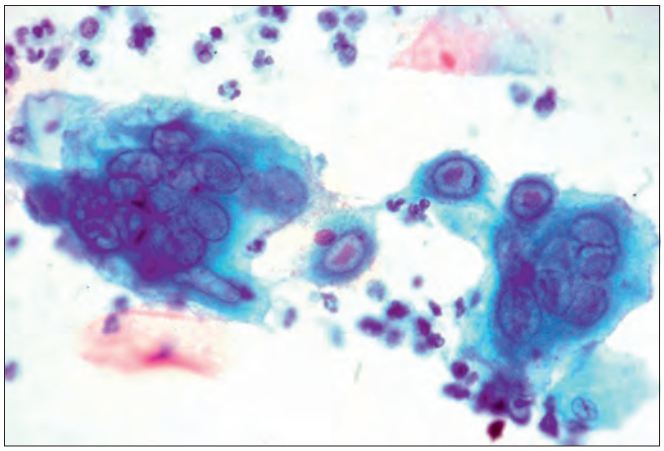

Fig. 11.14 Tzanck smear. This cytology can be performed rapidly as a touch prep or as a scraping smear of a suspicious lesion. The Tzanck smear should be performed on a fresh blister. Once identified: 1. Gently deroof the lesion with a scalpel. 2. Scrape the base of the lesion. 3. Smear the tissue onto a clean microscope slide. 4. Allow it to dry in the air. 5. Fix the specimen with preservatives. 6. Stain the slide and analyze it under microscope. Pathognomonic multinucleated giant cells are diagnostic of a herpetic infection. While not determinant of the type of herpes simplex virus, a test can be performed in minutes inexpensively, and a positive result indicates treatment.

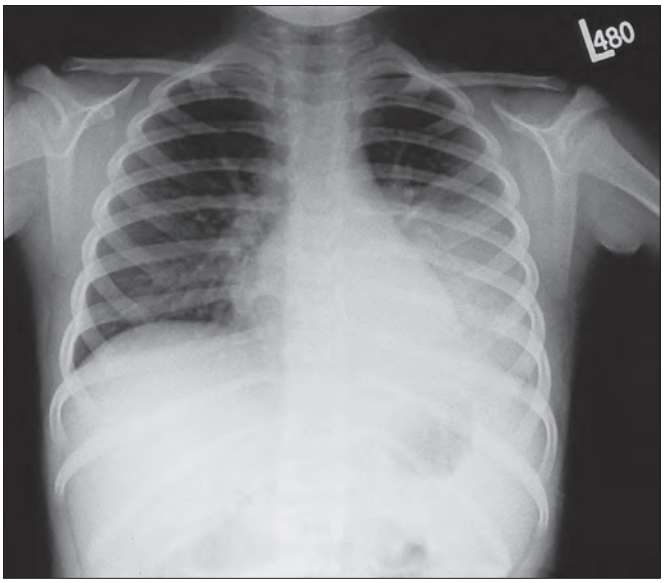

Fig. 11.15 Left lower pneumonia. Burn patient with typical radiographic picture of lobar pneumonia. The diagnosis of pneumonia in patients with inhalation injury and respiratory distress syndrome is still arduous.

approximately twice that expected for patients of similar age and burn size.

Split-thickness grafts provide adequate coverage of previously infected herpetic wounds,[144] but the coverage is frequently associated with secondary graft loss and the need for reoperation and patch grafting. Furthermore skin graft donor sites can convert to full-thickness injuries due to active herpetic infection. As such, skin donor sites should not be harvested for grafting for 10–14 days following infection resolution.[145] In burn patients with active herpetic infection, intravenous acyclovir or valacyclovir should be administered systemically for no less than 10 days and often longer.[146] Recent studies indicate that valacyclovir has greater bioavailability and steadier plasma concentration than acyclovir. While the best treatment remains controversial, both are acceptable for herpetic infection.[147]

VZV infection (chickenpox) is prevalent among school-aged children and rapidly spreads through inhalation of the virus. While rare in burned patients, VZV infections can be life-threatening in immunocompromised hosts, and small epidemics have occurred within pediatric burn units.[144] In the nonimmunized pediatric population, acute VZV infection directly correlates with morbidity and mortality.[148] Characteristic fluid-filled lesions appear in healed or healing partial-thickness burns, as well as in uninjured epithelium and mucous membranes. Owing to the fragility of newly healed or healing skin, the vesicles are much more destructive in injured than uninjured skin and may present as hemorrhagic, oozing pockmarks prone to secondary infection and subsequent scarring. Neovascularized skin grafts may be lost, and further grafting procedures should be delayed until the lesions are quiescent. Antiviral treatment with acyclovir is indicated in case of infection and, as suggested by Sheridan and colleagues, should be given prophylactically to nonimmunized pediatric patients.[148] The therapeutic effect of antiviral agents administered post-burn remains to be fully elucidated, as recently elaborated by Wurzer and Lee.[149]

Infections From Sources Other Than Wounds in the Burn Patient

Pneumonia is a leading cause of morbidity and mortality in burn patients.[1] Inciting infectious organisms can enter the lung either through direct contamination of the airway or hematogenously. Mechanical ventilation increases the risk of pneumonia; patients should be extubated as soon as clinically possible to prevent ventilator-assisted pneumonia (VAP), as discussed in Chapter 32 on critical care. Inhalation injury further increases the risk of VAP. Carrying a worse prognosis than pneumonias originating in the airways, the hematogenous etiology of pneumonia presents later in the hospital course and is often bilateral. Etiological organisms typically match those colonizing or infecting the burn wounds. Centers for Disease Control clinical diagnostic criteria of pneumonia are as follows: (1) chest X-ray revealing a new and persistent infiltrate, consolidation, or capitation[3,95] (Fig. 11.15); (2) sepsis (as defined for burn patients); and (3) a change or purulence in expectorated or aspirated sputum. If two of these criteria are found, a clinical diagnosis of pneumonia is then made, and, prior to the start of antimicrobial treatments, specimens should be collected for microbial analysis.

Tracheal aspirate, bronchoalveolar lavage (BAL), or protected bronchial brush (PBB) is performed to obtain a specimen. In burn patients, the possibility exists to use surface quantitative wound cultures (QWC) to predict pathogens found in VAP. Ramzy et al. investigated the relationship between burn wound flora and microbial pathogens in the tracheobronchial tree and found a 48% match. However, when strict quantitative criteria were applied, the match

rate fell to 14%. Burn size and inhalation injury had no significant effect on match rate.[150] The difference between qualitative and quantitative match rates suggests cross-colonization between the burn wound and tracheobronchial tree but little to no cross-infection. Thus both QWC and BLF cultures must be performed when determining antimicrobial specificity in the burned patient. However, wound cultures can be helpful in guiding empiric treatment for VAP and should be covered until BAL or PBB samples allow for culture-directed therapy.

BAL and PBB are recommended over tracheal aspirate for definitive diagnosis and treatment of VAP.[151] Positive microbiological results are tracheal aspirate showing 10^5 or more colony-forming units (CFU); BAL, 10^4 or more organisms; and PBB, 10^3 or more organisms. The data subsequently modify the clinical diagnosis in one of three ways:

- If a pathogen is isolated in sufficient quantities, then the clinical diagnosis is confirmed.
- If the clinical diagnosis was strong but the microbiologic data fail to confirm, then the diagnosis is probable.
- With low or moderate clinical suspicion, but with the presence of a positive specimen, the pneumonia diagnosis is possible.

In many quality assurance programs, a clinical diagnosis cannot be vacated by a lack of confirmation by the microbiology report, often resulting in inappropriately diagnosed and treated VAP.[3] In a 2005 study, Wahl and colleagues reported that negative BAL results ($<10^4$ CFU) reduced the clinical VAP diagnosis rate by 21%. Negative BAL results prompted the discontinuation of antibiotics administered based on clinical suspicion of VAP. In this study, none of the patients whose antibiotics were discontinued had antibiotics restarted based on clinical grounds.[152]

Regardless the tenets of pneumonia treatment remain consistent with standard critical care. Broad-spectrum antibiotics are instituted empirically to cover all likely etiologic agents. Utilization of ventilator support allows the patient to oxygenate and ventilate. Clinical diagnosis is made and confirmed with tracheal or bronchial cultures. Antibiotics are changed to treat the identified etiologic pathogen and discontinued after a finite course or when cultures are negative and the clinical condition resolved.[67]

Bloodstream infections in burn patients develop from a myriad of sources: burn wounds, urinary tract infections, pneumonias, translocation from the gut, or from the intravenous and intra-arterial lines essential to their care. Treatment of bloodstream infections is the same as for all infections: source control by removal of possible etiological causes, early institution of broad-spectrum antibiotics covering likely organisms, cultures of the blood and potential sources to make a definitive diagnosis, tailoring antimicrobials to the cultures, and discontinuation of the antibiotics following the course of treatment.[67] In most major burn patients, vascular access devices are requisite for treatment. Many central venous catheters (CVCs) must be placed through burned tissue or cannot have standard dressings applied due to poor skin quality or wound therapy. These limitations are known to increase central line–associated bloodstream infection (CLABSI) risk but are required for care. If burn patients demonstrate symptoms of SIRS or sepsis, their catheters should be removed or changed. Cultures should be performed of both the blood and catheters for evaluation as potential causes of sepsis. When there is concern of sepsis, dogmatic culturing of removed vascular access devices and blood is crucial to proper burn critical care. Rates of catheter-associated infection and septic thrombophlebitis in burn patients are as high as 57%.[153–155] One of the following two criteria must be met to diagnose a bloodstream infection: (1) the patient has two or more positive blood cultures for a known pathogen or one positive blood culture in the presence of sepsis, or (2) the patient has a common skin contaminant cultured from two or more blood cultures on separate occasions, as well as sepsis.[3] The bloodstream infection is considered primary if the same organism has not been cultured at another site. If the same organism is cultured at an alternate location, the bloodstream infection is considered secondary. A catheter-related bloodstream infection is present if a patient has sepsis and no other source of infection and if the signs of sepsis resolve within 24 hours of catheter removal. Unfortunately these administrative definitions do not often comport with the patient's clinical course and, generally, CLABSI is overdiagnosed. However, it is imperative to place the concerns of proper patient care and diagnosis exemplified by potential source control, early empiric antibiotics, and liberal use of cultures above inaccurate administrative definitions that fail to improve patient health.

Franchesi and coworkers[156] reported a 50% correspondence between the organisms cultured from the tip and connectors of the catheter within 2 days of placement. Furthermore, they found that a negative correlation existed between the frequency of catheter infection and the distance separating the point of catheter insertion from the burn wound. These data support the hypothesis that catheter infections arise primarily from burn wound contamination migrating to the catheter tip. Serious complications can often be avoided by following strict aseptic techniques. General guidelines for protecting against catheter-related infections are[157]: training health care staff on the correct procedures for inserting and maintaining catheters, including indications and suitable infection control practices; use of a mask, hat, gown, sterile gloves, and drapes during placement of CVCs; use of 2% chlorhexidine to prevent infection; and avoiding routine CVC changes. In the event that infection continues despite adhering to the guidelines, use short-term CVCs coated with an antibiotic, antiseptic, or both.

Suppurative thrombophlebitis should be suspected in patients with persistent positive blood cultures in the absence of signs of local infection. Often suppuration can occur subsequent to catheter removal, so cultures at the time of removal may be unreliable predictors of infection. Gross clinical signs of suppurative thrombophlebitis are frequently not present.[158] Upon confirmation of the diagnosis, immediate operative excision is essential to prevent progressive sepsis. Entire excision of a vein to the port of entry into the central circulation may be necessary because phlebitis tends to migrate to vein valves, leaving an apparently normal vein between infected foci. The subcutaneous tissue and skin should be packed open where a grossly purulent vein is removed and allowed to granulate and close by secondary intention (Fig. 11.16).

Gastrointestinal infections can limit clinical examination, thereby complicating burn care. Like all patients,

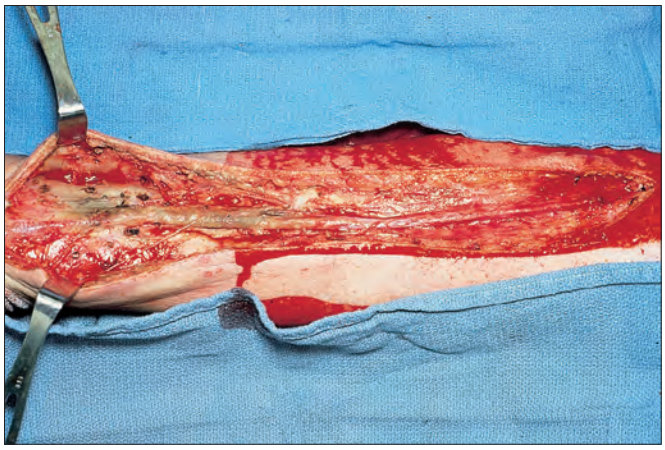

Fig. 11.16 Suppurative thrombophlebitis. Infection was noted along the length of vein. Proper treatment is total excision of the vein from the site of infection to the point of entry into central circulation.

those burned can develop conditions such as appendicitis, intussusception, ileus, and bowel obstruction. Ascetic fluid or peritoneal dialysis fluid can also become infected. Larger burns are associated with episodes of hypoperfusion, leading to sloughing of intestinal mucosa. Heme-positive mucoid, watery stools, abdominal distension, and diminished bowel sounds often characterize this condition. Diarrhea is a common issue, and osmotic causes from feeds should be excluded by testing for reducing substances. *C. difficile* is a well-known entity in critically ill patients, especially those with a history of antibiotic use and in immunocompromised patients. Current guidelines for the treatment of the first episode of *C. difficile* include oral or intravenous metronidazole, oral or rectal vancomycin, and fidaxomicin.[159] Possible complications due to *C. difficile* infections can be pseudomembranous colitis with the potential to progress to fulminant toxic colitis and bowel perforation. Should any of these develop, subtotal or total abdominal colectomy with an ileostomy may be required.[160] A loop ileostomy with colonic lavage using postoperative vancomycin colonic flushes via the ileostomy is an alternative surgical approach with perhaps lower morbidity and mortality.[161]

Necrotizing enterocolitis can occur in patients severely granulocytopenic from any cause, including burn. Splenic enlargement and tenderness are often present, along with high fever. Chest X-ray may reveal an elevated left hemidiaphragm, basilar pulmonary infiltrates, atelectasis, or a left pleural effusion, while abdominal X-rays can demonstrate a shift of the colon and stomach down and to the right, extraintestinal or bowel wall gas, or air–fluid levels in the upper left quadrant. Ultrasonography and computed tomography (CT) are the preferred diagnostic techniques for the determination of suspected splenic abscess and necrotizing enterocolitis. As with all infections, initial antibiotic therapy should have a broad spectrum of activity. A combination of antibiotics with activity against both aerobic and anaerobic gram-negative bacilli would be most appropriate. Free air or suspected necrotic bowel due to an unresolving lactic acidosis are indications for a laparotomy.[162]

Genitourinary infections occur from indwelling urinary catheters or hematogenous dissemination of bacteria. Fungi can lead to urinary tract infections in burn patients. These organisms are often introduced via the prolonged or unnecessary use of urinary catheters. This underlines, once again, the importance of infection prevention following the guidelines repeated earlier (e.g., aseptic techniques, catheter care, routine urine monitoring, and early removal). In some burn patients, especially those with genital burns or protracted shock, a prolonged catheterization may be well indicated, balancing the elevated risk of infection against the care benefit. If infection develops, patients should have their catheters removed or changed, urine cultured, appropriate empiric antibiotics administered, and then culture-directed antimicrobials utilized. In cases of highly resistant pathogens, urinary catheters may need to be discontinued, with the patient only intermittently catheterized.[163]

Chondritis typically occurs in full-thickness injuries to the ear resulting in infection of the auricular cartilage. The auricles have a comparatively low blood supply, and chondritis frequently follows tissue ischemia. Chondritis usually presents 3–5 weeks after thermal injury but may be seen earlier and may develop following partial-thickness injuries. Mafenide acetate cream has become the topical agent of choice for burned cartilaginous surfaces like the ear because it coats and adheres to the irregular surfaces well while deeply penetrating the wound and saturating the cartilage to prophylactically guard it against infection. With its use, the incidence of suppurative chondritis has significantly decreased[164] (Fig. 11.17). Chondritis presents with dull pain and a warm, red, tender, and edematous ear. Appropriate antibiotics should be immediately administered, and, if there is an identifiable site, the abscess immediately excised and drained, with culture and sensitivity obtained. Should induration and tenderness persist, a more extensive débridement is imperative. Generally the helix is bivalved at the posterior helical margin and all necrotic cartilage débrided. Difficulty may arise in distinguishing between viable and necrotic tissue, and normal cartilage is frequently sacrificed to ensure débridement. However, infected cartilage is usually soft, whereas normal cartilage will feel granular on curettage. If appropriate and sufficient excision of the necrotic tissue is not performed, the auricle can auto-amputate and suppurative chondritis can invade the mastoid bone, potentiating the formation of intracranial abscesses.[165]

Ophthalmic infections occur from injuries suffered in the initial trauma, from corneal exposure due to poor lid function due to edema or facial burns, herpetic reactivation, or hematogenous spread of infection. Corneal injury can lead to bacterial infection with subsequent corneal perforation and loss of the eye. The cornerstone of treatment is prevention through treatment of abrasions with topical antimicrobial agents, early eyelid release, and vigilance in protecting against risk of exposure trauma.[166] In incapacitated patients, the entire burn team must be vigilant and monitor the eye for injuries and infection. This topic is discussed in depth in Chapter 43 on burn injuries of the eye.

Suppurative sinusitis is an uncommon infection but can cause ICU sepsis. In patients with no identifiable source of sepsis, diagnosis can be made based on X-rays or CT scans. Therapy with broad-spectrum antibiotics and promotion of drainage should be initiated immediately. Surgical drainage of the involved sinuses may be necessary if the infection is

Fig. 11.17 Left ear with suppurative chondritis. Chondritis seen 3 weeks after flame burn to the left ear. Note the erythema and drainage from the helical rim.

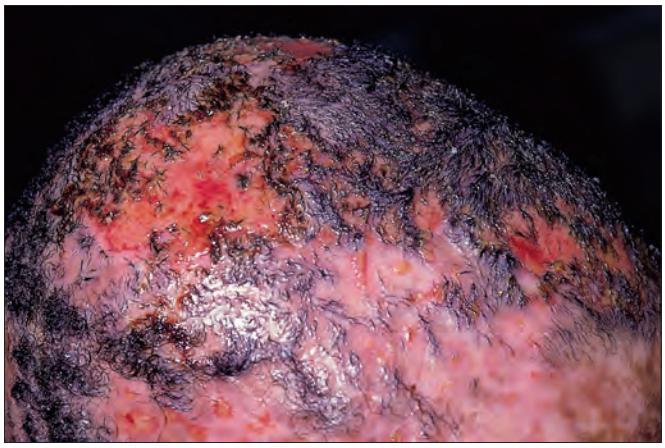

Fig. 11.18 Chronic folliculitis of the scalp. Hairs from hair-bearing areas are embedded in the granulation tissue of converted second-degree burns and donor sites, and microorganisms are entrapped, prolonging the healing process. Shaving of the affected area, topical treatment with mupirocin, and cleansing with soap and water typically resolve this problem in several days to a week.

unresponsive to the antibiotics. In the ICU, transnasal intubation and the use of nasogastric or nasoduodenal tubes for enteral feeding are considered risk factors. However, in 25 years of routine nasotracheal intubations and routine prolonged nasojejunal and nasogastric tube placements, we have not encountered a single case of suppurative sinusitis in Galveston. Oral intubation and nasogastric feeding may be employed as temporary measures, but if sinusitis becomes complicated and prolonged treatment is necessary, then a tracheostomy and/or orogastric feeding is indicated.

Folliculitis is an infection commonly occurring on the scalp, male face, and scalp skin graft donor sites. As in the case of impetigo, cultures commonly reveal *S. aureus*, particularly MRSA (Fig. 11.18). Treatment consists of twice-daily cleansing with soap and water, unroofing any abscesses, and twice-daily application of mupirocin. Shaving the hair is helpful both prophylactically and for treatment. Keratinocytes in the viable hair shafts allow rapid reepithelialization once bacterial counts are brought under control. Excision and grafting is rarely required.

Tetanus is a rare complication of burn wounds in the developed world. Routine prophylaxis at admission with 0.5 mL tetanus toxoid is given, if it has not been administered in the previous 3 years.[167,168] In addition, if the patient's last booster was more than 10 years prior, 250 U of tetanus antitoxin is also administered. Should *Clostridium tetani*, an anaerobic gut flora of ruminants, colonize or infect a burn wound in an unvaccinated individual, the resulting intoxication can lead to a horrific and easily avoided mortality.

HIV infection is endemic in areas such as sub-Saharan Africa; some countries have rates of 35%–39% in the total adult population. In the United States, the incidence is much lower, but since people with HIV do get burned, care of this disease in the burn unit is worth consideration. HIV seems to have an additive effect on the immunosuppression of the burn, as reflected in the CD4/CD8 cell counts. In a 2003 prospective study from Zimbabwe, Mzezewa and colleagues found that graft survival after split-thickness skin grafting of burn wounds in HIV-infected patients was impaired and hospital stay was prolonged, with significant alterations in the levels of pro- and antiinflammatory cytokines.[169] The authors concluded that HIV infection results in immune dysregulation, which might be related to impaired skin graft survival. Recent data have emerged describing a substantial burden of sepsis in the infected population receiving highly active antiretroviral therapy, in addition to a much poorer prognosis in this group compared with the uninfected population. Although there is a lack of literature regarding the implications of antiretroviral medications on burned patients and the effect on wound healing and graft take, using antiretroviral therapy to reduce septic incidences should be considered.[170]

Conclusion

Treatment of infection in the burn patient follows the same algorithm dominating treatment of all infections in every critically ill patient: (1) early source control, (2) culture identification of infecting microbes, (3) early institution of empiric antimicrobials with subsequent transition to culture-directed antibiotics when sensitivities are ascertained, and (4) discontinuation of antimicrobials following the administration of a sufficient course or when the wounds are closed. The considerations specific to burn care are (1) source control is determined by excising the burn wound and covering it with skin graft, (2) aggressive use of quantitative wound cultures guides antimicrobial selection, and (3) careful and frequent evaluation to diagnose sepsis and treatment with empiric antibiotics when indicated.

All eschar must be excised as quickly as possible, ideally within the first 48 hours post-burn, because eschar provides an ideal microbial culture medium. Burn wounds should be closed as rapidly as feasible with autograft. The tenet, "every donor, every time" should be employed in all large burns: every area of donor skin should be harvested and autograft applied at every operation. When insufficient autograft is available to cover the wounds, homograft should be used to temporize wounds. Homograft overlay of widely expanded autograft, in the methodology of Alexander, is an effective way to limit the wound surface area available to pathogens and maximize utilization of finite donor areas, as detailed in Chapter 12 on operative wound management. Every moment a burn wound lacks a complete epithelial surface, there is a cumulative risk for wound infection and resistant organisms to take hold. Source control is also obtainable by assiduous washing and débriding in hydrotherapy, which has been demonstrated to be an indispensible component of modern burn care. High concentrations of antimicrobials can and should be delivered topically to burn wounds for colonization and infection treatment and for prophylaxis.

Aggressive use of quantitative wound cultures is the standard of care in modern burn wound management, and sensitivities determined from these studies direct effective tailoring of antimicrobials to the patient's infecting microbiota, thereby reducing toxicity from superfluous antibiotics. All vascular access devices removed from a burn patient should be cultured to ensure that any colonizing or infecting bacteria are identified, correct diagnoses are made, and antimicrobial sensitivities are monitored.

Due to their hypermetabolic states, determining when a burn patient is septic is complicated. When a presumptive diagnosis of sepsis is made, broad-spectrum coverage should be instituted to cover all likely pathogens. The choice of initial agent is based on the local antibiogram; in many burn centers, carbapenems and vancomycin are appropriate choices. Once sensitivities return, empiric antibiotics should be de-escalated.

The ultimate infection control method in burn care is closing the burn wound with skin. In the setting of pan-resistant organisms, this is the only treatment. Every time the patient has skin available for grafting, this opportunity must be exploited to reduce the wound surface area available to pathogens and provide definitive prophylaxis and treatment of burn wound infections.

12 Operative Wound Management

MOHAMED E. ISMAIL ALY, MOAYAD DANNOUN, CARLOS J. JIMENEZ, ROBERT L. SHERIDAN, and JONG O. LEE

Introduction

Surgery for burn injury is a key component to the multidisciplinary care of the burn patient. It usually involves early procedures such as escharotomy and fasciotomy when indicated, followed by burn excision. Early intervention in the form of early burn wound excision and grafting has dramatically changed the outcome and survival of the burn patient.[1]

Following burn injuries, tissues affected, including skin, promote an inflammatory response at the junction between the eschar and the underlying viable tissue. The presence of microorganisms within the eschar attracts polymorphonuclear leukocytes that release large amounts of proteolytic enzymes and inflammatory mediators. Subsequent enzymatic action results in separation of the eschar, leaving granulation tissue. In large surface area burns, the inflammatory response at the burn injury site develops into a systemic response.

Mediators such as prostanoids, thromboxane, histamine, cytokines, and tumor necrosis factor are produced and released from the burn site. The serum levels of these mediators increase proportionally to the skin surface area of the burn. The hypermetabolic response with increased protein catabolism, increased energy expenditure, weight loss, poor wound healing, and immune depression continues until the outpouring of mediators abate.[2,3]

Advantages of Operative Wound Management

Early excision and skin grafting to achieve wound closure have been shown to reduce infection rates, reduce length of hospital stay, and improve survival in burn patients. Pediatric burn patients in particular have benefited from timely surgical intervention.[4,5] There has been a remarkable increase in the total burn surface area (TBSA) associated with a 50% mortality risk over recent decades. It is now fairly unusual for a child to succumb to burn injuries of any size, even in association with an inhalation injury (Tables 12.1 and 12.2). Early prompt fluid resuscitation, appropriate critical care, nutritional support, and treatment of infections have also played a major role in this achievement.

Early operative intervention, however, remains the major contributor to this major advance in burn care. In 1974, Burke and colleagues reported on the results of total excision of full-thickness burns where allografts were applied to cover burn wounds following excision; allograft rejection was controlled using immunosuppressants.[6]

Improved mortality, shorter hospital length of stay, and fewer metabolic complications were noted when early excision was retrospectively compared with late excision.[7] In another study, 32 children with an average age of 7 years and mean burn size of 65% (TBSA) who underwent either total excision or serial debridement were studied. Mortality, overall blood loss, and cumulative operating time were equivalent.[8] The early excision group, however, had their length of hospital stay almost halved (97 ± 8 days vs. 57 ± 5 days). Since then, hundreds of children with burns of more than 30% TBSA treated with early excision have demonstrated a hospital length of stay of less than 1 day/% TBSA burned.[9]

Tompkins et al. demonstrated that mortality of adult burn patients at Massachusetts General Hospital improved from 24% in 1974 to 7% in the time period from 1979 to 1984 after implementation of prompt eschar excision and immediate wound closure.[10] This study was later expanded to include 85 patients aged 17–55 years.[11] Those patients aged 17–30 years without inhalation injury showed significantly reduced mortality of 9% if treated by early excision, compared to 45% when treated conservatively. Patients with a concomitant inhalation injury or aged over 30 years, however, had no survival benefit from early excision.

In children with burn injuries, Xiao-Wu et al. showed that delays in the excision of extensive burn were associated with longer hospitalization, delayed wound closure, increased rates of invasive wound infection, and increased incidence of sepsis.[12]

Munster et al. demonstrated a statistically significant decrease in hospital length of stay correlating with a decrease in the interval between surgical interventions over a 14-year period.[13] Other variables such as burn size, inhalation injury, and age remained unchanged during the same time period; mortality rate decreased significantly.

Elderly burn patients have also been shown to benefit from early excision. Deitch et al. demonstrated that early surgical excision in patients with an average age of 68 led to 40% reduction in mean hospital length of stay compared to the national average and reduced mortality.[14] Many studies show that early excision can be safely performed in the elderly with clear benefits of reducing hospital length of stay and the number of septic episodes.[15–19]

Hypertrophic scar formation is common following burn injuries, with dark-skinned patients more prone to hypertrophic scar development. However the most important factor in the development of hypertrophic burn scars is delayed wound healing. Deitch et al. demonstrated that in wounds requiring more than 10 days to heal, the risk of hypertrophic scarring is significant and rises to 80% if healing is delayed beyond 21 days.[20] Operative treatment also limits the duration of pain caused by the burn wound.

In conclusion, early burn wound excision is lifesaving, offers improved cosmetic and functional outcomes, and is cost-effective.

Techniques of Burn Wound Excision

EXCISION OF A SMALL BURN

Operative intervention is indicated without delay once the burn injury is determined to be a "deep" injury. Deep burn injuries are clearly either full-thickness or deep partial-thickness burns that are unlikely to heal within 3 weeks and are typically flame or contact burns. Heimbach et al. noted that deep partial-thickness burns did not convert to full-thickness burns when topical antimicrobials were used to control infection.[21] Although these wounds eventually healed after several weeks, they showed persistent blistering, pruritus, hypertrophic scar formation, and poor functional outcomes. These observations prompted a prospective trial of early excision and grafting versus nonoperative treatment of indeterminate depth in burns of less than 20% TBSA.[22] Shorter hospitalization, lower cost, and reduced time away from work, but greater use of blood products were seen in patients treated with early excision. Those patients treated nonoperatively required more late skin grafting to achieve wound closure and developed more hypertrophic scars.

Table 12.1 Mortality Following Burn Over Time for Different Age Groups, Shown as the Burn Size at Which 50% Live or Die

	LA50 (% TBSA)		
Age [years]	**1942–1952**	**1980–1991**	**1992–2004**
0–14	49	98	99
15–44	46	70	88
45–64	27	46	75
>65	10	19	33

TANGENTIAL EXCISION

Tangential excision, as a technique, is the meticulous removal of burned skin while preserving underlying viable tissue. Body contours are better preserved with tangential excision than with fascial-level excision, which removes underlying subcutaneous fat; hence, it is the standard excision technique for burns.

Tangential excision was originally described by Janzekovic, who observed that deep skin graft donor sites could be grafted with thinner split-thickness skin grafts taken from another area.[23] Later she extended this concept to partial-thickness burns by repeatedly excising thin layers of the burned skin until viable tissue was reached (Fig. 12.1). Then split-thickness skin grafts were immediately applied.

The technique of tangential excision and autografting of partial-thickness burns was a major advance in burn care at the time. Prior to its introduction, only full-thickness burns were excised, including subcutaneous fat and accompanying lymphatics down to the underlying layer of investing fascia (Fig. 12.2). Janzekovic analyzed the results of the use of tangential excision in more than 2000 patients. She found that, compared to fascial excision, hospital length of stay, pain, and reconstructive procedures were decreased.[24]

A number of different instruments can be used to perform tangential excision of the burn wound. The Goulian knife, Watson knife, and the Versajet Hydrosurgery System are used for tangential excision (Fig. 12.3).[25] Deep partial-thickness burns are debrided down to white, viable dermis with punctate bleeding. In full-thickness burns, excision continues layer by layer until viable subcutaneous tissue with a yellow glistening appearance is encountered. Dull yellow color, purple discoloration, or thrombosed vessels indicate nonviable tissues that are not suitable for grafting and require deeper excision (Fig. 12.4). When excision is performed on limbs with a pneumatic tourniquet, these features are particularly important.

There are noninvasive imaging tools available for predicting burn depth and healing time in adult burns. These include laser Doppler imaging (LDI), which is the current gold standard; infrared thermography (IRT); and spectrophotometric intracutaneous analysis (SIA). LDI uses a low-intensity laser beam to scan across the tissue surface. Laser is both absorbed and scattered by tissue matrix and the blood flow in the vessels. Flux is then determined by processing the photocurrent resulting from both absorbed and scattered light. The device generates a colored map of the

Table 12.2 Pediatric-Specific Mortality Rates Over Time; Near-Total Early Excision Is the Basis of These Excellent Results.

	MORTALITY SORTED BY BURN SIZE (% TBSA)							
Years	**<20%**	***n***	**21%–40%**	***n***	**41%–60%**	***n***	**61%–100%**	***n***

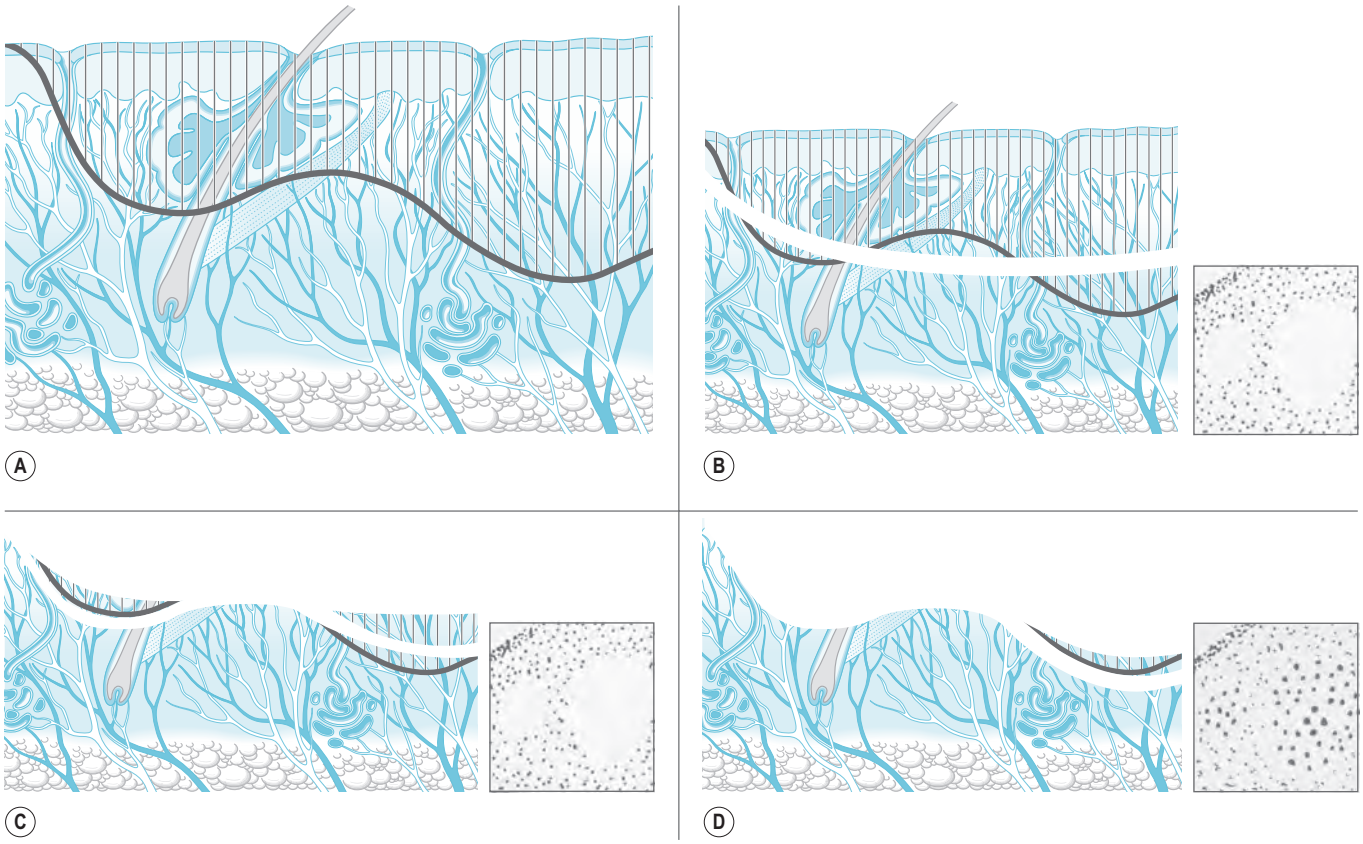

Fig. 12.1 (A–D) Schematic representation of tangential excision; sequential slices are taken until punctate hemorrhage is evident (From Janzekovic Z. A new concept in the early excision and immediate grafting of burns. *J Trauma.* 1970 Dec;10(12):1103–1108.)

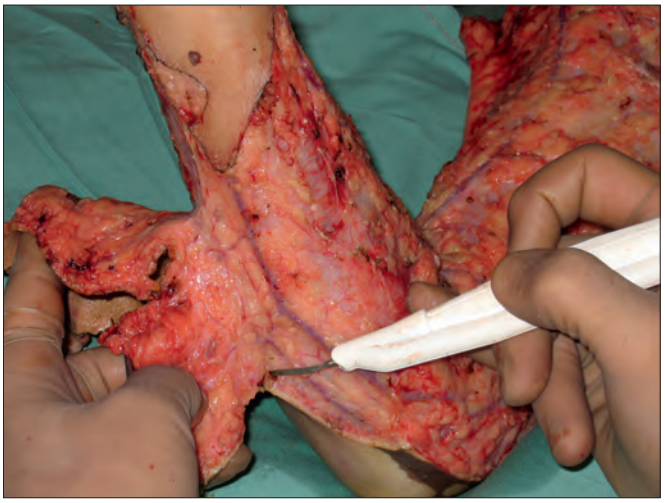

Fig. 12.2 Fascial-level excision using cutting diathermy and an incorporated smoke evacuator.

Fig. 12.3 A selection of hand-cutting dermatomes available for use for tangential excision. Most have the ability to set the aperture to the desired depth, while the Goulian has a large series of blade changeable guards.

wound correlating with the extent of the injury. LDI can be a useful tool in surgical decision-making in indeterminate-depth burns.[26]

IRT uses the heat signature resulting from tissue perfusion to predict the depth of burn injury. Superficial burns retain a bright color compared to the surrounding normal tissue due to increased perfusion, whereas deeper burns appear darker in color due to decreased or lack of perfusion.[27,28] SIA is used in the diagnosis of pigmented skin lesions such as melanoma. It uses spectrally filtered images using polarized light ranging from 400 to 1000 nm. A complex set of mathematical algorithms determines the melanin and hemoglobin content of the epidermis and papillary dermis, then presents them in high-resolution images.

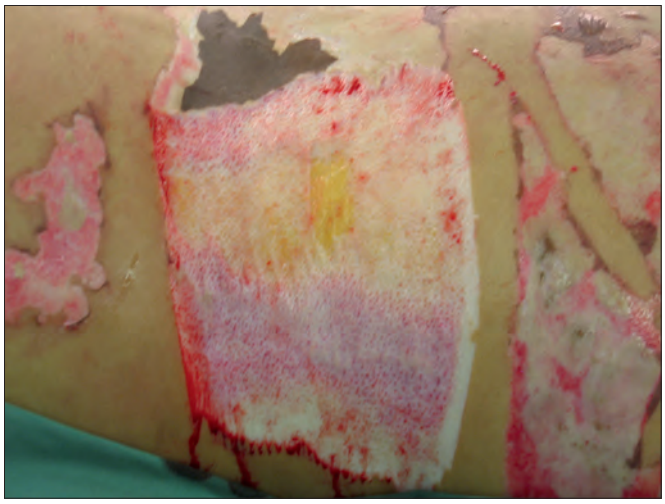

Fig. 12.4 A deep flame burn on the left thigh that is in the process of being debrided. The wound has been tumesced with 1 : 1 000 000 epinephrine in normal saline and shows minimal bleeding. The lower part of the wound demonstrates residual dead dermis with dull appearance and staining from lyzed cells. The area just above demonstrates shiny yellow, living fat and (mostly) surviving shiny white dermis with a few patches needing another slice.

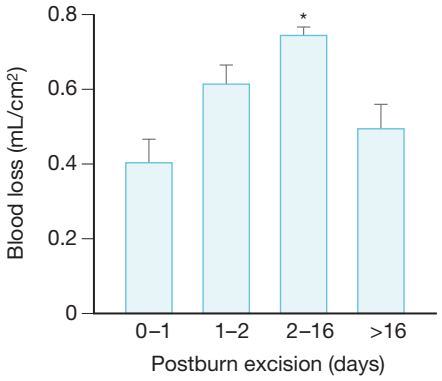

Fig. 12.5 Blood loss is almost halved by operating within 24 hours of injury. (From Desai MH, Herndon DN, Broemeling L, Barrow RE, Nichols RJ Jr, Rutan RL. Early burn wound excision significantly reduces blood loss. *Ann Surg.* 1990 Jun;211(6):753–759; discussion 759–762.)

The additional analysis of pigment available using SIA may more accurately indicate the depth of burn compared with perfusion alone.[29]

Ultrasounds with frequencies higher than 20 MHz have shown promising results in quantitative assessment of burn depth in animal models.[30] Currently only LDI has been validated for use in burn depth assessment.[29] It has been shown to reduce wound healing time in patients requiring surgery with a potential cost saving of about $1200 per patient.[31] Unfortunately LDI costs in excess of $70,000 in addition to annual servicing costs.

FASCIAL EXCISION

Skin and subcutaneous tissue are excised en-bloc using electrocautery in fascial excision. This involves excision of the full thickness of the integument, including all subcutaneous tissues down to the investing deep fascia. It is usually performed to reduce blood loss in extensive burns or in cases of severe infection to control the source of infection.

Fascial excision can limit the amount of blood loss because control of the deeper perforating vessels is achieved during the excision, bypassing the extensive capillary network present in the skin and subcutaneous tissue. Fascial excision is also required for areas where subcutaneous tissue has been involved in the burn injury. The advantages of this technique include improved graft take on fascia and reduced blood loss.

Fascial excision is also indicated in cases of life-threatening invasive wound infection or sepsis, particularly fungal infections such as *Aspergillus* and *Mucor*, and in cases of failed graft take in extensive burns in critically ill patients. Episodes of sepsis lead to ischemic necrosis of the subcutaneous fat due to poor peripheral perfusion and microvascular stasis. This represents a considerable problem in patients with extensive burns leading to late graft loss, and the ischemic areas are transformed into portals for invasive wound infection. The disadvantages of fascial excision are lymphedema due to the interruption of the subcutaneous lymphatics and contour deformities due to the loss of subcutaneous fat.

CONTROLLING BLOOD LOSS DURING BURN EXCISION

Excision of large burns can result in considerable, if not massive, blood loss. Tangential excision can lead to large blood loss unless measures are taken to limit hemorrhage. The simplest measure is to operate within 24 h of the burn injury. Vasoactive metabolites, in particular the potent vasoconstrictor thromboxane, are in abundance during this time to limit blood loss.[32] Desai et al. demonstrated in a prospective trial of 318 pediatric patients with burns of more than 30% TBSA that early excision of burns is associated with an overall reduction in blood loss. The average blood loss per surface area excised (mL/cm^2) was compared at various post-burn excision time points. The total blood loss during excision performed within the first 24 hours after burn was 0.4 mL/cm^2 excised, compared to 0.75 mL/cm^2 excised if performed between days 2 and 16 post burn. The blood loss dropped to 0.49 mL/cm^2 excised if the procedure was performed after the 16th day. Overall mortality was 5% for an average burn size of 60% TBSA. Early excision had no adverse effect on mortality. Very early excision led to a halving of blood loss for both large and small burns[32,33] (Fig. 12.5).

Other factors associated with increased blood loss during excision of burns are old age, male gender, larger body size, large full-thickness burns, high wound bacterial count, total area excised, and operative time.[33]

Several techniques to reduce blood loss during burn wound excision can be employed in the operating room. Adjunctive measures to limit blood loss include tourniquets for the extremities, pre-debridement tumescent infiltration with epinephrine solutions, topical application of epinephrine 1: 10 000–1: 20 000, fibrin sealant, autologous platelet

gel, calcium-enriched alginate sheets, and immediate bandaging with delayed grafting.

The application of tourniquets to the extremities is a very effective method of minimizing blood loss, especially for excision of burns involving hands and digits. As with tumescent infiltration, the absence of bleeding can make the estimation of the right depth of excision difficult. To counteract this, the tourniquet can be released briefly to check the adequacy of excision and then reinflated. The larger vessels are controlled by electrocautery or ligation and the wound is covered with sheets of calcium alginate or sponges, which are soaked in epinephrine solution. Following the release of the tourniquet, the limb should be elevated for about 10 min prior to graft application.

Tumescent solution made of epinephrine containing saline can be injected into the burn wound prior to excision. This technique is particularly useful for burn excision of areas such as the trunk, scalp, and face; 1.6 mL of 1 : 1000 epinephrine (0.8 mL in pediatric patients) is added to 500 mL of 0.45% normal saline solution. The resulting local vasoconstriction will minimize blood loss, and one-way syringes, such as the Multi-Ad Fluid Dispensing System or a pneumatic infuser, can make the injection process easier (Fig. 12.6).

Monitoring the patient's hemodynamics is necessary because epinephrine may cause tachycardia and hypertension, which can worsen bleeding. Another drawback of this technique is that the lack of bleeding from the wound bed may make the adequacy of excision difficult to assess.

When dealing with large areas of disrupted capillaries, one of the most effective ways to safely limit blood loss is rapid excision followed by coverage with epinephrine-soaked sponges or gauze and compressive bandages.

Delayed grafting after excision is used in some centers to limit blood loss. In case of delayed skin grafting, the wound bed needs to be kept moist and clean prior to skin grafting. The wound can be covered with bulky cotton dressings with tubes through the dressing to the wound surface for continuous or intermittent irrigation with antibiotic solution. The patient returns to the operating room within 24 h and undergoes a second procedure of procurement and application of skin grafts. This may be a practical approach in cases of large surface area excision, where coagulopathy can develop due to large blood loss or hypothermia. The authors of this chapter adhere to a hemoglobin (Hgb) threshold of 7 for transfusion. One study suggested a possible decrease in infection rate when compared to a more liberal transfusion strategy.[34]

TECHNIQUES OF WOUND CLOSURE

Once procured, the autograft skin can be used in different ways depending on the size of body surface area burned that requires grafting.

Autografts are classified as full- or split-thickness depending on the depth of dermal layer included when harvesting the skin. Full-thickness autografts have better cosmetic results and reduced scarring compared to split-thickness autografts because the dermis provides flexibility and elasticity. The main caveat is that the increased amount of dermis in the full-thickness autograft can compromise its own viability during the imbibition, inosculation, and neovascularization phases of graft take. The donor site completely devoid of dermis must be closed primarily or grafted. Therefore, split-thickness skin grafts are mainly used in the treatment of extensive burn injuries.

If the burn is small, skin grafts can be applied without meshing as a "sheet." The advantage of nonmeshed skin is better cosmetic outcomes. The disadvantage is the possible accumulation of seroma or hematoma underneath the skin graft that can compromise the apposition of the skin graft to the wound bed. Seroma or hematoma should be identified and removed by aspiration with a 25- or 27-gauge needle. The skin graft can be secured to the wound bed with quilting sutures or the application of a bolster dressing, which can reduce shearing of the skin graft. These grafts are best laid perpendicular to the long axis of limbs, particularly across joint flexural creases, which is in line with the general rule of placing potential scars perpendicular to the dominant muscle contraction in the area, thus reducing the degree of contracture if it occurs. Possible exceptions are the dorsum of the hand and forearm, where one may contend that longitudinally placed grafts are cosmetically superior.

In large burns where donor sites are limited, autografts are usually meshed. This allows the autograft skin to be expanded to cover a wider area compared to its original size. The most commonly utilized mesh ratios are 2 : 1 and 4 : 1, although other ratios of expansion can be employed. The main advantages of 2 : 1 meshed autograft skin is the ease of handling and application and the extensive network of slits that allows drainage of seroma or hematoma. The main disadvantage is that the interstices leave a visible pattern once healed. Much larger areas can be covered when autografts are meshed 4 : 1 or greater and widely expanded. This widely meshed skin graft requires an overlay coverage of nonexpanded allograft skin to decrease the risk of graft loss, and this is applied over the autograft skin in a sandwich pattern (Fig. 12.7).[35] The large interstices, which require a considerable amount of time to heal by epithelialization; the need for an allograft skin overlay; and the less desirable cosmetic result limit the use of 4 : 1 meshed autograft skin to massively burned patients. Even in massive

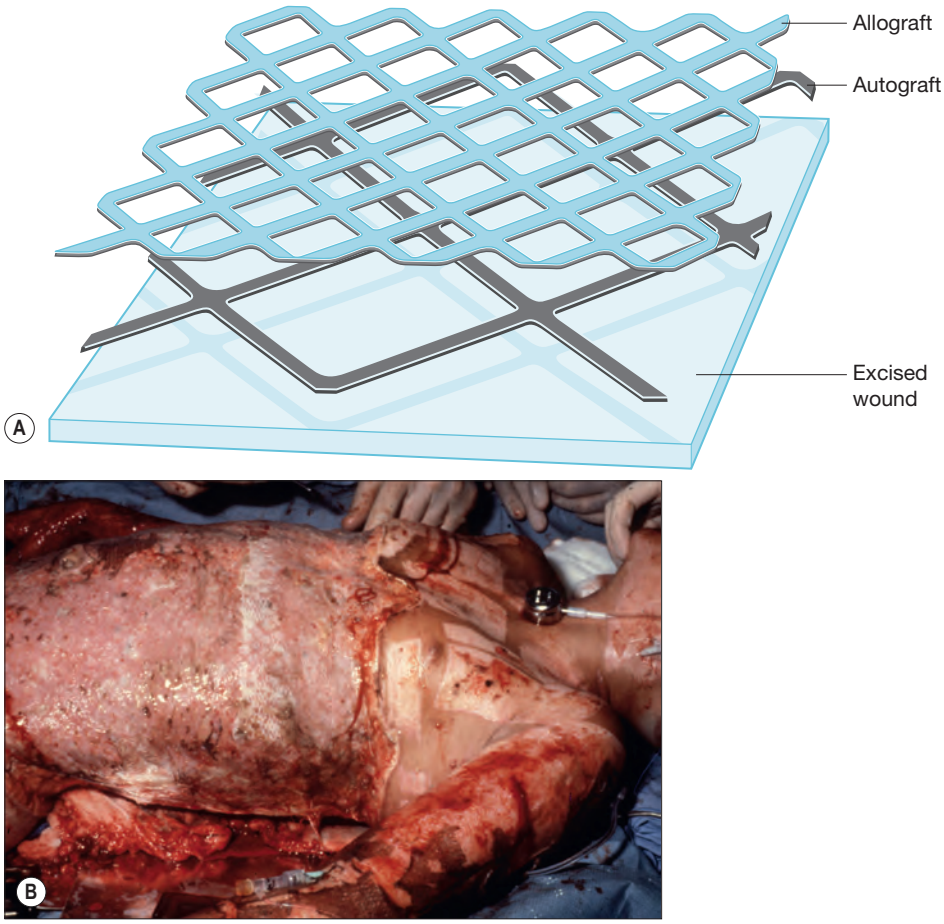

Fig. 12.7 (A) Schematic representation of "sandwich" technique of allograft overlay. (B) Sandwich technique on the chest of a boy with massive deep burn having a return surgery a week after sandwich grafting. Most of the (fresh) allograft has vascularized with one piece obviously whiter than the rest. The mesh pattern of the underlying widely meshed autograft is visible. (From Alexander JW, MacMillan BG, Law E, Kittur DS. Treatment of severe burns with widely meshed skin autograft and meshed skin allograft overlay. *J Trauma.* 1981 Jun; 21(6): 433–438.)

burns, the face, neck, and hands are still grafted with nonmeshed split-thickness skin graft due to the unacceptable outcome of using widely meshed skin grafts in these areas.

The Meek technique, which was later modified by Kreis et al., is another tool to cover extremely large burn surface areas.[36,37] It uses autografts cut into small squares with the aid of a dermatome and a cork board. The squares are then pressed onto prefolded pleated gauze that is expanded in all four directions, leaving uniformly distributed islands of autograft skin that are then applied to the wound bed. Ratios of expansion can vary from 3 : 1 to 9 : 1. This technique has similar disadvantages to 4 : 1 meshed autografts.

Advances in Wound Closure

DERMAL REPLACEMENT

The flexibility, elasticity, and strength of normal skin are provided mainly by the dermis. Excision of full-thickness burn removes the entire dermis, and the lack of the dermal layer prevents the healed skin from having the properties of normal skin. The use of dermal replacements in the treatment of burns can provide the highly desired characteristics of normal dermis. Integra is a dermal substitute composed of a porous matrix of cross-linked bovine collagen and glucosaminoglycans providing a scaffold for cellular invasion and capillary growth. It is applied to the wound bed following burn excision, and the matrix is fully incorporated into the wound bed in 2–3 weeks; then, thin split-thickness autograft skin is applied. Except for a possible increased risk of infections, the use of Integra is safe and effective.[38] Skin graft take is usually aided by the use of negative-pressure wound therapy such as VAC Therapy (Fig. 12.8).[39]

Another dermal analog available for the treatment of full-thickness burns is Alloderm, consisting of cadaveric dermis devoid of cells and epithelial elements. Its applications are similar to other dermal analogs, and it has shown favorable results.[40]

CULTURED EPIDERMAL AUTOGRAFTS

Cultured epidermal autografts (CEA) remain an important tool in the management of patients with massive burns. In full-thickness burns involving more than 90% TBSA, it may be the only treatment available, given that procurement of

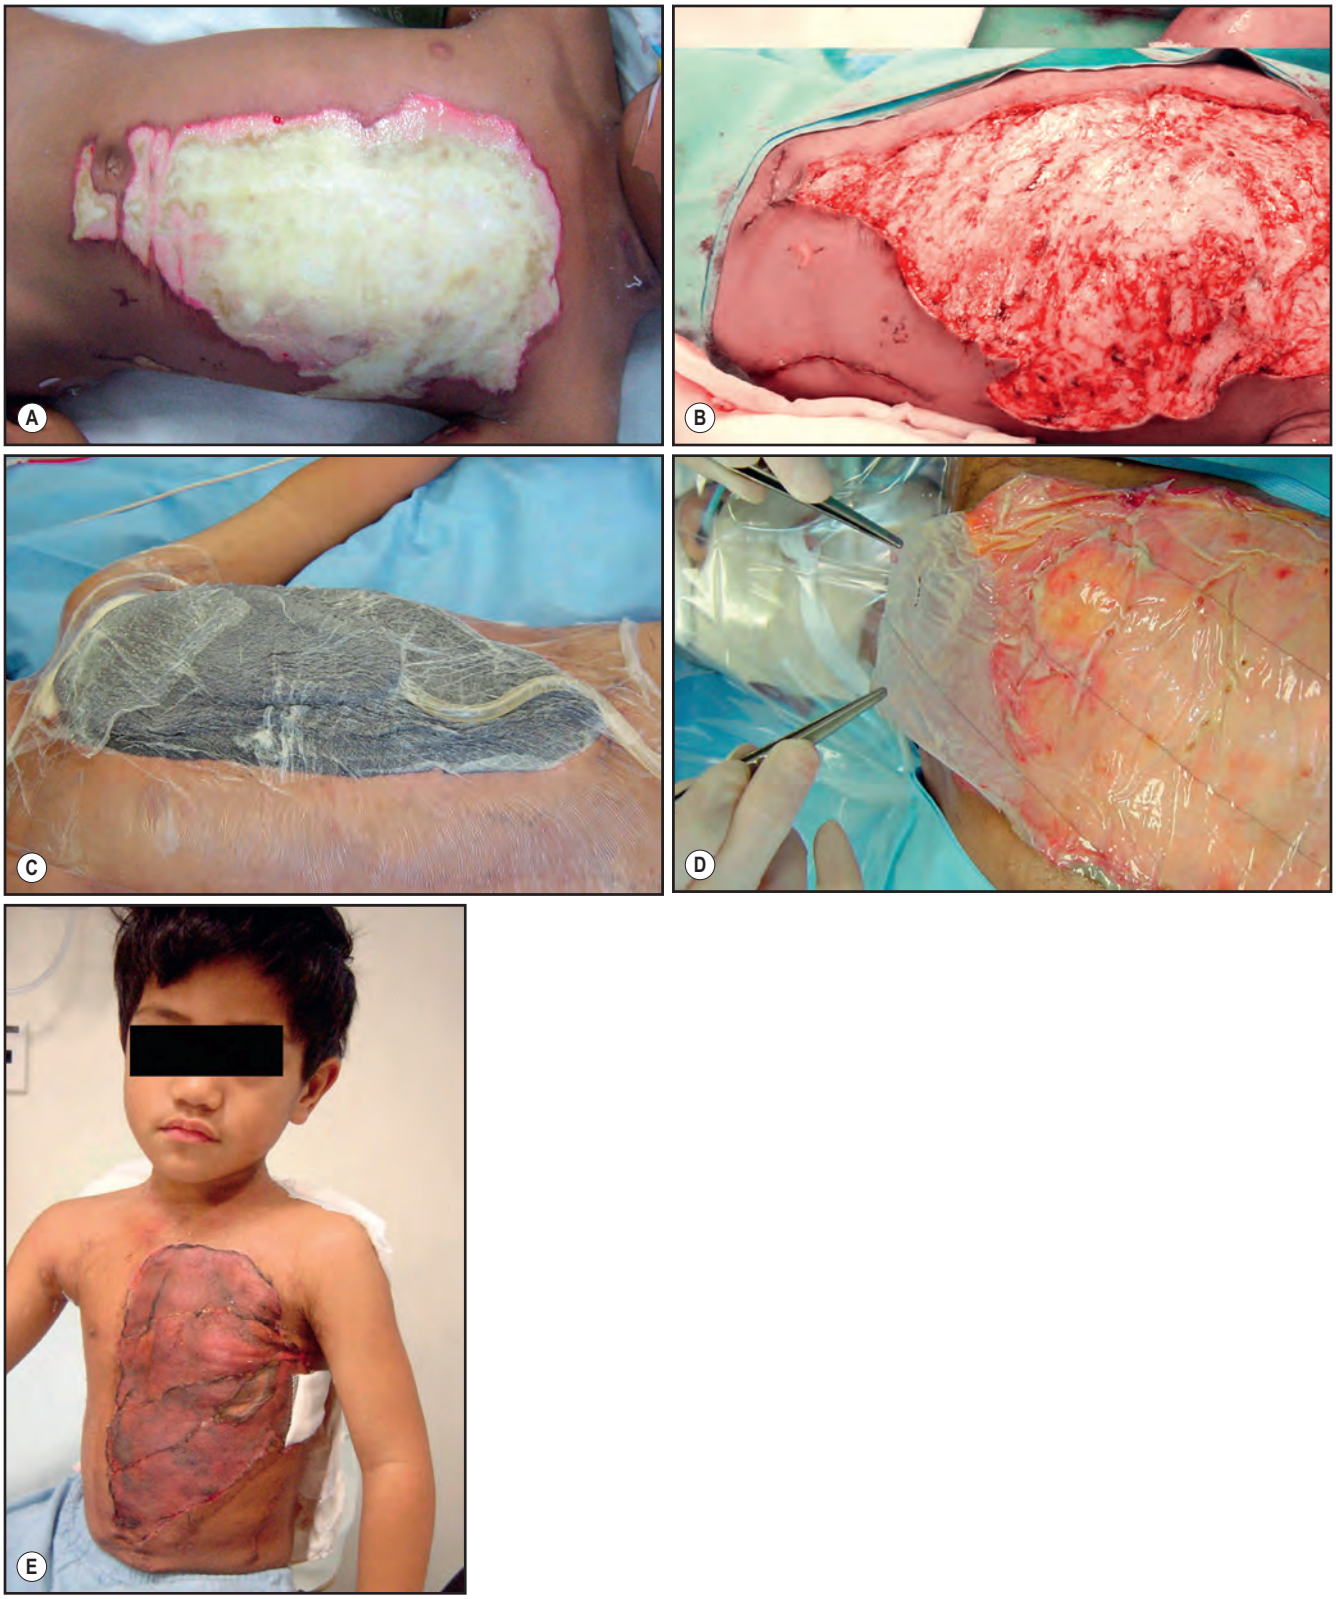

Fig. 12.8 (A–C) Deep flame burn on a boy's chest treated with early excision and Integra with VAC. (D) The silicone layer being removed on day 12 ready for thin grafting with well-vascularized dermal template underneath. (E) The pleasing final result.

the unburned skin will not be sufficient to cover the patient's wounds.

Munster has shown that the use of CEA in the massively burned patient reduced mortality.[41] CEA requires two 2 × 6-cm full-thickness unburned skin specimens. The skin is processed and cultured in vivo in the presence of murine fibroblasts to promote growth. The culture is expanded over a period of 3 weeks until thin sheets of keratinocytes, 2–8 cells thick, are available for grafting. Shearing and blistering are common problems for many months following application. The long-term survival of CEA in extensively burned patients has been reported at between 5% and 50% in the literature, and CEA applied to areas such as the back, buttocks, and posterior lower extremities are prone to shearing and graft loss. Barret et al. compared the use of CEA with widely meshed autograft skin and allograft skin overlay in a group of children with more than 90% TBSA.[42] Once healed, the CEA has a better cosmetic result than healed 4:1 meshed autograft skin but is associated with longer hospital length of stay and increased number of reconstructive procedures. Despite these limitations, including substantial cost, series from different burn centers have shown promising results when used in conjunction with allograft dermis. Sood et al. reported a graft take rate of greater than 72%.[43]

Tissue engineering technology is a rapidly advancing field where fetal skin constructs have been successfully introduced [44] and reproduced in vitro using genetic replication.[45] Bilaminar cultured skin substitutes showed promising results,[46] and, recently autologous engineered skin substitutes reduced mortality and requirements for donor skin in full-thickness burns of greater than 50% TBSA.[47]

SKIN PROCUREMENT

Many factors are considered when choosing the best donor site for skin grafting. Donor sites represent new wounds that would add significant morbidity to the patient; patients usually complain of more pain at the donor site compared to the burn wound or graft site. Whenever possible, skin grafts should be obtained from donor sites matching the color of the recipient area. The face and neck should be grafted with skin obtained from the area above the line of the nipple for the best color match. Thigh, hip, and back are commonly used as donor sites because the skin is flat for easy procurement, and scars are easily covered under clothing. The scalp may represent an ideal donor site because it is associated with less pain and faster healing, given the rich blood supply. The subsequent scar can be hidden after the regrowth of hair.

Good quality skin grafts of consistent depth are obtained using an electric or pneumatic-powered dermatome. The depth of the skin harvest can be precisely adjusted, with thickness usually between 0.006 and 0.018 inches.

Patients with extensive burns have few potential available donor sites. Anatomical regions that are usually spared and represent viable options for skin graft are the axilla, the mons pubis, and the scrotum. Given the irregular topography, tumescent fluid can be infiltrated to facilitate skin graft procurement.

In extensively burned patients, multiple operations are required to achieve complete wound coverage since donor sites are limited. A limiting factor to repeat grafting is the healing time of the donor sites. Donor site healing is a result of migration and proliferation of the epithelial cells from hair follicles, sweat glands, and sebaceous glands within the dermis. Early re-epithelialization after a week can allow reprocurement of thin split-thickness skin grafts from donor sites.

MANAGEMENT OF DONOR SITE

Careful management of the donor site is required to expedite wound healing. Smaller donor sites can be treated with occlusive or adherent dressings such as Opsite or Biobrane. Another technique is the use of alginate sheets or hydrocolloid dressings, which produce a moist environment that promotes healing and diminishing pain. The wounds can be also covered with gauze impregnated with an oil-based ointment. The most common examples are Xeroform or locally prepared dressing containing olive oil, petrolatum, lanolin, and the chemotactic agent "Sudan red." Silver-impregnated dressings such as Acticoat, Mepilex Ag, or Aquacel Ag seem to diminish bacterial overgrowth and can be used directly on the donor site. The healing time of donor sites depends on the depth of skin graft, vascularity of the donor site, wound management, and general condition of the patient.

DRESSINGS

After burn excision and skin grafting, the grafts are covered with nonadherent dressings. At our institution, gauze impregnated with a petrolatum-based ointment and a mixture of an antibacterial (Polymyxin/Bacitracin) and an antifungal (Mycostatin) is used. This is followed by the placement of a layer of fluff gauze and an elastic bandage. With areas of the body prone to shearing, such as the back and axilla, the application of a bolster dressing to protect the skin grafts can be beneficial. The application of negative-pressure wound therapy can also be useful in splinting and protecting the grafts. Dressings are usually removed on postoperative day 3. This time frame is normally sufficient to allow for adherence of the skin graft to the wound bed.

TEMPORARY SKIN SUBSTITUTES

Providing wound coverage with skin substitutes, even if it is temporary, has many advantages. Wound coverage prevents water and electrolyte losses as well as tissue desiccation, therefore maintaining a moist environment that allows faster epithelial cell migration and proliferation. Other benefits include reducing pain, creating a barrier to bacterial contamination, and preventing protein loss. Available temporary skin substitutes are either biological, such as allografts, xenografts, or amniotic membrane, or artificial, such as Biobrane.

Allografts remain an effective temporary burn wound coverage after excision if autograft skin is not available.[48] Allograft skin can be stored in a cryopreserved state for an extended period of time and become adherent and vascularized when applied to a viable wound bed. This process can also serve as a test for wound bed viability after burn excision, with immune rejection occurring

3–4 weeks after application. When allografts are used as a temporary coverage to the face and hands, they should be applied as sheet grafts. This prevents the formation of granulation tissue between the interstices, which can cause scarring and poor cosmetic outcome following definitive autografting.

Xenografts are another option for temporary wound coverage. Only porcine xenograft skin is currently available for clinical use.[49] Their main application is on partial-thickness burns following superficial debridement, as well as on donor sites. As with allografts, xenografts become adherent and provide the benefits of temporary wound coverage, such as pain control, while the underlying wound re-epithelializes, but the xenograft does not vascularize.

Amniotic membrane can also be used to provide temporary coverage to superficial burns. Given its flexibility and pliability, amniotic membrane is useful for application on irregular surfaces such as the face. Despite not reducing healing time or scarring, it provides some of the benefits of wound coverage and reduces the number of dressing changes required until healing is achieved.[50]

Management of Specific Types of Burns

SCALD BURNS

Small or moderate size scald burns have been shown to be the exception to the general rule of early excision. Young children who had scald burns up to 20% TBSA required less area to be excised and had smaller blood loss if operated on in the second or third week post burn.[51]

A subsequent prospective trial randomized 24 children to early or late excision if their scald burn was of clinically indeterminate depth.[52] There was no significant wound infection or sepsis resulting from late excision. Only half of the delayed excision group ultimately required surgical intervention, and a significantly smaller area of excision was necessary.

In light of the previous evidence, children with scald burns of less than 20% TBSA can be appropriately treated with a topical antimicrobial such as silver sulfadiazine for about 2 weeks. This approach needs to be balanced with the knowledge that the longer a wound remains open, the greater the inflammatory response and subsequent scar formation. A number of techniques are available to cover the partial-thickness burn. When successful, they have the advantage of reducing the pain associated with frequent dressing changes. Biobrane is a useful dressing for smaller and more superficial wounds.[53]

At the time of the first wound dressing application, all loose skin and blisters are removed to leave a clean, moist surface. Biobrane is a nylon/silicone bilaminated composite skin substitute that becomes adherent to the exposed dermis, thereby acting as a neo-epidermis. Lal et al. reported no increase in infection rates using Biobrane.[54] Infections occur rarely as a result of nonadherence and accumulation of fluid. Other alternatives include the use of silver-impregnated dressings such as Acticoat, allografts, and xenografts.

EXTENSIVE BURNS

Patients with burns of greater than 40% TBSA pose unique challenges with increased demands for donor sites, which are of limited availability. Ideally, near-total excision should be completed as soon as possible in the first few days following injury, definitely within a week. The back, buttocks, and posterior thighs are covered with autograft skin taken at thickness between 0.008 and 0.010 inch and meshed at an expansion ratio of 4:1. Allografts are the best option to apply as an overlay to protect widely meshed autografts.

Consideration needs to be given to the use of dermal replacement therapies (e.g., Integra). Dermal replacements are an expensive option but produce good results in relation to scarring. Integra is a bilaminar composite that has a neo-dermis of bovine collagen held in a matrix pattern of shark cartilage chondroitin-6-sulfate. A layer of rubberized silicone is press sealed as a top layer. The abdomen, anterior thigh, forearm, leg, and male chest are sites where Integra can be easily applied (Fig. 12.9).

. The neo-dermis is vascularized from the underlying wound bed, and the process takes 2–3 weeks to complete. The neo-dermis often develops a pink or plum color due to staining of the matrix during the vascularization process. If hematoma or seroma develops, it can be aspirated with a 27-gauge needle, or the overlying Integra is incised, the hematoma removed, and the edges are stapled down.

The neo-dermis is "ready" or adequately vascularized when it has a straw color. Close inspection under magnification will reveal widespread telangiectasia. The second-stage operation involves gentle removal of the silicone layer and application of 0.006-inch autograft skin, which can be meshed up to an expansion ratio of 3 :1. CEA has been used as epidermal cover for vascularized Integra neo-dermis.[55]

Debate continues regarding the role of Integra in wound coverage of patients with burns of greater than 70% TBSA. The incidence of failure due to infection rises dramatically as the burn size approaches greater than 75% TBSA. The first priority remains excision of all the burn wounds, wound coverage with autografts, and application of allografts to the remaining areas, with a return to the operating room planned once used donor sites are healed.

The Operating Room

The burn operating room is usually an extension of the burn intensive care unit. Large, heated, humid, and well-lit rooms are ideal for burn surgery. The procedures are long, intense, and require multiple individual setups for different types of equipment and instrumentation.

A very important perioperative issue for safe management of a patient undergoing extensive burn excision is the maintenance of body temperature. The patient is usually completely exposed with little intact skin, particularly after procurement of donor skin, leading to rapid heat loss. A number of strategies can be used to counteract heat loss and maintain normothermia. The operating room should be warmed to 32°C, since the latent heat of water evaporation is 31.5°C. Above this temperature, the energy source for evaporation will come from the environment rather than the patient. Radiant heaters are useful in perioperative thermoregulation. Other adjunctive measures include the use of space blankets, aluminum foil coverings, plastic

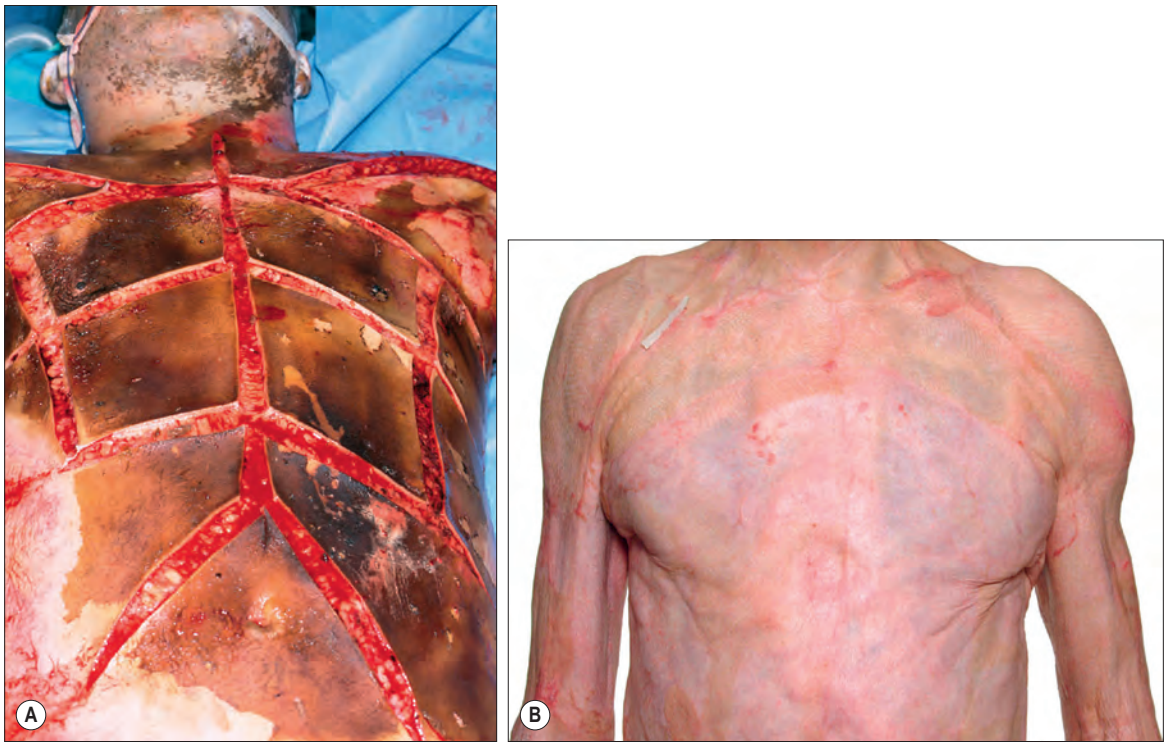

Fig. 12 9 (A,B) High-voltage electrical flash burn treated by fascial excision and Integra. Flat anterior surfaces are particularly amenable to use of Integra.

sheets over the head and face, and heated intravenous fluids at 38°C. Repeated applications of warm sterile blankets, forced air warming systems, warm irrigation fluids, and active heating via either infrared or ceramic heaters have also been used.

The ideal operating room environment should allow only minimal evaporative loss from the patient. Reliable vascular access is required, and the central access lines should be sutured securely to prevent dislodgment during patient positioning.

The Operation

At our institution, excision commences with the patient in the prone position, during which excision of the shoulders, back, buttocks, and upper thighs is performed. Wide-meshed autografts with allograft overlay are applied. If insufficient autografts are available, the excised wound is covered with allografts. Other alternatives include skin substitutes such as Integra, xenografts, or allografts. Dermal replacement materials are prone to failure due to increased rates of infection in extensive burns, particularly on dorsal surfaces, but can be applied selectively on ventral surfaces. Sutures are inserted in a row along the posterior axillary lines and tied over the bulky gauze dressing as a bolster to prevent shearing of skin grafts on the back and buttocks. The patient is then placed in the supine position

As soon as donor sites are healed, patients return to the operating room for further autografting and replacement of nonadherent allografts or infected skin substitutes. In children with considerably extensive burns, treatment with recombinant human growth hormone (GH) demonstrated donor site wound healing was accelerated by 25%. GH-treated patients required less infused albumin to maintain normal serum levels, and this was an indication of the net positive protein balance.[56] The usual hospital length of stay of 42 days for a 30 kg patient with a 60% TBSA burn was reduced to 32 days. This remarkable decrease in length of hospital stay produced a net saving of 15% in total hospital costs, and mortality was reduced from 45% to 8%.[57] Although it must be acknowledged that two European studies in critically ill adults of mixed etiology showed increased mortality among the GH-treated groups, this experience has not been repeated in the extensively burned pediatric population in North America.[58] Other anabolic agents have shown promise as a means of stimulating wound healing in severely injured catabolic burn patients.[59] Oxandrolone 20 mg/day has demonstrated a positive effect on protein kinetics and wound healing in clinical trials.[60,61] In oxandrolone-treated severely burned adults, donor site healing was accelerated by 20% compared to nontreated patients.[59] Although these pharmacological agents provide great support to the extensively burned patient, they are only an adjunct to early near-total excision and prompt wound coverage.

Operative Management of Burns Involving Special Areas

THE HAND

Survival after serious burns has improved dramatically over the past 30 years; however despite generally satisfactory long-term quality of life, many patients will have significant physical disabilities. Many of these disabilities can be traced to compromised hand function following severe burn

injuries. If optimal function is to be restored after extensive burn injuries, proper care of the injured hand is essential. These early efforts should be directed at preservation of tissue, maintenance of normal hand anatomy, and development of a strategy for wound closure.

Escharotomy and Fasciotomy

A critical part of the initial care of hand burn is to maintain soft tissue perfusion in the acute phase following the burn injury. Decompression of high compartment pressure caused by burned skin and tissue edema is an area in which early surgical intervention can produce a remarkable difference to the final outcome of hand function. Hands at risk of ischemia include circumferential or near-circumferential burns, very deep burns, and any electrical injuries involving high- or intermediate-range voltage. It is important to elicit clinical signs of ischemia subtler than the loss of palpable pulse at the wrist. Mean arterial pressure in the central vascular system is three times higher than capillary pressure, and blood flow can be maintained in these vessels despite impaired flow in distal soft tissues. If the hand is warm, soft, and has pulsatile flow detectable by Doppler in the palmar arch and the digital vessels, and it has a normal pulse oximetry signal at the tip of the digit, then flow is adequate. As flow becomes progressively impaired, the hand will become firm and cold, with decreased Doppler flow and loss of the pulse oximetry signal. Decompression should be performed to prevent otherwise avoidable ischemic injury as a result of compartment syndrome. Pressure measurement confirmation is generally not required if serial examinations suggest diminished tissue perfusion.

Escharotomy should be performed using electrocautery. Longitudinally oriented medial and lateral incisions are made through eschar on the arm and forearm, stopping at the metacarpophalangeal joints of the first and fifth digits (Fig. 12.10A).

The hand is then re-examined for perfusion prior to performing hand and digital escharotomies. If blood flow is restored adequately following arm and forearm decompression, additional escharotomy may be unnecessary.

The efficacy and safety of digital escharotomies are debatable. One study demonstrated a reduced incidence of amputation if digital escharotomies were performed on circumferentially burned digits.[62] However, particularly in small children, improperly performed digital escharotomies can result in significant injury, and therefore caution must be used. When digital perfusion remains inadequate despite decompression of the arm, forearm, and hand, escharotomies of full-thickness burns of the digits should be performed. Longitudinal incisions are carefully made with pinpoint electrocautery mid-laterally between the neurovascular bundle and the dorsal extensors, avoiding both structures. A single longitudinal incision is made on the radial aspects of the thumb and little finger and the ulnar aspects of the digits. This places the incisions on the side of the digit with the least functional importance should the digital nerve be exposed by separation of edematous tissue after escharotomy. The central digital incision can be extended proximally onto the dorsum of the hand between the metacarpals to enhance decompression (Fig. 12.10B).

The line of incision along a given digit can be found by putting the fingers in maximal flexion, marking the lateral extensions of the flexor wrinkles and completing them to a continuous line (Fig. 12.10C).[63] Meticulous hemostasis is maintained throughout the procedure, and the outcome of decompression is confirmed using Doppler.

Escharotomy can generally be performed at the bedside or in the emergency department under moderate sedation supplemented with sub-eschar injections of local anesthetic. Some patients will require general anesthesia in the operating room for the procedure to be performed appropriately.

Fasciotomy might be required for edema developing within the fascial compartments of the forearm and hand. Clinically this is often seen following high-voltage electrical injuries or exceptionally deep thermal injuries. Upper extremity fasciotomy may include volar and dorsal decompression, carpal tunnel release, and dorsal hand fasciotomy. A curvilinear incision is ideal for volar exposure of the compartments of the forearm. This approach allows access to all individual muscle bundles in the volar forearm. It also allows decompression of the carpal tunnel through a palmar extension of the incision, and creates a well-vascularized skin flap to cover the median nerve at the wrist

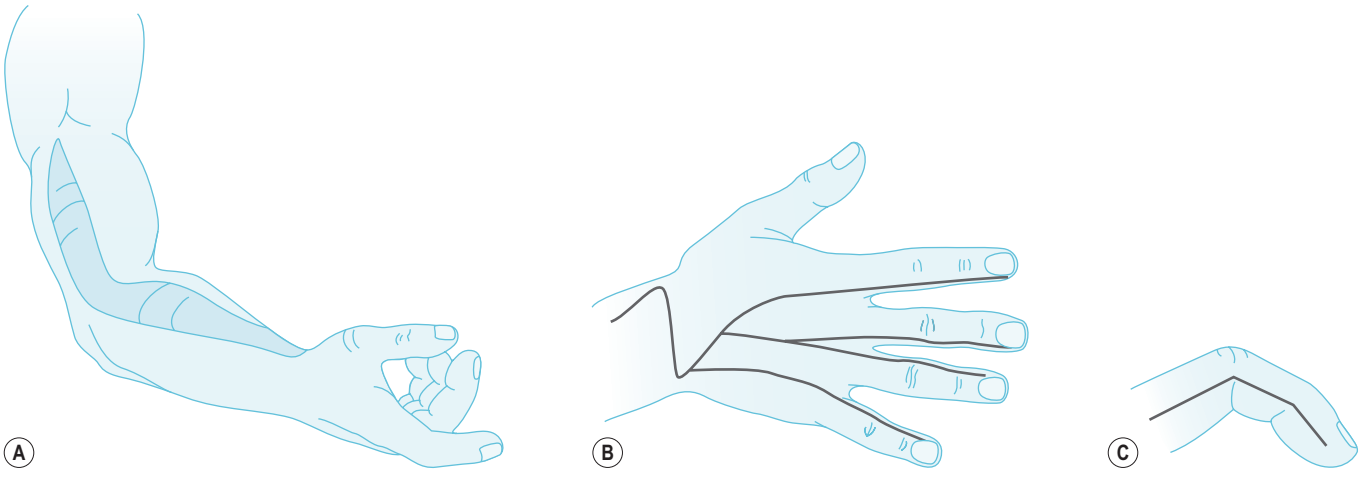

Fig. 12.10 (A) Arm escharotomy. (B) Hand escharotomy. (C) Finger escharotomy. (From fig. 61.6ABC in Green DP, Pederson WC, Hotchkiss RN, et al. ed. *Green's operative hand surgery*, Philadelphia: Elsevier/Churchill Livingstone; 2005:2164.)

upon completion of the fasciotomy. When needed, straight linear incisions are adequate for decompression of the dorsal aspect of the forearm, and inter-metacarpal incisions on the hand allow decompression of the intrinsic muscles of the hand.

Techniques of Excision and Grafting

It has become increasingly clear that allowing hand injuries to heal by secondary intention over the course of many weeks produces poor long-term aesthetic and functional results.[64] Usually surgery is indicated for any deep dermal or full-thickness hand burn that will not promptly heal within 3 weeks. This need is apparent to an experienced examiner within 5 days of the injury (Fig. 12.11).

The skin on the dorsum of the hand is much thinner than the palmar skin. There is a general consensus that earlier surgery is associated with a better functional outcome and a reduced need for reconstructive procedures in the future.

Different options for wound coverage include split-thickness autografts, full-thickness autografts, and groin or abdominal flaps. Split-thickness nonmeshed autograft is the optimal coverage for most hand burns. Full-thickness grafts are ideally reserved for palmar surface burns, particularly deep wounds of limited extent, or for reconstructive operations. Groin and abdominal flaps can be useful when managing isolated injuries with exposed tendons without paratenon, exposed bone without periosteum, or exposed neurovascular bundles.

Deep partial and full-thickness hand burns generally require tangential excision and autografting. These procedures are ideally performed under a pneumatic tourniquet to reduce blood loss, and tangential excision is performed until a bed of viable tissue is encountered. Viability is recognized by the appearance of a pearly white moist dermis, punctate bleeding, or the presence of bright yellow subcutaneous fat without thrombosed small vessels or extravascular blood staining. Recognition of viable tissue in an exsanguinated extremity under tourniquet is an acquired skill that greatly facilitates low-blood-loss excisions.

The hand is then wrapped in epinephrine-soaked gauze prior to deflation of the pneumatic tourniquet. After 5–10 min to allow for spontaneous hemostasis, definitive hemostasis is secured with careful use of pinpoint electrocautery. The hand is covered with sheet autograft skin. Finally grafted hands are covered with a gentle compressive gauze wrap and placed in a thermoplastic splint in position of function. Hands are elevated and immobilized for 3–4 days prior to reinstituting passive and active hand therapy.

Only about 15% of palmar burns require grafting. Because the palmar skin is much thicker than the dorsal skin, it is not uncommon to wait for 2–3 weeks before a decision to graft is made. Palmar burns that require skin grafting are usually covered with thick, split-thickness sheet autografts if the defect is large, and full-thickness autografts if the defect is small. In deep palmar burn injuries with loss of range of motion, the hand is splinted with metacarpophalangeal joints (MCPJ) in extension, both during topical care of the burn and following surgery. Skin grafts from the instep area have been advocated for aesthetic reasons, but functional results with full-thickness or thick split-thickness grafts are generally acceptable.

Fig. 12.11 Deep dermal burn of the dorsal hand that underwent excision and grafting. (A) Post-burn day 7. (B) 6 weeks post injury.

Hands are splinted in the position of function: the MCPJ at 70–90 degrees of flexion, the interphalangeal joints (IPJ) in extension, the wrist in 20 degrees of extension, and the thumb in palmar abduction and external rotation. Special attention should be given to the position of the fifth digit because it is particularly prone to flexion contractures resulting in fixed IPJ flexion. In the hand, failure of early wound closure may compromise the ability to participate in early physical therapy and possibly compromise long-term outcomes.

If the extensor mechanism is compromised by direct injury or subsequent desiccation and rupture, the dorsal collateral bands migrate volarly, and the proximal interphalangeal joint (PIPJ) develops a flexion contracture from which recovery might be impossible. In some cases, this unfortunate sequence of events can be prevented by ensuring prompt coverage of the PIPJ. If the depth of injury compromises the extensor mechanism, splinting in extension and inserting axial Kirschner wire (K wires) across the joint for 2–3 weeks may facilitate healing with improved stability. If the overlying extensor mechanism is damaged in an open PIPJ, a partially functional joint can sometimes be salvaged by K-wire fixation for 2–3 weeks, which may allow granulation tissue to bridge the open joint; this can subsequently be skin-grafted.

Techniques to Salvage Length in Fourth-Degree Hand Burns

In the presence of fourth-degree burns involving the underlying extensor mechanism, joint capsule, and bone, management can be more complex with less satisfactory outcomes. Patients with small surface area burns are candidates for early debridement with groin or abdominal flap coverage (Fig. 12.12).[65]

A common pattern is deep dorsal burn with exposure of the proximal interphalangeal joints, and dorsal phalanges with viable volar tissue. If these wounds are kept moist and

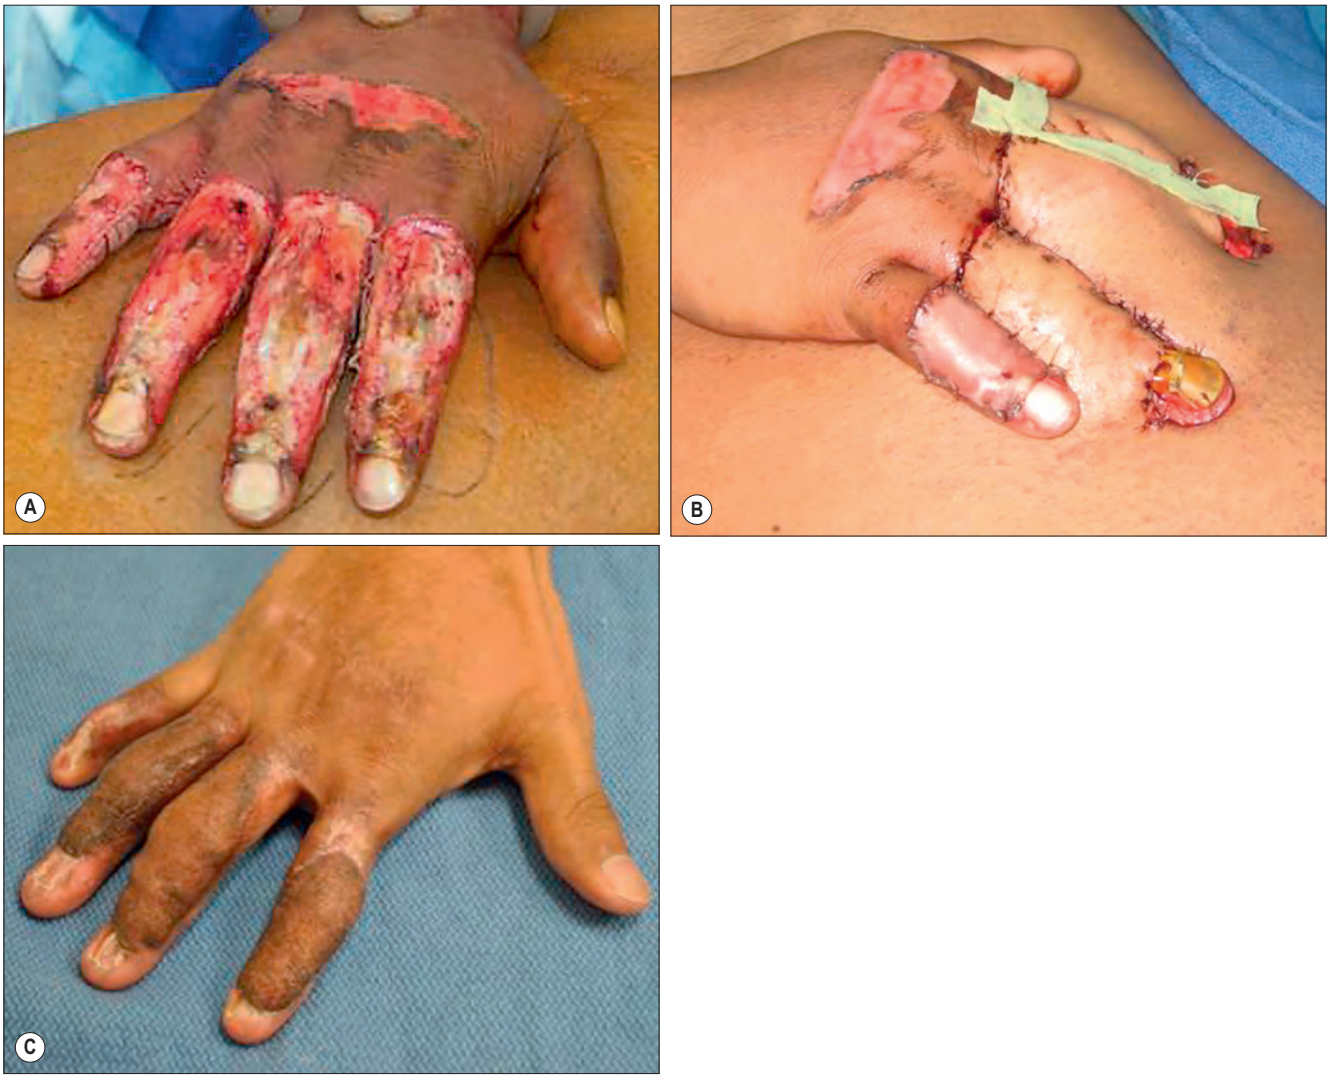

Fig. 12.12 Abdominal flap coverage of fourth-degree dorsal finger burns. (A) Deep dorsal burns and intraoperative positioning of the hand on the abdomen. (B) Flaps in position. (C) Final result.

clean, with position of function maintained, often the avascular tissue will granulate and can be skin grafted with an acceptable result.

When the extensor mechanism is exposed, maintaining the position of function during granulation tissue formation is critical to the final outcome. Granulation tissue formation may be facilitated by meticulously debriding remnants of burned cortical bone. Positioning may not be reliable when only splints are used, therefore K-wire insertion can be helpful to maintain the IPJ position while metacarpophalangeal joint flexion is maintained with the splints. Wires are passed axially from the tip of the finger proximally, stopping when the PIPJ is immobilized. Autografting is performed whenever possible, and exposed joints and bones are allowed to granulate and subsequently are covered with autograft skin (Fig. 12.13). Joints that remain unstable following coverage are fused by open arthrodesis at a later stage.

Fig. 12.13 Preservation of digital length in fourth-degree dorsal burn of the hand in a 9-year-old boy with 85% TBSA burn. (A) Day 7 post-burn. (B) Day 12 post-burn. (C) Day 61 post-burn.

THE SCALP

Scalp and skull burns are a major challenge due to the location of these injuries representing a complex wound with the possibility of injury to underlying structures. These injuries can be classified into two groups: injuries limited to soft tissue and injuries that involve the calvarium. Surgical management of the burned scalp can vary from simple soft tissue debridement and skin grafting to management of complicated calvarial bone injury.

Scalp burns without bony involvement are treated similarly to any other burn, with debridement and skin grafts or flap coverage.[66] There are several classifications for scalp burn wounds based on the depth and extent of the injury. Calvarial burn that does not involve the inner table can be managed by careful burring and skin grafting. The use of a fine diamond-tipped drill allows controlled layer-by-layer removal of nonviable bone without risking penetration into the intracranial cavity. Complex defects involving full-thickness bone loss with exposure of the dura will require reconstruction using local, regional, or free flaps.

The use of bone grafts or tissue expanders is deferred until after the acute burn phase. The priority is wound debridement and adequate coverage without compromising the underlying tissues. Surgical debridement includes the removal of necrotic soft tissue and bone, avoiding injury to the dura. Surgical excision stops at a viable layer to apply a skin graft.

Central nervous system infections are a possible complication, and antibiotic prophylaxis should be considered prior to the procedure.

THE FACE

Burns to the face can have potentially devastating consequences to the patient and can adversely impact the patient's return to premorbid activity. Attention to details, adequate excision, wound coverage and postoperative management are essential in the preservation of vital functions and cosmesis.[67] Facial burns can involve injuries to vital structures such as the upper airway and sensory organs such as the eyes and ears.

There have been no large randomized outcome trials comparing early excision and grafting of the face compared to grafting after eschar separation and granulation tissue formation. Most authors have applied the general principle of early excision to prevent contractures and provide the best aesthetic outcome, with a suggested maximal waiting period of 18 days.[68]

Once a decision has been made to proceed with excision and grafting, site and thickness of donor skin need careful consideration. If possible, the donor skin should be procured from the area above the line of the nipples for the best color match. Skin grafts from the scalp provide excellent color match but carry a risk of follicle transplantation if taken too deeply and subsequent hair growth of the recipient site and alopecia of donor site. An alternative site is the upper back.

Excision of facial burns can be performed using various methods; the mainstay of excision remains use of the Goulian/Weck knife. If there are any doubts regarding the depth of the burn, tangential excision using a Goulian knife is more appropriate to preserve viable dermis, which is essential for optimal results (Fig. 12.14).

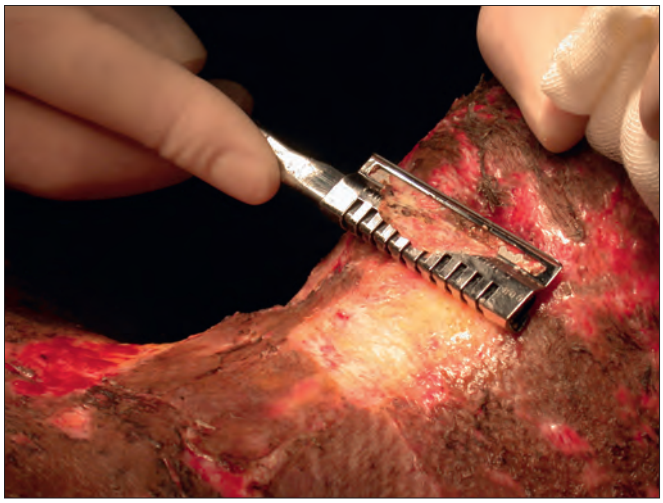

Fig. 12.14 Tangential excision being applied with a Goulian knife to the chin. Previous grafting had been largely successful. The instrument is useful for small and tricky areas.

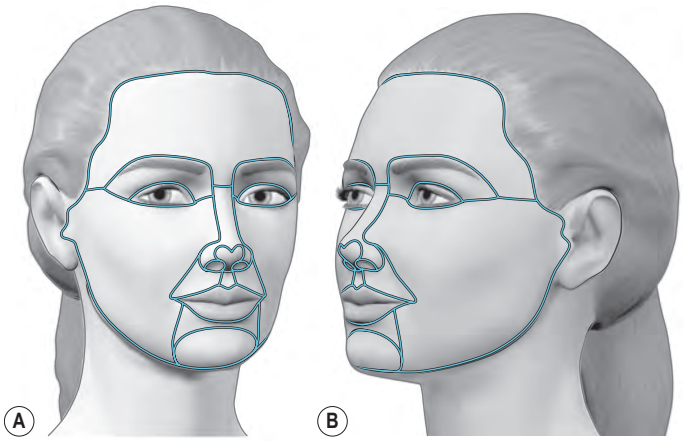

Fig. 12.15 Aesthetic units of the face. (A) Frontal view. (B) Lateral view. (From McCauley RL, Obeng MK. Reconstruction of cheek deformities. In: McCauley RL, ed., *Functional and aesthetic reconstruction of burned patients*. Boca Raton, FL: Taylor and Francis Group; 2005: 270.)

Previously described "water dissectors" such as the Versajet Hydrosurgery System can also be used in areas of contour for more controlled and precise excision, thus avoiding potential injuries to viable deeper layers.

Owing to the rich capillary networks in the face, large amounts of blood may be lost at the time of the excision. Epinephrine clysis is an appropriate pre-emptive measure to reduce blood loss during facial excision.[69,70] Epinephrine-moistened topical sponges are helpful, and electrocautery can be useful for accurate hemostasis.

Placement of skin grafts on the face should be carried out with respect to aesthetic units, where sheet autografts are placed to reconstruct an entire aesthetic unit. For aesthetic purposes the face is divided into cosmetic units (Fig. 12.15),[71] and the periorbital, nasal, and upper cheek areas

are grafted as a single aesthetic unit.[71] Grafts should be taken as widely as possible to reduce the number of seams between the grafts, then secured with sutures, glues, or fibrin sealant.

The use of fibrin sealant, a hemostatic adjunct and adhesive underlay, has been shown in studies to reduce seroma and hematoma formation as well as minimize the need for staples or sutures, producing equal or better outcome.[72] Medical-grade glue such as 2-cyano-butyl acrylate (Histoacryl) can be used to secure the edges of skin grafts.

Once the skin grafts are secured in place, tubes and lines should be positioned appropriately to avoid disruption of the grafts. Nasal septal ties can be used to secure the endotracheal tube and avoid facial ties that can disrupt the skin grafts.

Sheet grafts on the face should be evaluated frequently for fluid collection or hematoma, which can be drained with a small-gauge needle. Some centers delay autografting the face to reduce graft loss from hematoma formation. Temporary wound coverage with allografts remains a good option until definitive coverage.[73]

In areas of extensive soft tissue injury with no underlying bony injuries, such as the buccal area, acute reconstruction with regional or free tissue transfer can be considered. If the maxillary sinuses are exposed, the dead space may be filled using free vascularized omental transfers, as described in cases of facial trauma.[74]

EYELIDS

Deep burns to the eyelids should be excised and grafted early because they can result in cicatricial ectropion, leading to lagophthalmos, exposure keratitis, corneal ulceration, and, ultimately, perforation leading to blindness.[75] Post-burn cicatricial ectropion is a serious complication, with unconscious ventilated patients at particular risk. Release of burn scars and full-thickness skin grafts to the lower eyelids and split-thickness skin grafts to the upper lids should be undertaken as soon as the condition is diagnosed.[76]

Ophthalmic lubricant drops and ointments should be applied frequently to keep the eyes moist to avoid exposure keratitis, especially in unconscious patients. If post-burn ectropion develops, early tarsorrhaphy or release of the contracted eyelids may be necessary.

Tarsorrhaphy can be carried out at the bedside under local anesthesia. A U-stitch is placed using a fine nonabsorbable suture at the lid margin, anterior to the gray line to avoid corneal irritation. The upper and lower eyelids are approximated at their lateral and/or medial portions. Lateral tarsorrhaphy is more commonly used. The suture should be secured through material such as a rubber pledget to prevent the suture from being pulled through skin. The suture should incorporate the ridge of tarsus but not traverse it, and an adequate tarsorrhaphy will permit the passive closure of the eyelids to protect the cornea.

Upper and lower eyelid releases can be carried out using local flaps, full-thickness skin grafts, or split-thickness skin grafts. Full-thickness eyelid defects require layered reconstruction using hard palate mucosa or acellular dermis as the inner lamella and split skin grafts or local skin flaps as the outer lamella.[77]

GENITAL BURNS

Genital burns can produce significant morbidity and long-term consequences for mobility, urine elimination, and sexual function. Spontaneous epithelialization will likely occur with scald burns in this region owing to the rich supply of hair follicles and skin appendages.

Recommendations for acute management include selective urethral catheterization to allow urine collection and urethral stenting in the case of circumferential constricting burns.

Most partial-thickness burns of the scrotum will heal spontaneously because scrotal skin is thick and contains multiple hair follicles. Testicular function should be evaluated by measuring stimulated testosterone levels if testicular injury is suspected.[78]

Small full-thickness burns to the scrotum can be excised and closed primarily, and large full-thickness burns will require skin grafting. Along the shaft of the penis, full-thickness burns are excised using Goulian knife or Versajet and grafted using unmeshed split-thickness skin grafts. Full-thickness burns involving foreskin can be managed with circumcision because phimosis is a common sequela.

Scald burns to the genitalia are best managed conservatively because they are usually partial thickness and heal with acceptable outcomes. Deep burns to the glans penis may be allowed to demarcate and proceed to eschar separation, then the underlying granulation tissue is skin grafted later. Full-thickness burns to the labia majora should be excised and grafted as a delayed procedure to avoid scar contractures in the long term.

Perianal burns are seen in association with extensive burns in adults and in children with scald burns. Early excision and grafting is recommended to prevent bacterial colonization and infection from fecal contamination. Some centers recommend bowel diversion to aid healing and graft take.[79] If skin graft failure occurs, it is important to try regrafting because prolonged healing time by secondary intention can cause perianal circular contractures.

THE BREAST

The scarring and disfigurement associated with breast burns can be a source of significant psychological stress in developing girls and young women.[80] All efforts should be made to preserve the breast bud in prepubescent girls and the breast mound in a postpubertal women. Small burns, especially linear ones, may be excised and closed primarily or allowed to form scar and later excised.

The nipple-areola complex, especially in women, requires particular attention; it is best left un-excised because healing can occur from the deep glandular structures that are usually preserved.

Conclusion

One of the most important components of modern burn care is early operative wound management. The available evidence is clear that prompt burn wound excision and closure is lifesaving for massively burned patients. Skin substitutes and dermal replacement have made operative

wound care even more accessible in terms of providing temporary wound coverage. This offers an alternative to topical antimicrobial therapy and conservative management for full-thickness wounds.

Introduction

Continuous improvement in burn care since World War II has resulted in a steady increase in the rate of survival after large burn injury.[1] These improvements have been attributed to aggressive fluid resuscitation, early excision and grafting of burn wounds, more effective antimicrobials, advances in nutritional support, and development of burn centers. Today most patients with more than 80% total body surface area (TBSA) burned will survive if promptly treated in a modern burn unit with adequate resources. In their study of risk factors for death following burn injuries Ryan et al. identified three variables that can be used to estimate the probability of death: age greater than 60 years, burns of more than 40% TBSA, and the presence of inhalation injury.[2] Mortality increased in proportion to the number of risk factors present: 0.3%, 3%, 33%, or approximately 90% mortality depending on whether zero, one, two, or three risk factors were present, respectively. The incidence of mortality is also influenced by significant coexisting disease or delays in resuscitation. O'Keefe et al. observed an approximately twofold higher death risk of death in women aged 30–59 years compared with men with similar burns and age.[3] Although it has been assumed that very young children are also at increased risk of death from burn injuries, Sheridan et al. found very low rates of mortality in children younger than 48 months who had suffered large burns.[4] One group that has not benefited as much from advances in burn care is the elderly. The morbidity and mortality (as expressed as lethal dose 50 for burns) associated with serious burns in elderly patients has not improved over the past three decades.[5] Some burn patients develop refractory burn shock soon after injury and cannot be resuscitated.[6]

Major burn injury results in pathophysiological changes in virtually all organ systems. Box 13.1 lists and Figs. 13.1 and 13.2 illustrate some of the challenges presented by the acutely burned patient during the perioperative period. In addition to the predictable challenges relating to airway management, monitoring, and vascular access, patient positioning requires close communication and teamwork. Burns involving posterior areas may require turning the patient to the prone position for optimal access (Fig. 13.1). Vascular catheters and the endotracheal tube must be secured with confidence and due care given to these life lines during patient turning. Several highly informative reviews of anesthetic management for burn surgery have been written during the past decade, each with its own special areas of concentration.[7–10]

Patients suffering burn injuries often require surgical treatment for years after the initial injury in order to correct functional and cosmetic sequelae. Anesthetic management for reconstructive burn surgery presents many special problems[11] but this chapter will concentrate on the care of acute burn patients. The acute phase of burn injury is defined as the period from injury until the wounds have been excised, grafted, and healed.

Modern burn care depends on coordination of a multidisciplinary team including surgeons, intensivists, nurse clinicians, nutritionists, rehabilitation therapists, pulmonary care therapists, and anesthesia providers. Rational and effective anesthetic management of acute burn patients requires an understanding of this multidisciplinary approach so that perioperative care is compatible with the overall treatment goals for the patient. The current standard of surgical treatment calls for early excision and grafting of nonviable burn wounds, which may harbor pathogens and produce inflammatory mediators with systemic effects resulting in cardiopulmonary compromise. After an extensive burn injury, the systemic effects of inflammatory mediators on metabolism and cardiopulmonary function reduce physiological reserve, and the patient's tolerance to the stress of surgery deteriorates with time. Assuming adequate resuscitation, extensive surgery is best tolerated soon after injury, when the patient is most fit. However it must be recognized that the initial resuscitation of patients with large burns results in large fluid shifts and may be associated with hemodynamic instability and respiratory insufficiency. Reynolds et al. reported that more than half of deaths after burn injuries occur due to failed resuscitation.[6]

Effective anesthetic management of patients with extensive burn injuries requires an understanding of the pathophysiological changes associated with large burns and careful preoperative evaluation to assure that resuscitation has been optimized and an appropriate anesthetic plan has been formulated.

Preoperative Evaluation

The preoperative evaluation of burn patients requires knowledge of the continuum of pathophysiological changes that occur in these patients from the initial period after injury through the time that all wounds have healed. The dramatic changes that occur in all organ systems following burn injury directly affect anesthetic management. The following discussion will describe the pathophysiological changes that occur in the acutely burned patient as they relate to the preoperative evaluation. In addition to the routine features of the preoperative evaluation, evaluation of acute burn patients requires special attention to airway

Box 13.1 Perioperative Challenges in the Acute Burn Patient

- Compromised airway
- Pulmonary insufficiency
- Altered mental status
- Associated injuries
- Limited vascular access
- Rapid blood loss
- Impaired tissue perfusion due to:
- Hypovolemia
- Decreased myocardial contractility
- Anemia
- Decreased colloid osmotic pressure
- Edema
- Dysrhythmia
- Impaired temperature regulation
- Altered drug response
- Renal insufficiency
- Immunosuppression
- Infection/sepsis

Fig. 13.1 Many of the technical challenges regarding airway management, intravenous access, application of monitors, temperature regulation, and expectation of extensive bleeding associated with anesthetic care of patients with major burn injury.

management and pulmonary support, vascular access, adequacy of resuscitation, and associated injuries. The severely burned patient presents with numerous preoperative concerns, as listed in Box 13.2. The preoperative evaluation must be performed within the context of the planned operative procedure, which will depend on the location, extent, and depth of burn wounds; time after injury; presence of infection; and existence of suitable donor sites for autografting.

INITIAL EVALUATION OF BURN INJURY

Destruction of skin by thermal injury disrupts the vital functions of the largest organ in the body. The skin provides several essential protective and homeostatic functions (Box 13.3). Treatment of patients with burn injuries must compensate for loss of these functions until the wounds are covered and healed. As a barrier to evaporation of water,

Fig. 13.2 Occasionally patients requiring burn wound excision present with special needs, as with this 3-day-old patient. Cardiovascular, hepatic, and renal physiological systems are immature, and vascular access adequate to keep up with extensive blood loss can be technically difficult.

Box 13.2 Major Preoperative Concerns in Acutely Burned Patients

Age of patient
Extent of burn injuries (total body surface area)
Burn depth and distribution (superficial or full thickness)
Mechanism of injury (flame, electrical, scald, or chemical)
Airway patency
Presence or absence of inhalation injury
Elapsed time from injury
Adequacy of resuscitation
Associated injuries
Coexisting diseases
Surgical plan

Box 13.3 Functions of Skin

1. Protection from environmental elements (e.g., radiation, mechanical irritation, or trauma)
2. Immunological: antigen presentation, antibacterial products (sebum), barrier to entry of pathological organisms
3. Fluid and electrolyte homeostasis: helps maintain protein and electrolyte concentrations by limiting evaporation
4. Thermoregulation: helps control heat loss through sweating and vasomotor regulation of superficial blood flow
5. Sensory: extensive and varied sensory organs in skin provide information about environment
6. Metabolic: vitamin D synthesis and excretion of certain substances
7. Social: appearance of skin has strong influence on image and social interactions

the skin helps maintain fluid and electrolyte balance. Heat loss through evaporation and impairment of vasomotor regulation in burned skin diminishes effective temperature regulation. The skin's barrier function also protects against infection by invading organisms. Wound exudate rich in

protein depletes plasma proteins when large body surface areas are injured.

In addition to loss of important functions of the skin, extensive burns result in an inflammatory response with systemic effects that alter function in virtually all organ systems. Preoperative evaluation of the burn patient is guided largely by a knowledge of these pathophysiological changes.

Much of the morbidity and mortality associated with burn injuries are related to the size of the injury. The extent of the burn injury is expressed as the TBSA burned. Estimates of TBSA burned are used to guide fluid and electrolyte therapy and to estimate surgical blood loss. These estimates can be made with Lund Browder charts developed from age-specific nomograms (Fig. 13.3). Simplified "Rule of Nines" charts are available in emergency departments for rapid estimates of TBSA involvement. A knowledge of the burn depth is also critical to anticipating physiological insult as well as planned surgical treatment. First-degree or superficial second -degree burns may heal without scarring or deformity and do not require surgical excision. Deeper second-degree and third-degree burns require surgical debridement and grafting with associated surgical blood loss.

Accurate estimates of blood loss are crucial in planning preoperative management of burn patients. With extensive wound excision or debridement, large amounts of blood can be lost rapidly. Adequate preparation in terms of monitors, vascular access, and availability of blood products is essential. Surgical blood loss depends on area to be excised (cm^2), time since injury, surgical plan (tangential vs. fascial excision; Fig. 13.4), and presence of infection.[12] Blood loss from skin graft donor sites will also vary depending on whether it is an initial or repeat harvest. These variables are valuable predictors of surgical blood loss, which is a critical factor in planning anesthetic management (Table 13.1).

AIRWAY AND PULMONARY FUNCTION

Special attention must be paid to the airway and pulmonary function during preoperative evaluation. Burn injuries to the face and neck can distort anatomy and reduce range of mobility in ways that make direct laryngoscopy difficult or impossible. Specific alterations include impaired mouth opening and edema of the tongue, oropharynx, and larynx, as well as decreased range of motion of the neck. The tissue injury and sloughing present after severe facial burns may make mask ventilation difficult. Inhalation injury may impair pulmonary gas exchange and lead to respiratory insufficiency or failure. The level of respiratory support must also be assessed. The level of required support may range from supplemental blow-by or mask oxygen to intubation and ventilation with high positive end-expiratory pressure (PEEP) and FIO_2. Acute lung injury can occur from inhalation of chemical irritants, systemic inflammation from burn wounds or difficulties with resuscitation, or ventilator-induced injury. Common pathologies include upper airway thermal injury, pulmonary parenchyma damage from chemical irritants or inflammation, and lower airway obstruction from mucus plugs and epithelial casts, as well as pulmonary edema due to acute lung injury or volume overload. With very high levels of PEEP or peak inspiratory pressure, it must be determined if the anesthesia ventilator is adequate or if an ICU ventilator will need to be brought to the operating room. If the patient is intubated at the time of the preoperative evaluation, it is essential to know what the indications for intubation were so that an appropriate plan for postoperative support can be made.

Table 13.1 Calculation of Expected Blood Loss

Surgical Procedure	Predicted Blood Loss
<24 h since burn injury	0.45 mL/cm^2 burn area
1–3 days since burn injury	0.65 mL/cm^2 burn area
2–16 days since burn injury	0.75 mL/cm^2 burn area
>16 days since burn injury	0.5–0.75 mL/cm^2 burn area
Infected wounds	1–1.25 mL/cm^2 burn area

There is general recognition that smoke inhalation injury increases morbidity and mortality for burn patients.[13] The presence of an inhalation injury in combination with a cutaneous burn increases the volume of fluid required for resuscitation by as much as 44%.[14] Numerous studies have also shown an increased incidence of pulmonary complications (pneumonia, respiratory failure, or acute respiratory distress syndrome [ARDS]) in patients with burns and inhalation injury when compared with burns alone.[15] Sequelae of inhalation injury include upper airway distortion and obstruction from direct thermal injury as well as impaired pulmonary gas exchange due to effects of irritant gases on lower airways and pulmonary parenchyma. These two components of the inhalation injury have separate time courses and pathophysiological consequences.

Foley described the findings of 335 autopsies performed on patients who died from extensive burns.[16] Intraoral, palatal, and laryngeal burns were not uncommon among patients with inhalation injuries. The most common sites of laryngeal injury were the epiglottis and vocal folds where their edges were exposed. In contrast, thermal necrosis below the glottis and upper trachea was not observed in any of these patients. The lower airways are nearly always protected from direct thermal injury by the efficiency of heat exchange in the oro- and nasopharynx unless the injury involves steam or an explosive blast. This has been demonstrated in an experimental model.[17] Inhalation injury to the lower airways and pulmonary parenchyma is, therefore, almost always due to the effect of toxic or irritant gases.

Clinical suspicion of inhalation injury is aroused by the presence of certain risk factors such as history of exposure to fire and smoke in an enclosed space or a period of unconsciousness at the accident scene, burns including the face and neck, singed facial or nasal hair, altered voice, dysphagia, oral and/or nasal soot deposits, or carbonaceous sputum. The earliest threat from inhalation injury, aside from asphyxia or systemic poisoning, is upper airway obstruction due to edema. Early or prophylactic intubation is recommended when this complication threatens. However exposure to smoke does not always lead to severe injury and, in the absence of overt evidence of respiratory distress or failure, it may be difficult to identify patients who will experience progressive inflammation and ultimately require intubation of the trachea. In a retrospective study, Clark

Fig. 13.3 Modified Lund and Browder for use at Shriners Hospital, Galveston. Relatively precise estimation of the percent of total body surface area affected by burns is possible with the use of the chart, which normalizes areas of different surface structures with changes that occur with age. A more rapid estimate can be made using a "Rule of Nines" chart that only distinguishes between infants and adults.

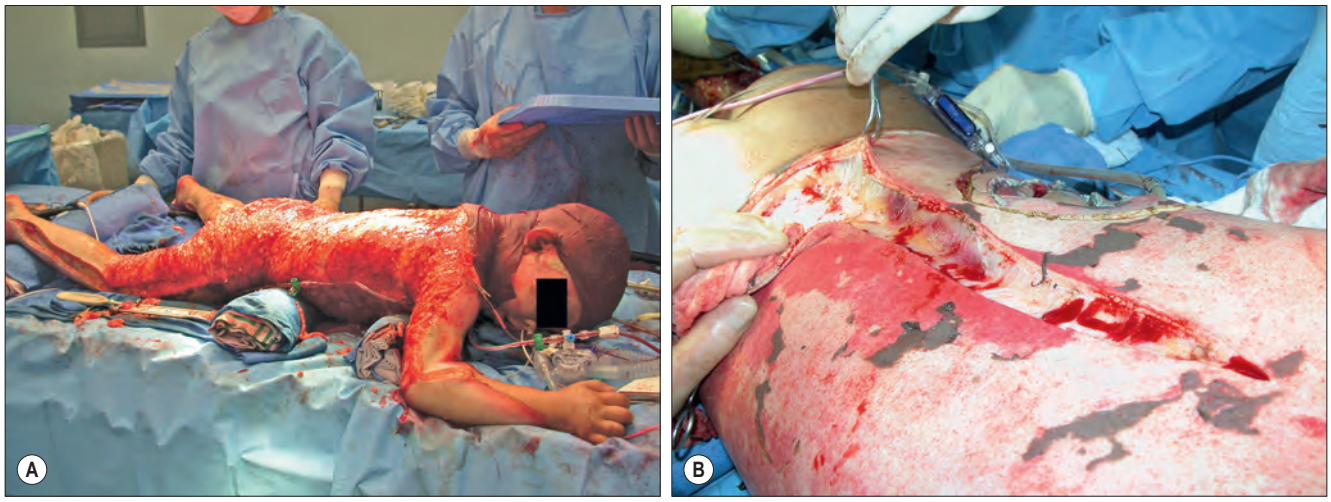

Fig. 13.4 (A) An important determinant of bleeding is surgical technique. Here the burn wound is excised tangentially with a Watson knife down to viable tissue, which is recognized by bleeding. (B) Bleeding during burn wound excision is less when the wound is excised down to the fascial layer, as in this image. Notice also the thick gelatinous layer of edematous tissue beneath the burn wound compared with the unburned tissue at the left of the image.

et al. reported that 51% of their patients exposed to smoke inhalation did not require intubation.[18] Unnecessary intubation in the presence of an inflamed laryngeal mucosa risks further damage to the larynx and subglottic area.[19,20]

Traditional clinical predictors of airway obstruction have been found to be poor predictors of airway compromise in patients with risk factors for inhalation injury.[21,22] More objective criteria for evaluation of the risk of airway obstruction are often needed. Hunt et al. found fiberoptic bronchoscopy to be a safe and accurate method for diagnosis of acute inhalation injury.[23] They described observations of severe supraglottic injuries associated with mucosal edema obliterating the piriform sinuses and causing massive enlargement of the epiglottis and arytenoid eminence. Haponic et al. made serial observations by nasopharyngoscopy in patients at risk for inhalation injury and found distortions of the upper airway described as compliant, edematous mucosa of the aryepiglottic folds, and arytenoid eminences that prolapsed to occlude the airway on inspiration.[24] Progressive upper airway edema in these patients was correlated with body surface area burned, resuscitative volume administered, and rate of infusion of resuscitative fluids. For patients who are at risk for inhalation injury but lack definitive indications for intubation, fiberoptic nasopharyngoscopy is effective in identifying impending airway compromise. Serial exams may help avoid unnecessary intubations and at the same time identify progressive inflammatory changes and allow intubation before severe airway obstruction and emergent conditions develop.[20]

Lower airway and parenchymal injuries develop more slowly than upper airway obstruction. Prior to resuscitation clinical signs and symptoms relating to respiratory function, chest x-ray, and blood gas analysis may be within normal limits despite significant injury that eventually progresses to respiratory failure requiring intubation and mechanical ventilation.[25]

Linares et al. studied the sequence of morphological changes following smoke inhalation in an experimental sheep model.[26] They observed four discrete but overlapping phases of injury described as exudative, degenerative, proliferative, and reparative. During the first 48 hours the exudative phase was characterized by polymorphonuclear (PMN) infiltration, interstitial edema, loss of type I pneumocytes, and damage to the tracheobronchial epithelium in the form of focal necrosis, hemorrhage, and submucosal edema. The degenerative phase occurred between 12 and 72 hours and was characterized by progressive epithelial damage with shedding of necrotic tissue and formation of pseudomembranes and casts. Hyaline membranes developed over alveolar surfaces. Macrophages began to accumulate to begin absorption of necrotic debris. A proliferative phase was described between days 2 and 7, during which type II pneumocytes and macrophages proliferated. After the fourth day, reparative changes were observed with regeneration of epithelium from spared epithelium from the orifices of glands.

Several reviews provide lucid descriptions of pathophysiological changes resulting from smoke inhalation.[27–29] Decreased dynamic compliance increases the work of breathing. Increased closing volume and decreased functional residual capacity lead to atelectasis and shunt resulting in hypoxia. Airways become plugged by sloughed epithelium, casts, and mucus. Impaired ciliary action exacerbates the airway obstruction by decreasing the clearance of airway debris. These changes lead to further shunt and allow colonization and pneumonia. Treatment for inhalation injury is empiric and supportive with tracheal intubation and mechanical ventilation. The application of aggressive pulmonary toilet, high-frequency percussive ventilation, and respiratory therapy protocols designed to mobilize obstructing debris are also highly beneficial. As with treating ARDS, it has been suggested that reduced tidal volumes and airway pressures may limit ventilator-induced lung injury in patients with smoke inhalation injury.[30,31] Recently, however, Sousse et al. examined the effect of reduced tidal volumes on clinical outcomes in patients with inhalation injury requiring mechanical ventilation. Historical controls

were patients previously ventilated with tidal volumes of 15 mL/kg. Outcomes of these patients were compared with current patients receiving 9 mL/kg. Patients in the group with lower tidal volumes required fewer ventilator days and had a lower incidence of atelectasis and ARDS.[32] Where the pathophysiology of ARDS relates primarily to alveolar flooding with protein rich fluid, smoke inhalation injury involves more small airway obstruction (cast and necrotic debris) resulting in increased airway resistance, decreased compliance, and V/Q mismatch. It may be that these two disease processes require different treatments.

Carbon monoxide (CO) and cyanide are two major toxic components of smoke. The burn patient with evidence of smoke inhalation injury should be evaluated for the presence of toxicity resulting from these compounds. CO binds hemoglobin 200 times more avidly than oxygen.[33] Therefore CO markedly impairs the association of oxygen with hemoglobin and decreases oxygen-carrying capacity. CO also shifts the oxy-hemoglobin dissociation curve to the left, thus decreasing the release of oxygen into tissues. These factors result in decreased oxygen delivery to tissues and, at critical levels, lead to anaerobic metabolism and metabolic acidosis. Signs and symptoms of CO poisoning include headache, mental status changes, dyspnea, nausea, weakness, and tachycardia. Patients suffering CO poisoning have a normal Pa_{O_2} and oxygen saturation by routine pulse oximetry. They are not cyanotic. Carboxyhemoglobin must be detected by co-oximetry. Carboxyhemoglobin levels above 15% are toxic and those above 50% are often lethal. The major treatment approach is administration of 100% oxygen and, in severe cases, hyperbaric treatment to increase the partial pressure of oxygen in blood.[34]

Cyanide is also a component of smoke, resulting from the burning of certain plastic products.[35] Cyanide directly impairs the oxidative apparatus in mitochondria and decreases the ability of cells to utilize oxygen in metabolism. These alterations result in conversion to anaerobic metabolism and the development of metabolic acidosis. Signs and symptoms include headache, mental status changes, nausea, lethargy, and weakness. Hydrogen cyanide levels above 100 ppm are generally fatal.[36,37]

Treatment of cyanide toxicity begins with a high inspired oxygen concentration, which may increase intracellular oxygen tension enough to cause nonenzymatic oxidation of reduced cytochromes or displace cytochrome oxidase and potentiate the effects of administered antidotes. Pharmacological intervention includes methemoglobin generators such as the nitrates (amyl nitrite inhalation 0.2 mL, or sodium nitrite, intravenous 10 mL of 3% solution for adults and 0.13–0.33 mL/kg of 3% solution for pediatrics) and dimethylaminophenol (3.25 mg/kg) to increase methemoglobin levels. Methemoglobin competes with cytochrome oxidase for cyanide. However excessive levels of methemoglobin lead to decreased oxygen-carrying capacity and may be toxic. Direct binding agents have a high affinity for cyanide. Di-cobalt edetate (20 mL of 15% solution for adults or 0.3–0.5 mL/kg of 15% solution for pediatrics) is extremely rapid in action but has significant toxicity, whereas hydroxocobalamin (adults 5–10 g or pediatrics 70 mg/kg), the precursor of vitamin B_{12}, has been shown to be safe with few systemic side effects, is actively metabolized by the liver, and avoids renal absorption. Sulfur donors such as sodium thiosulphate (adults 25 mL of 50% solution or pediatrics 1.65 mL/kg of 25% solution) accentuate the bodies' enzymatic conversion of cyanide to thiocyanate in the presence of the mitochondrial enzyme rhodanese, thus decreasing its toxicity and increasing elimination.[36,37]

EFFECT OF BURN INJURY ON CIRCULATION

Thermal injury has profound effects on the systemic circulation, and hemodynamic management is a major component of perioperative care. The skills and clinical experience of anesthesiologists match very well with the needs of patients presenting with serious burn injury, and anesthesiologists are often asked to participate in the initial resuscitation. Patients may also require surgical intervention such as escharotomy, fasciotomy, or wound excision during the first 24 hours after injury; that is, during the initial fluid resuscitation. Because of this, it is important for anesthesiologists to understand the fundamentals of burn resuscitation. It is also critical for the anesthesiologist to be able to evaluate the quality of the resuscitation and assess the hemodynamic status and physiological reserve of the patient after the initial acute resuscitation. These require familiarity with phasic changes in cardiovascular function that follow major burn injuries.

During the first few days after a large burn injury there is a biphasic change in cardiovascular function. With loss of fluid from the vascular space, hypovolemia develops quickly without aggressive replacement. This is associated with decreased cardiac output and increased systemic resistance. Over the next 2–3 days, if resuscitation is successful, this pattern is reversed. A hyperdynamic pattern develops with significantly elevated cardiac output and decreased systemic vascular resistance. Evaluation of physiological status and planning for perioperative care requires knowledge of these changes.

After massive thermal injury, a state of burn shock develops due to intravascular hypovolemia and, in some cases, myocardial depression. This state of burn shock is characterized by decreased cardiac output, increased systemic vascular resistance, and tissue hypoperfusion.[38,39] Intravascular hypovolemia results from alterations in the microcirculation in both burned and unburned tissues, leading to the extensive loss of intravascular fluid to the interstitium. Cutaneous lymph flow increases dramatically in the immediate post burn period and remains elevated for approximately 48 hours.[40] The forces responsible for this massive fluid shift involve all components of the Starling equilibrium equation,[41]

$$J_v = K_f[(P_c - P_{if}) - \sigma(\pi_c - \pi_i)],$$

where K_f is the capillary filtration coefficient, P_c is the capillary pressure, P_{if} is the interstitial hydrostatic pressure, σ s the reflection coefficient for protein, π_c is the plasma colloid osmotic pressure, and π_i the interstitial colloid osmotic pressure. The specific alterations include:

- Increase in microvascular permeability (k_f and σ) due primarily to the release of local and systemic inflammatory mediators;

- Increase in intravascular hydrostatic pressure (P_c) due to microvascular dilatation;
- Decrease in interstitial hydrostatic pressure (P_i);
- Decrease in intravascular oncotic pressure (π_c) due to leakage of protein from the intravascular space
- Relative increase in interstitial oncotic pressure due to a smaller decrease in interstitial oncotic pressure (π_i) compared to intravascular oncotic pressure (π_c).

The leakage of protein and fluid into the interstitial space often results in a washout of interstitial colloid and markedly increased lymph flow. The net effect of these changes is the development of massive edema during the first 24–48 hours after thermal injury with a concomitant loss of intravascular volume. The hypotension associated with burn injury is also due, in part, to myocardial depression. It has been 50 years since Baxter and colleagues first described burn-induced cardiac dysfunction.[42] They postulated that a circulating depressant "factor" was present in the plasma, resulting in reduced myocardial contractility. Since then, numerous groups have confirmed similar findings.[43,44] Although, this "factor" has not been specifically isolated, cytokines including tumor necrosis factor-α (TNF-α), interleukin 1-β (IL-1β), gut-derived factors from plasma and mesenteric lymphatics, and other neurohumoral mediators have been shown to reduce contractility and relaxation properties of the heart.[45-49] Both systemic activation and local tissue levels of cytokine expression are responsible for early burn-induced myocardial depression (first 2–6 hours) that begins to resolve days within days after injury.[47] There is pronounced synergy among burn injury, sepsis, and other forms of shock with regard to myocardial depression, suggesting a common pathway(s) in cardiac dysfunction.

Clinically the incidence of myocardial dysfunction following severe burn injury and its related sequelae remain somewhat controversial. Studies have often been small, underpowered, and use differing methodologies, and data have been collected at different time periods. Indirect assessments of ventricular function throughout the acute resuscitation period using right heart catheterization found that left ventricular function was hypocontractile in the context of high circulating catecholamine levels.[6,50] On the other hand, normal cardiac function has also been reported in the initial resuscitation period following burn injury. Goodwin et al., reported an increase in internal fiber shortening using M-mode echocardiography following burn injury.[51] Others reported similar findings at similar time after injury.[52] More recently diastolic dysfunction in the resuscitation period was found to be associated with increased cytokine levels and death.[53] Myocardial injury, indicated by increased plasma troponin, has also been described and associated with reduced stroke work and diastolic dysfunction.[54] Autopsy data in burns show evidence of myocardial ischemia (30–60% cases, for all age groups), suggesting non–coronary artery causes for ischemia.[55] Myocardial ischemia is likely from reduced supply (tachycardia) and increased demand (tachycardia + contractility) due to catecholamine surge and sympathetic activation. Thus cardiac dysfunction in the early (ICU) phase is likely due to myocardial stunning since fibrosis would take longer (e.g., months).[56]

If the patient survives the initial burn shock and is adequately resuscitated, a state of hyperdynamic circulation develops over the following 2–3 days that is supported by a variety of inflammatory mediators. This state of systemic inflammation has been termed the *systemic inflammatory response syndrome* (SIRS) and is characterized in burned patients by tachycardia, a marked decrease in systemic vascular resistance, and increased cardiac output. SIRS is expressed as a continuum of severity ranging from the presence of tachycardia, tachypnea, fever, and leukocytosis to refractory hypotension, and, in its most severe form, shock and multiple organ system dysfunction. In thermally injured patients, the most common cause of SIRS is the burn itself; however, sepsis (SIRS with the presence of infection or bacteremia) is also a common occurrence.

As a result of these pathophysiological mechanisms, burns involving more than 20% of the patient's TBSA will produce a state of burn shock. In patients with reduced physiologic reserve this can occur with less extensive burns (e.g., 10% TBSA burned). Initial survival from this insult requires aggressive replacement of intravascular fluid. At the same time overresuscitation can cause serious morbidity which, in extreme cases, can be lethal. Several resuscitation protocols utilizing various combinations of crystalloids, colloids, or hypertonic fluids have been developed as guides for administration of the large amounts of fluid needed by patients with acute burns (Table 13.2). Alvarado and colleagues have provided a history of the evolution of these protocols.[57] As these authors point out, little theoretical progress has been made in our understanding of burn resuscitation since current protocols were introduced in the 1970s. As a result, considerable controversy continues regarding such basic decisions as to what fluids to use or what physiological variables to use to titrate volume replacement. Whereas in the past colloid solutions were often avoided during the first 24 hours after burn injury, colloids, especially as albumin or plasma, are returning into favor.

Isotonic crystalloid is still the most commonly used fluid for resuscitation in U.S. burn centers. The most popular fluid resuscitation regimen, the Parkland Formula, uses isotonic crystalloid solutions and estimates the fluid requirements in the first 24 hours to be 4 mL/kg per TBSA burned. Another popular formula is the modified Brooke formula recommending 2 mL/kg per TBSA burned. With both of these protocols, half is given during the first 8 hours and half given over the next 16 hours. The American Burn Association "consensus formula" recommends resuscitation with 2–4 mL/kg/TBSA burned.[58]

These formulas are only estimates, and fluid requirements will vary considerably among patients with similar percentage of TBSA burned for a variety of reasons; rates and volumes must be titrated according to the patient's response. Fluid administration is generally titrated to maintain mean blood pressure above 70 and urine output at 30–50 mL/h in adults and 0.5–1.0 mL/kg per hour in pediatric patients. The use of invasive hemodynamic monitors allows targeting of determinants of oxygen delivery, which should intuitively lead to more physiologically precise resuscitation. Such efforts, however, have not improved clinical outcome and have generally resulted in more aggressive fluid administration and consequent overresuscitation.[59,60]

When evaluating the quality of resuscitation, estimates of fluid requirements based on these protocols can reveal significant departure from predicted needs. Review of the

Table 13.2 Formulas for Estimating Adult Burn Patient Resuscitation Fluid Needs

Colloid formulas	Electrolyte	Colloid	D5W
Evans	Normal saline 1.0 mL/kg/% burn	1.0 mL/kg/% burn	2000 mL/24 h
Brooke	Lactated Ringer's 1.5 mL/kg/% burn	0.5 mL/kg	2000 mL/24 h
Slater	Lactated Ringer's 2 liters/24 h	Fresh frozen plasma	75 mL/kg/24 h
Crystalloid formulas			
Parkland	Lactated Ringer's	4 mL/kg/% burn	
Modified Brooke	Lactated Ringer's	2 mL/kg/% burn	
Hypertonic saline formulas			
Hypertonic saline solution (Monafo)	Volume to maintain urine output at 30 mL/h Fluid contains 250 mEq Na/liter		
Modified hypertonic (Warden)	Lactated Ringer's +50 mEq $NaHCO_3$ (180 mEq Na/liter) for 8 hours to maintain urine output at 30–50 mL/h Lactated Ringer's to maintain urine output at 30–50 mL/h beginning 8 hours postburn		
Dextran formula (Demling)	Dextran 40 in saline—2 mL/kg/h for 8 hours Lactated Ringer's—volume to maintain urine output at 30 mL/h Fresh frozen plasma—0.5 mL/kg/h for 18 hours beginning 8 hours postburn		

patient's physiological status provides evidence of over- or underresuscitation. Crystalloid solutions generally provide adequate volume resuscitation; however the large volumes that are needed result in substantial tissue edema and hypoproteinemia. In addition, a trend toward administration of more fluid than the Parkland Formula would predict has been termed "fluid creep."[61] As mentioned earlier, overresuscitation can be associated with serious morbidity and even mortality. This has led to a search for interventions that can reduce the volume of fluid needed for resuscitation.

Although colloid was included in earlier resuscitation formulas, it was dropped during the 1970s. An overall clinical benefit was difficult to demonstrate for colloid solutions, especially when given during the first 12 hours after injury. Pruitt and colleagues reported that the addition of colloids to resuscitation fluid during the first 24 hours did not increase the intravascular volume more than crystalloid fluid alone.[62] It was also suggested that colloid use could contribute to pulmonary edema during the postresuscitation period.[51] Because of the added cost with little established benefit, colloid solutions have not been used routinely for initial volume resuscitation in burned patients in the United States until recently. In 1998, a highly publicized Cochrane meta-analysis concluded that albumin administration increases mortality in critically ill patients, including patients with severe burn injuries.[63] As relating specifically to burn-injured patients, there were serious methodological flaws with this meta-analysis sufficient for most clinicians to discount the Cochrane conclusion that albumin administration increases mortality among burn patients.[64,65] In a recent review, Saffle reported that, in nearly all studies of burn resuscitation, the use of colloid solutions has reduced the volume required as well as the complications of overresuscitation in these patients.[60] When administered specifically for the therapeutic goal of limiting the volume necessary for resuscitation, the use of colloid solutions is a rational choice for many clinicians.

In a prospective randomized study, the use of plasma for volume resuscitation was found to reduce volume infused and weight gain along with intra-abdominal pressure and the incidence of abdominal compartment syndrome (see later discussion).[66] These outcome variables have not been used for comparing crystalloid and colloid resuscitation in the past. With the trend toward larger volumes for initial resuscitation, with associated morbidity, it may be that the use of colloid is beneficial for larger injuries. The use of plasma during resuscitation may involve more than just volume and increased colloid osmotic pressure. Kozar and colleagues demonstrated that plasma but not crystalloid resuscitation partially reverses hemorrhage-induced endothelial damage in an experimental animal model.[67] Restoration of the endothelial glycocalyx may help recovery of the capillary function and reduce fluid extravasation.

Crystalloid solutions alone provide adequate intravascular expansion without unacceptable complications in many patients. However not all patients respond favorably to crystalloid resuscitation. Box 13.4 provides a list of a number of factors that can significantly increase the volume of fluid needed for resuscitation. For patients with these features, and in other patients for unknown reasons, very large volumes of crystalloid are needed to support blood pressure and maintain urine output. In these cases the excessive volume of fluid can result in dangerous morbidity, such as abdominal compartment syndrome (Fig. 13.5). For example, patients who receive more than 250 mL/kg during the first 24 hours are at risk for abdominal compartment syndrome.[68] It is important to recognize when resuscitation is difficult so that measures can be taken to limit morbidity.

Box 13.4 Factors That May Increase Fluid Needs for Resuscitation of Patients with Acute Burn Injuries

- Inhalation injury
- Delay in resuscitation
- Crush injury
- Electrical injury
- Large full-thickness burns
- Methamphetamine lab accidents
- Associated injuries

Box 13.5 Criteria for Adequate Fluid Resuscitation

- Normalization of blood pressure
- Urine output (1–2 mL/kg/h)
- Blood lactate (<2 mmol/L)
- Base deficit (<–5)
- Gastric intramucosal pH (>7.32)
- Central venous pressure
- Cardiac index (CI) (4.5 L/min/m^2)
- Oxygen delivery index (DO_2L) (600 mL/min/m^2)

Fig. 13.5 Large volumes of crystalloid solution required for resuscitation of patients with acute burns can result in compromise of circulation in various compartments. Escharotomies or fasciotomies may be required for extremities. Laparotomy may be required for abdominal compartment syndrome when other measures do not adequately decompress the abdomen.

Extensive recent experience with burn injuries resulting from military conflicts has produced protocols that include administration of albumin for managing patients who do not have an adequate response to appropriate volumes of crystalloid fluid.[69] Likewise many civilian burn centers have adopted "colloid rescue" for patients with inadequate response to resuscitation. Lawrence and colleagues[70] evaluated responses of burn patients as an hourly ratio (I/O) of volume of fluid infused (mL/kg/%TBSA burned/h) to urine output (mL/kg/h). Patients who responded favorably to fluid administration maintained a ratio of less than 0.4, but poor responders had progressively increasing ratios to a maximum of 1.97. When patients were identified as poor responders, 5% albumin was added to their resuscitation fluid regimen. After addition of albumin each of the patients responded with a prompt decrease in the I/O ratio for the remainder of the resuscitation. In this study albumin rescue was initiated more than 12 hours after injury. The authors noted that these patients still received large volumes of fluid and that this volume might have been reduced if colloid had been given earlier. In the future it may be feasible to recognize poor responders early during resuscitation to allow earlier intervention. This study also emphasizes the heterogeneity of the burned patient population with regard to response to treatment. This heterogeneity may also explain in part why it has been difficult to show benefit from colloid administration. It would be difficult to show benefit from an intervention if it is given to a group of patients comprising both responders and nonresponders.

The use of hypertonic saline, either alone or in conjunction with colloids, has also been advocated by some in the initial resuscitation of burned patients. Among the potential benefits are reduced volume requirements to attain similar levels of intravascular resuscitation and tissue perfusion compared to isotonic fluids.[71] Theoretically, the reduced volume requirements would decrease the incidence of pulmonary and peripheral edema, thus reducing the incidence of pulmonary complications and the need for escharotomy. Hypertonic saline dextran solutions have been shown to expand intravascular volume by mobilizing fluids from intracellular and interstitial fluid compartments. Although hypertonic saline dextran solutions will transiently decrease fluid requirements, there is potential for a rebound in fluid resuscitation needs.[72] Therefore most burn centers continue to employ isotonic crystalloid fluids rather than hypertonic solutions for initial resuscitation of patients in burn shock.

Unfortunately there is no single physiological variable that is always reliable as an end point to guide resuscitation in acute burn patients. Several variables are used to assess the adequacy of volume resuscitation in burned patients (Box 13.5). The overall goal is early volume resuscitation and establishment of tissue perfusion. Traditionally urine output (0.5–1 mL/kg per h) and normalization of blood pressure (mean arterial blood pressure of greater than 70 mm Hg) have been used as endpoints. However, some studies indicate that these parameters may be poor predictors of adequate tissue perfusion. Jeng and colleagues showed that attaining urine outputs of greater than 30 mL/h and mean blood pressures of greater than 70 mm Hg correlated poorly with other global indicators of tissue perfusion such as base deficit and blood lactate levels.[73] In order to maintain perfusion of vital organs such as heart and brain, blood flow is often redistributed away from splanchnic organs. Persistent hypoperfusion of these organs ultimately results in tissue injury and may be a contributing factor to multisystem organ dysfunction. Several studies have shown that normalization of blood pressure, heart rate, and urine output alone does not by itself

correlate with improved outcome.[74,75] Therefore during the preoperative assessment of the burn patient, the anesthesiologist should not base the cardiovascular assessment on one variable but use a more global approach to evaluating the patient's physiological status and reserve.

When vital signs and urine output are within normal limits, measurements of metabolic function may provide more subtle evidence of impaired perfusion. In burn patients, tissue perfusion is not uniform. Perfusion of the splanchnic beds may be sacrificed in order to maintain the perfusion of heart, brain, and kidneys. Blood lactate and base deficit provide indirect metabolic global indices of tissue perfusion. Lactic acid is a byproduct of anaerobic metabolism and is an indicator of either inadequate oxygen delivery or impaired oxygen utilization. In the absence of conditions such as cyanide poisoning or sepsis that alter oxygen utilization at the cellular level, lactate level may be a useful marker of oxygen availability.[76] Wo and colleagues found serum lactate to be the most predictive index of adequate tissue perfusion, and a lactate level of less than 2 mmol/L in the first 24–72 hours after burn injury correlated with increased survival.[75] Base deficit is another indirect indicator of global tissue perfusion. The base deficit is calculated from the arterial blood gas using the Astrup and Siggard-Anderson nomograms. Although it is a calculated and not directly measured variable, base deficit provides a readily obtained and widely available indicator of tissue acidemia and shock. Base deficit has been shown to correlate closely with blood lactate and provides a useful indicator of inadequate oxygen delivery. A retrospective study by Kaups et al. showed that base deficit was an accurate predictor of fluid requirements, burn size, and mortality rate.[77]

Overresuscitation can also be a serious complication of fluid administration to acute burn patients. Blindness due to ischemic optic neuropathy has been reported as a complication of burn resuscitation.[78] Greenhalgh and Warden first described the association of increased abdominal pressures and compartment syndrome with burn resuscitation.[79] Several studies since then have described the common occurrence of increased intra-abdominal pressure with large-volume burn resuscitation. Intra-abdominal hypertension is termed abdominal compartment syndrome when it is associated with impaired respiration, circulation, and urine output. Mechanical ventilation is impaired by pressure on the diaphragm, circulation is impaired by restricted venous return due to caval compression, and urine output is impaired by compression of renal vessels. When this pattern presents, the patient should be examined for elevated intra-abdominal pressure. This can be accomplished by measuring bladder pressure: 50 mL of saline is instilled into the bladder through the Foley catheter and the height of the saline column above the symphysis pubis is measured (1.36 cm of H_2O = 1 mm Hg).[80] Conservative treatment of elevated intra-abdominal pressure includes attempts to limit the volume of intravenous fluid needed for resuscitation. The inclusion of plasma with resuscitation fluids has been found to reduce the volume required and was associated with significantly lower intra-abdominal pressures.[66] When intra-abdominal hypertension occurs it can be relieved to a degree by optimizing sedation and analgesia. Diuresis with furosemide and muscle relaxants to reduce muscle tone have been used to reduce intra-abdominal pressure. More invasive measures include escharotomies,[81] percutaneous peritoneal dialysis catheter drainage,[82] and laparotomy.[79]

Serious burns can also be caused by contact with caustic or corrosive chemicals. An increasingly common specific example is burns related to the illicit production of methamphetamine.[83–85] There has been a dramatic increase in burn injuries from explosions and fires related to methamphetamine production in illegal labs. Victims of these accidents present unique challenges for a variety of reasons. Substances used in methamphetamine production include chemicals that are corrosive and toxic (e.g., anhydrous ammonia, hydrochloric acid, red phosphorous, and ephedrine). Other ingredients are flammable (acetone, alcohol, and gasoline), and explosions can coat the victims with all these chemicals. As a result, in addition to the victim's toxic exposure, contacting incompletely decontaminated victims of these accidents has injured first responders and hospital workers.[86,87]

In addition to exposures just described, these patients are usually intoxicated with methamphetamine, as demonstrated by positive urine screen, and may have inhaled toxic fumes such as phosphine gas. Santos et al. found the incidence of inhalation injury twice as great in victims of methamphetamine-related burns as in age- and burn-matched controls.[85] Among their patients requiring intubation for inhalation injury, methamphetamine users also required roughly twice as many ventilator days. Clinical studies have consistently observed increased fluid requirements for resuscitation of methamphetamine patients.[85,86] For example, Santos et al. found that resuscitation volumes were 1.8 times greater for methamphetamine users with burns than for controls.[85] In addition, methamphetamine users with burns experienced more behavioral problems. These patients are more often agitated and require restraints. Santos et al. reported that all their methamphetamine patients required greater than normal doses of sedatives and displayed what they referred to as "withdrawal-type syndrome."[85] This behavior may be due to withdrawal of methamphetamine from chronic users.

EFFECT OF BURN INJURY ON RENAL FUNCTION

Acute kidney injury (AKI) is a very common and devastating complication of severe burn injuries. The incidence is often estimated at 30% or more and can increase the mortality in these patients to more than 80%.[88] The risk of AKI with burns increases with all the features intuitively associated with poor outcome. Despite improvements in critical care, AKI continues to complicate burn care and increase mortality. There have been some indications of an improvement, however. Jeschke and colleagues have shown a decrease in mortality in pediatric burn patients with ARF to 56% since 1984.[89] Also, Chung and colleagues found that early application of continuous venovenous hemofiltration in patients with evidence of AKI, especially in the presence of inhalation injury, improved survival compared with conventional care that included hemodialysis after more stringent criteria were met.[90]

The pathogenesis of AKI in burn patients is complex and can involve a number of interconnected mechanisms. A

difference between AKI that occurs early after injury has been distinguished from injury developing later.[91] Early AKI is associated with reduced renal blood flow resulting from acute burn shock, whereas AKI that occurs later is associated with sepsis and exposure to nephrotoxic drugs. Early AKI carries a worse prognosis than the late form.[88] Continuous evaluation of the patient's response to fluid resuscitation is necessary for the early recognition and correction of under- or overresuscitation to prevent early AKI.

Another mechanism of early AKI is caused by myoglobinemia resulting from rhabdomyolysis due to compartment syndrome or electrical injury.[92,93] Treatment of this form of AKI is difficult. Brown and colleagues found that rates of renal failure, dialysis, or mortality were not altered by treatment of rhabdomyolysis with bicarbonate and mannitol.[94] Early diagnosis and treatment of compartment syndrome or muscle damage due to electrical injury is, therefore, critical to preventing its development.

The presence of renal failure complicates intraoperative management. It seriously reduces the margin of error for fluid replacement of blood loss. A central venous catheter (CVC) to monitor filling pressure may be more useful in these patients. Electrolyte balance, especially potassium, should be watched closely and extra caution with dosage and rate of administration of nephrotoxic drugs such as antibiotics is needed.

METABOLIC CHANGES ASSOCIATED WITH BURN INJURY

Increased metabolic rate is the hallmark of the metabolic alterations that take place after thermal injury. The magnitude of the hypermetabolism is influenced by the size of the burn wound, how the burn patient is treated, and the ambient temperature of the patient.[95,96] Within the range of 30–70% TBSA burn injury, the hypermetabolism tends to be proportional to the size of the burn wound. With burns beyond this range, the hypermetabolism appears to plateau and only increases in smaller increments.[97] Septic complication is an important factor that can increase the metabolic response, as does the physiologic stress of pain. It has been observed that modern-day treatment of burn injuries with early excision and closed-wound treatment ameliorates this hypermetabolism.[98] Burn patients increase their metabolic rate in an effort to generate heat according to a new threshold set point for the body temperature that is influenced by the size of the burn (see the section "Thermoregulation in Burn Patients"). The recognition of this fact has led to an increased awareness of the importance of the ambient temperature in modulating the hypermetabolism of the burn patient. By indirect calorimetry, patients with major burn injuries treated according to current standards have resting energy expenditures that are 110–150% above values recorded in nonburned subjects.[99]

As a result of this hypermetabolic response, the acutely burned patient has an increased O_2 consumption along with an increased CO_2 production that demands a higher respiratory effort. The anesthetic care of the acute burned patient has to accommodate these changes, and frequently this has to be done in patients with compromised pulmonary function due to burn injury.

The hypermetabolic pattern also increases caloric needs. Numerous studies have shown that optimized nutritional care not only can ameliorate the burn-associated state of catabolism and immune suppression, but also can improve wound healing.[96] Oral or enteral feeding is recognized as the optimal feeding route of the burned patient. Frequently the acute burn patient is fed continuously over extended time periods. If standard guidelines for perioperative fasting are implemented, recurrent operative procedures can significantly impinge on the nutritional needs of the patient and ultimately cause a caloric deficit. Each surgical procedure requiring general anesthesia theoretically necessitates a 10-hour interruption of enteral nutritional support (fasting for 8 hours preoperatively and 2 hours postoperatively). To avoid this interruption of nutritional support, continuation of feeding via a post-pyloric feeding tube has been used. One study indicates that this practice provides a favorable gut oxygen balance.[100] Varon et al. reviewed records of 17 patients fed intraoperatively through post-pyloric feeding tubes and 16 patients fasted for surgery. These patients had an average of seven surgical procedures each.[101] There were no clinical adverse effects with intraoperative feeding, and these patients met nutritional goals sooner than patients fasted for surgery. Larger studies are necessary to establish the safety of intraoperative feeding but many practitioners consider this safe in the presence of a cuffed tracheal tube.

Severe insulin resistance with hyperglycemia and concurrent hyperinsulinemia is a key feature of the metabolic alterations of burn injury.[95] Critical care of burn patients often involves parenteral nutritional support and may also include insulin infusions. It is important to recognize these interventions during the preoperative evaluation of the burn patient in the ICU. Oxygen consumption and glucose balance are altered when general anesthesia, muscle relaxation, and mechanical ventilation are employed. Increased sympathetic tone due to the stress of surgical trauma can also alter glucose production and insulin resistance. These changes often result in significant changes in blood glucose levels that require treatment.

THERMOREGULATION IN BURN PATIENTS

Maintenance of proper body temperature is an important factor in the care of severely burned patients. The thermoregulatory system is controlled by three major components. These include the afferent system that senses changes in core body temperature and transmits this information to the brain, the central regulatory mechanisms located primarily in the hypothalamus that process afferent input and initiate responses, and the efferent limb that mediates specific biological and behavioral responses to changes in core body temperature (Fig. 13.6). Temperature is sensed by Aδ and C fibers present in peripheral tissues such as skin and muscle, as well as in core tissues such as brain, deep abdominal tissues, and thoracic viscera. The vast majority of afferent input arises from the core tissues. Because the skin is in direct contact with the environment, it senses immediate changes in environmental temperature. However the overall afferent input of the skin and other peripheral tissues is estimated to be only 5–20% of total afferent thermoregulatory input.[102] Therefore loss of skin following a burn injury is not likely to markedly alter overall afferent input. Wallace

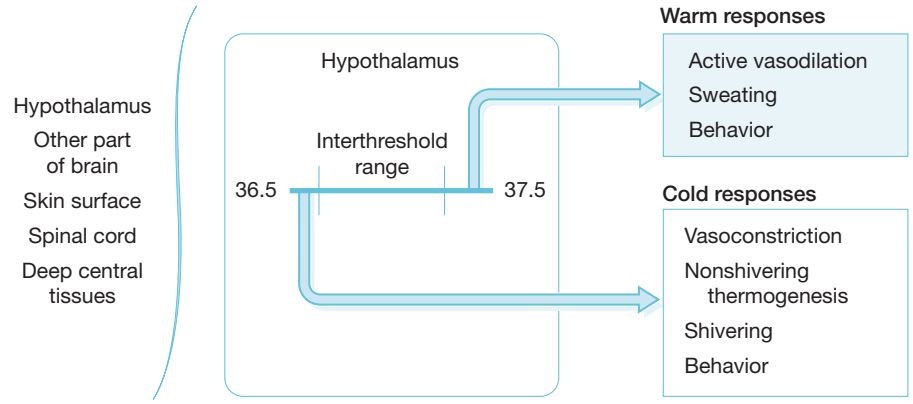

Fig. 13.6 Thermoregulatory control mechanisms. Afferent inputs from a variety of sites, most notably skin, central tissues, and brain, are processed in the central nervous system. Based on input, a variety of efferent thermoregulatory responses are initiated. (From Sessler DI. Temperature monitoring. In: Miller R, ed. *Anesthesia*, 3rd edn. New York: Churchill Livingstone; 1990.)

and colleagues have shown that burn patients perceive changes in ambient temperature as effectively as normal controls.[103] This is likely due to the retained ability of burn patients to sense changes in core temperature and transmit this information to the central nervous system. Central control of temperature is a complicated system that is not well understood. The hypothalamus plays an important role in temperature regulation, but the complete mechanism of temperature control is likely to be multifaceted and is an area of intense research. Regardless of the ultimate control mechanisms, temperature control can be divided into three main functions: threshold, gain, and maximum response intensity.

Threshold encompasses a set point at which responses to temperature change are initiated. In normal individuals the threshold range is generally near 36.5–37.5°C. In burn patients, the threshold set point is higher, and the increase is proportional to the size of the burn. The work of Caldwell and colleagues predicts that the temperature set point will increase by 0.03°C/%TBSA burn.[104] This increase in temperature threshold appears to be due to the hypermetabolic state and the presence of pyrogenic inflammatory mediators such as TNF, IL-1, and IL-6 that are present after thermal injury. The elevated temperature set point can be decreased by administration of indometacin, which suggests that prostaglandins act as final common mediators of this response.[105,106]

Gain describes the intensity of response to alterations in temperature. In most cases the gain of thermoregulatory responses is very high, with response intensity increasing from 10% to 90% with only a few tenths of a degree change in core temperature. This response is maintained in most burn patients, resulting in a further increase in metabolic rate.[103] Burn patients respond with a brisk increase in heat generation and metabolic rate in response to changes in core body temperature.[103] However work by Shiozaki and colleagues has shown that burn patients who are slow to respond to postoperative hypothermia are at increased risk of mortality.[107] The decreased responsiveness may be due, in part, to tissue catabolism, poor nutrition, or sepsis. In addition, the response to relative hypothermia is characterized by increased catecholamine release, tissue catabolism, and hypermetabolism. These responses further stress burn patients and decrease their ability to respond to their primary injury.[108]

The most important efferent responses to hypothermia are behavioral responses such as gaining shelter, covering up, and seeking a more desirable ambient temperature. In the acute postburn setting, most of these behaviors are impeded by positioning, sedation, and inability to seek a more favorable environment. Therefore caregivers must be attentive to the patient's temperature and perception of cold so that measures can be undertaken to optimize the patient's temperature. Cutaneous vasoconstriction is another important mechanism for preserving heat and core body temperature. In unburned persons, a temperature gradient of 2–4°C exists between skin and core tissues. This gradient is maintained by cutaneous vasoconstriction. Without cutaneous vasoconstriction, heat is redistributed from the core compartment to the periphery. This heat is ultimately lost to the environment. Peripheral vasoconstriction minimizes temperature redistribution and acts to maintain core body temperature. This mechanism of heat preservation is lost with the loss of large areas of skin, particularly if cutaneous tissues are excised down to the fascial level. The loss of skin facilitates the loss of core body heat into the environment and places the burn patient at risk for core hypothermia. Another mechanism of heat loss in burn patients is evaporation. Burn patients can lose as much as 4000 mL/m^2 burned per day of fluids through evaporative losses.[109] Mechanisms of nonshivering heat production and shivering remain intact in burn patients. However, shivering increases metabolic requirements and is likely deleterious.

The induction of anesthesia results in relative ablation of thermoregulatory mechanisms and puts the patient at further risk for developing hypothermia. Patients under general anesthesia exhibit a markedly decreased threshold for responding to hypothermia (Fig. 13.7). This is particularly important in burn patients, given their high temperature set point and the deleterious effects of further stress responses and hypermetabolism. Most anesthetics decrease nonbehavioral responses to hypothermia such as vasoconstriction, nonshivering thermogenesis, and shivering. Of course, behavioral responses are ablated during general anesthesia. Therefore, it is the responsibility of the

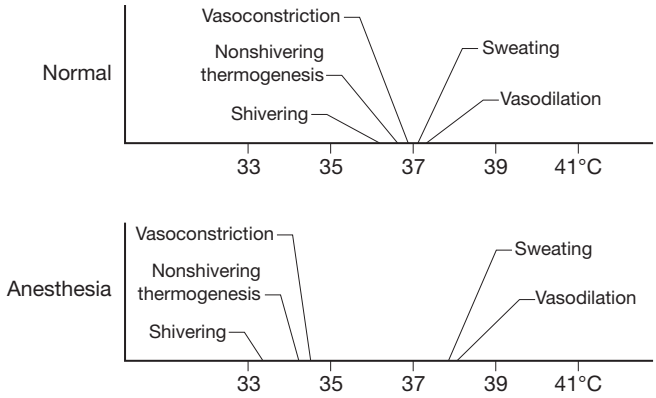

Fig. 13.7 Effects of anesthesia on thermoregulatory mechanisms. (From Sessler DI. Temperature monitoring. In: Miller R, ed. *Anesthesia*, 3rd edn. New York: Churchill Livingstone; 1990.)

intraoperative caregivers to monitor and maintain patient temperature.

Actions such as maintaining higher ambient air temperature, covering extremities and head, applying warm blankets, utilizing radiant heaters and forced air warming devices, warming fluids and blood, and warming gases are usually effective in maintaining core temperature if applied aggressively. Ideally hypothermia should be corrected prior to transport to the operating room.[110] Hypothermia revealed in the preoperative evaluation may be due to inadequate resuscitation or metabolic instability. Either situation may predispose burn patients to intolerance of anesthetic drugs or the stress of surgery.

Pharmacological Considerations

Burn injury and its treatment result in physiological changes that may profoundly alter the response to drugs. These changes alter both pharmacokinetic and pharmacodynamic determinants of drug response. Altered drug response in burned patients may require deviation from usual dosages to avoid toxicity or decreased efficacy.[111] The complex nature of the pathophysiological changes and interpatient variation in the nature and extent of burn injuries, as well as the dynamic nature of these changes during healing and recovery make it difficult to formulate precise dosage guidelines for burn patients. However an understanding of the systemic response to large burn injuries can help predict when an altered drug response can be expected and how to compensate.

The two distinct phases of cardiovascular response to thermal injury can affect pharmacokinetic parameters in different ways. During the acute or resuscitation phase the rapid loss of fluid from the vascular space due to edema formation results in decreases of cardiac output and tissue perfusion. Volume resuscitation during this phase dilutes plasma proteins and expands the extracellular fluid space especially, but not exclusively, around the burn injury itself. Decreased renal and hepatic blood flow during the resuscitation phase reduces drug elimination by these organs. Also, decreased cardiac output will accelerate the rate of alveolar accumulation of inhalation agents, which may result in an exaggerated hypotensive response during induction of general anesthesia.

After approximately 48 hours, the hypermetabolic and hyperdynamic circulatory phase is established with increased cardiac output, oxygen consumption and core temperature. During this phase, increased blood flow to the kidneys and liver may increase clearance of some drugs to the point where increased doses are required.[112]

Many drugs are highly protein bound. Drug effects and elimination are often related to the unbound fraction of the drug that is available for receptor interaction, glomerular filtration, or enzymatic metabolism. The two major drug-binding proteins have a disparate response to burn injury. Albumin binds mostly acidic and neutral drugs (diazepam or thiopental) and is decreased in burn patients. Basic drugs (pKa >8, propranolol, lidocaine, or imipramine) bind to α-acid glycoprotein (AAG). AAG is considered an acute-phase protein and its concentration may double after burns. Since these drug-binding proteins respond in opposite ways to thermal injury it can be expected that changes in drug binding and function will depend on which of these proteins has the highest affinity for the drug in question. Martyn et al. observed decreased plasma albumin concentration and increased plasma AAG concentration in burn patients.[113] These observations were associated with an increased unbound fraction for diazepam (bound by albumin) and a decreased unbound fraction for imipramine (bound by AAG).

Volume of distribution (V_d) is changed by alterations to either extracellular fluid volume or protein binding. Large changes in both of these variables occur with thermal injuries. Drugs with high protein binding and/or a V_d in the range of the extracellular fluid volume may be associated with clinically significant alterations of V_d in burned patients. V_d is the most important determinant of drug response following a rapid loading dose. However adjustments in dose to compensate for altered V_d are indicated only when V_d for the drug is small (<30 L) because with larger V_d only a small fraction of the drug is present in the plasma.[111]

Clearance is the most important factor determining the maintenance dose of drugs and can influence the response to drugs given by infusion or repeated bolus during anesthesia. Drug clearance is influenced by four factors: metabolism, protein binding, renal excretion, and novel excretion pathways. The characteristic hepatic extraction of a particular drug influences changes in its clearance that occur after thermal injury. Drugs vary greatly in their extraction by the liver. Hepatic clearance of drugs highly extracted by the liver depends primarily on hepatic blood flow and is insensitive to alterations in protein binding. Clearance of these drugs may increase during the hyperdynamic phase when hepatic blood flow is increased. In contrast, clearance of drugs that have a low hepatic extraction coefficient is not affected by changes in hepatic blood flow but is sensitive to alterations in plasma protein levels.[111] For these drugs it is the unbound fraction of the drug that is metabolized. As noted, changes in unbound fraction depend on whether the drug is bound by albumin or AAG. Changes in protein levels produce clinically significant pharmacokinetic changes only for drugs that are highly bound (>80%).[114]

During resuscitation, renal blood flow may be reduced and renal excretion of drugs may be impaired. Later, during the hypermetabolic phase, renal blood flow is increased as a result of the elevated cardiac output. During this period excretion of certain drugs can be increased to the point that the dose may need to be increased. Loirat et al. reported increased glomerular filtration rates and reduced half-life of tobramycin in burn patients.[115] However, this was age-dependent and patients over 30 years of age did not have increased glomerular filtration or reduced half-life.

Burn patients may also experience altered drug clearance due to novel excretion pathways. Glew et al. found that 20% of a daily gentamicin dose was eliminated in the exudates lost to wound dressings.[116] In addition, rapid blood loss during surgery may speed the elimination of drugs when blood loss and transfusion amount, essentially, to an exchange transfusion.

Hepatic clearance of drugs with low extraction coefficients is also sensitive to alterations of hepatic capacity (enzyme activity). There is evidence of impairment of hepatic enzyme activity in burn patients.[111] Phase I reactions (oxidation, reduction, or hydroxylation by the cytochrome P-450 system) are impaired in burn patients, whereas phase II reactions (conjugation) seem to be relatively preserved.[112] However, these generalizations do not always produce predictable alterations in pharmacokinetic parameters. For example, contradictory observations of morphine clearance in burn patients have been reported. Morphine metabolism is by glucuronidation. This is a phase II reaction that is normally retained in thermally injured patients. Morphine clearance in burn patients has been reported unchanged or decreased.[117,118] With so many variables involved, such as hepatic blood flow, V_d, plasma proteins, multiple drug exposure, and variation in burn injury, this inconsistency is not surprising. The key to effective drug therapy in burn patients is to monitor drug effects and carefully titrate the dose to the desired effect.

In terms of anesthetic management, the most profound and clinically significant effect of burn injuries on drug response relates to muscle relaxants. Burn injuries of more than 25% TBSA influence responses to both succinylcholine and the nondepolarizing muscle relaxants. In burned patients, sensitization to the muscle-relaxant effects of succinylcholine can produce exaggerated hyperkalemic responses severe enough to induce cardiac arrest.[119–121] In contrast, burned patients are resistant to the effects of nondepolarizing muscle relaxants.[122–124] These changes are explained by up-regulation of skeletal muscle acetylcholine receptors.[125–127]

Martyn and Richtsfeld have recently reviewed the mechanisms of exaggerated hyperkalemic responses to succinylcholine.[127] There are several disease states, including burns, denervation, and immobilization, that are associated with potentially lethal hyperkalemic responses to succinylcholine. The molecular mechanism appears to be both quantitative and qualitative changes in skeletal muscle postsynaptic nicotinic acetylcholine receptors. Animal and human studies consistently demonstrate an association of increased numbers of skeletal muscle acetylcholine receptors with resistance to nondepolarizing muscle relaxants and increased sensitivity to succinylcholine. In addition, the distribution of the new receptors is altered. Nicotinic receptors are normally restricted to the neuromuscular synaptic cleft, but, in these disease states, new receptors are distributed across the surface of the skeletal muscle membrane. The new receptors are also a distinctly different isoform (α7AChR) that has been referred to as an immature, extrajunctional, or fetal receptor. The immature receptors are more easily depolarized by succinylcholine, and their ion channel stays open longer. The immature receptors are also strongly and persistently depolarized by the metabolite of acetylcholine and succinylcholine, choline. It has been suggested that the hyperkalemic response to succinylcholine after burn or denervation injury results when potassium is released from receptor-associated ion channels across the entire muscle cell membrane rather than just the junctional receptors. Depolarization persists because the channels stay open longer and the breakdown product of succinylcholine, choline, is also a strong agonist for the immature receptors.

Cardiac arrest in burned patients after succinylcholine administration was first reported in 1958.[119] It was not until 1967, however, that an exaggerated hyperkalemic effect was identified as the cause of this phenomenon.[120,121] However, considerable individual variability exists, and only a few patients in these series developed dangerously high potassium levels. The size of the increase was greatest about 3–4 weeks after injury. The earliest exaggerated hyperkalemic response described occurred 9 days after injury, and normal responses were observed in the remaining patients in this series for up to 14–20 days.[128] The shortest post-burn interval of an association of succinylcholine with cardiac arrest was 21 days when a 4-year-old patient experienced a fatal cardiac arrest during a fourth anesthetic induction and intubation with succinylcholine. Controversy has surrounded recommendations regarding the safe use of succinylcholine after burn injury. Various authors recommend avoidance of succinylcholine at intervals ranging from 24 hours to 21 days after burn injury.[129,130] A series of letters from experts in this area to the editor of *Anesthesiology* illustrates the controversy.[131,132] It was pointed out by Martyn that, at the time when the mechanism of the cardiac arrest after succinylcholine was elucidated, surgical treatment of burns was delayed for approximately 2 weeks until the eschar spontaneously separated.[132] As a result, there are few clinical data regarding potassium changes during this early period. On the basis of indirect evidence from experimental data, Martyn recommended avoidance of succinylcholine starting 48 hours after injury.[132] This seems rational and prudent. Brown and Bell described the super-sensitivity of burned pediatric patients to the relaxant effect of succinylcholine.[133] They observed more than 90% depression of muscle activity with 0.2 mg/kg succinylcholine without dangerous hyperkalemia. Despite these observations Brown and Bell state that it is generally advisable not to use succinylcholine in patients with large burns. The question remains: in the presence of life-threatening laryngospasm in a burn patient, is it acceptable to give a small dose of succinylcholine (e.g., 0.1 mg/kg) to relieve laryngospasm without full paralysis and accept a theoretical risk of treatable hyperkalemia in order to treat a real and immediate risk of asphyxia? Administration of a large dose of a nondepolarizing relaxant requires more time for onset than succinylcholine and

produces total paralysis. There is not enough clinical evidence to answer this question conclusively, and, at present, it remains a matter of clinical judgment.

In some cases another clinical choice is now available since the U.S. Food and Drug Administration (FDA) approval of sugammadex in December 2015. Sugammadex is a reversal agent with a novel and unique mechanism of action. It is a cyclodextrin that irreversibly chelates aminosteroid muscle relaxants by forming a 1 : 1 tight complex (encapsulation) with the relaxant molecule, which reduces the concentration of the free drug in plasma below the minimum necessary for muscle relaxation. A Cochrane review found sugammadex to be an effective reversal agent without evidence of increased frequency of adverse effects when compared to neostigmine.[134] In fact, sugammadex has been found to provide more rapid recovery of more than 90% twitch strength than either spontaneous recovery with succinylcholine or reversal with neostigmine.[134] Sugammadex has a lower affinity for pancuronium, and higher doses are required for this agent than for rocuronium or vecuronium. Although the frequency of adverse effects due to sugammadex has been very low, there have been some serious complications associated with its administration, including anaphylaxis and severe bradycardia requiring chest compressions. Another more common issue relates to the potential for sugammadex to inactivate hormonal contraceptives. Female patients treated with contraceptives should be advised to use an alternative form of contraception for a period after receiving sugammadex.

As of this writing (January 2017), sugammadex has not yet received FDA approval for pediatric patients, and most reported pediatric data are in the form of case reports and small studies. The clinical experience with sugammadex in children has been reviewed by Tobias.[135] Sugammadex has been found to be an effective rescue agent in situations where pediatric patients cannot be intubated or ventilated. It has also proved useful in pediatric patients with neuromuscular diseases such as Duchenne muscular dystrophy and myotonic dystrophy.[135] In some situations rocuronium might be an additional choice to relieve laryngospasm in an acute burn patient when there is a risk of intubation or ventilation impossibility if sugammadex is available since it can reverse relaxation with rocuronium faster that spontaneous recovery from succinylcholine. Still, the onset of action for rocuronium is slower than for succinylcholine.

Responses to nondepolarizing relaxants are also altered by burn injury. Three- to fivefold greater doses are required to achieve adequate relaxation.[122] Resistance is apparent by 7 days after injury and peaks by approximately 40 days. Sensitivity returns to normal after approximately 70 days. Two reports described slight but measurable resistance to nondepolarizing relaxants persisting for more than a year after complete healing of the wounds. The mechanism of the altered response appears to involve pharmacodynamic rather than pharmacokinetic changes. Up-regulated immature receptors are less sensitive to nondepolarizing relaxants. Burns of greater than 25% TBSA require higher total dose and greater plasma concentrations of nondepolarizing blockers to achieve a given level of twitch depression.[124]

Proliferation of acetylcholine receptors across the muscle membrane has been used to explain both resistance to nondepolarizing muscle relaxants and the exaggerated hyperkalemic response to succinylcholine.[127] The observation of resistance of a patient to metocurine for up to 463 days after the burn has been used to suggest that hyperkalemic responses to succinylcholine also could persist for more than a year.[123] However, no pathologic hyperkalemic responses to succinylcholine in burned patients have been reported more than 66 days after burns.[129]

In contrast to other nondepolarizing neuromuscular blockers, mivacurium dosage requirements in pediatric patients appear to be unchanged by the burn injury. The time to onset of drug action, the degree of paralysis achieved by a specific dose, and the rate of infusion required to maintain a given level of relaxation were all the same in burn patients as values reported for nonburned control patients.[136] Plasma cholinesterase activity is reduced in burn patients.[137] In a study by Martyn, the observation of an inverse relationship between plasma cholinesterase activity and recovery time of 25–75% twitch tension suggests that reduction of metabolic degradation of mivacurium may compensate for other factors that induce resistance to relaxants.[136] This observation suggests that mivacurium can be administered to burn patients in normal doses that would avoid cardiovascular perturbations associated with required larger doses of other relaxants in burn patients. It also illustrates the complex nature of altered drug responses in burned patients.

Airway Management

If injuries do not preclude conventional airway management (i.e., mask fit, jaw lift, and mouth opening), standard induction and intubation procedures are appropriate. Hu et al. reported that gastric emptying was not delayed in patients with severe burns so that a rapid-sequence induction is not necessary.[138] However, attention should be given to gastric residuals during enteric feeding. Development of sepsis can slow gastric emptying, which can result in retained fluids in the stomach and risk of aspiration.

When burns include the face and neck, swelling and distortion may make direct laryngoscopy difficult or impossible. In addition, loss of mandibular mobility may impair airway manipulation and make mask ventilation difficult. Fiberoptic intubation while maintaining spontaneous ventilation is a safe and reliable technique under these conditions. Fiberoptic intubation can be performed in awake adults but pediatric patients are unable to cooperate and must be sedated. Since most anesthetics cause the collapse of pharyngeal tissues and airway obstruction, they are unsuitable for fiberoptic intubation in patients whose airway would be difficult to manage with a mask.[139] Ketamine, however, is unique among anesthetic drugs because it maintains spontaneous ventilation and airway patency.[140]

Ketamine anesthesia has been found safe and effective for airway management in infants with difficult airways caused by congenital airway anomalies. Reports of successful nasotracheal intubation in infants with congenital airway malformations have been made both by manipulations guided by fiberoptic nasopharyngoscopy and the conventional technique of fiberoptic intubation with the endotracheal tube mounted on the fiberscope.[141,142] In the latter case an ultra-thin bronchoscope (2.7 mm) was required

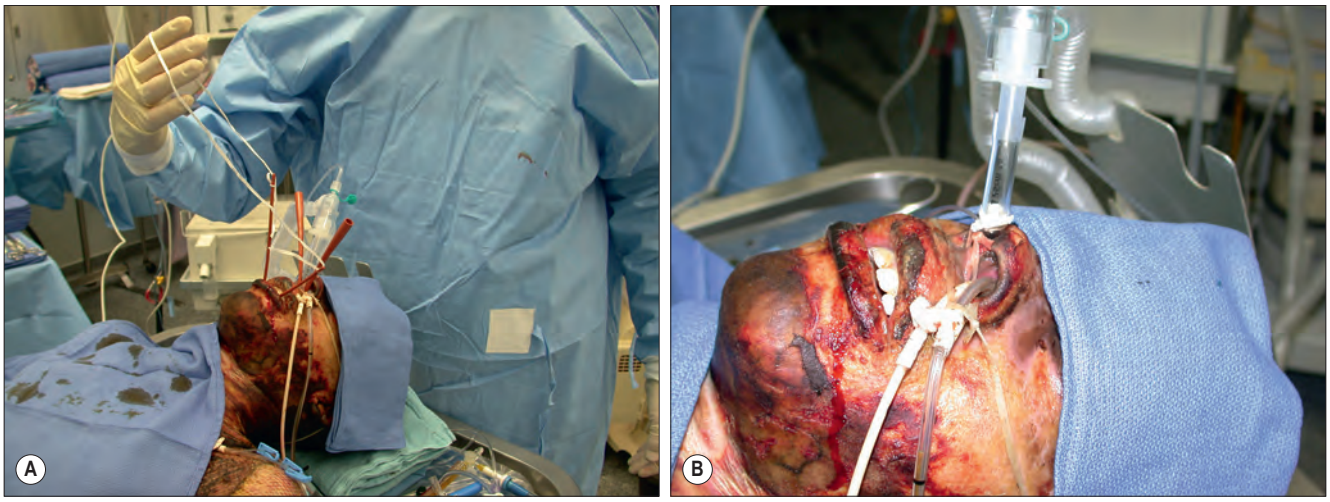

Fig. 13.8 A nasotracheal tube can be secured with confidence with a loop of umbilical tape around the bony nasal septum. (A) Red rubber catheters have been passed through each naris and retrieved from the oropharynx using McGill forceps. A length of umbilical tape is then tied to each of the catheters. When the catheters are pulled from the nose, the umbilical tape can be tied in a loop around the nasal septum. (B) Endotracheal tube, nasogastric tube, and duodenal feeding tube are all secured in place after being tied to the septal bridal. When fastened in this manner the endotracheal tube is very secure, and tape or ties do not irritate burn wounds of the face and neck.

because a larger fiberscope would not fit through the appropriate-sized endotracheal tube. To facilitate intubation under ketamine anesthesia, topical anesthesia of the larynx with lidocaine prior to instrumentation of the larynx is advised. Since the ultra-thin bronchoscope lacks a working channel for administration of topical lidocaine, fiberoptic intubation with the 2.7-mm bronchoscope was preceded by nasopharyngoscopy with a 3.5-mm fiberscope for administration of topical lidocaine. At SBH Galveston we have also found this technique, utilizing two fiberscopes, effective in infants with burn injuries. Wrigley et al. evaluated the use of a 2.2-mm intubating fiberscope during halothane anesthesia in ASA 1 or 2 children aged 6 months to 7 years.[143] In this series of 40 patients, a number of complications were experienced including laryngospasm and failure to achieve intubation with the fiberscope. This experience is in contrast to numerous reports of safe and effective airway management with ketamine.

Securing an endotracheal tube in a patient with facial burns presents a variety of problems, and numerous techniques have been described.[144] Tape will not adhere to burned skin and ties crossing over burned areas will irritate the wound or dislodge grafts. In addition, if the head is burned, especially if the patient has also required a large fluid resuscitation, then during the first few days after injury, the head is swelling due to edema formation or shrinking as edema resolves. Under these conditions tape surrounding the head will become loose or too tight within hours. A useful technique to avoid these problems involves the use of a nasal septal tie with one-eighth-inch umbilical tape (Fig. 13.8). The umbilical tape is placed around the nasal septum using 8 or 10 French red rubber catheters that are passed through each naris and retrieved from the pharynx by direct laryngoscopy and McGill forceps. A length of umbilical tape is tied to each of the catheters, and, when the catheters are pulled back through the nose, each end of the umbilical tape is pulled out of its respective naris, producing a loop around the nasal septum. Before securing with a knot, care should be taken to assure that the uvula is not captured in the loop. A knot in the nasal septal tie should be snug enough to prevent excessive movement of the endotracheal tube but loose enough to prevent ischemic necrosis of the underlying tissues. Nasal endotracheal tubes are often avoided in ICUs due to concern for sinusitis. However, nasogastric or nasal feeding tubes carry similar risk. Over the past 25 years our hospital has had two patients with suspected sinusitis. Sinus cultures from these patients were negative for bacterial growth (unpublished observations). The nasal endotracheal tube is much more secure than an oral tube, better tolerated by the patient, and the patient cannot occlude the nasal tube by biting it.

A red rubber catheter may also be used to secure an oral endotracheal tube (Fig. 13.9). A red rubber catheter is placed in a nostril and brought out the mouth by direct laryngoscopy and MacGill forceps. A loop is formed which the endotracheal tube is secured to with umbilical tape. This is very secure and avoids ties around the neck, which can irritate wounds and grafts, and the problem of changing head circumference due to formation and resolution of edema.

Airway management using a laryngeal mask airway has also been used successfully during burn surgery for children. McCall et al. reported their experience with 141 general anesthetics administered to 88 pediatric burn patients.[145] Nineteen (14.5%) of the procedures were complicated by respiratory events such as unseating, desaturation, and partial laryngospasm that required intervention. Two of these events required intraoperative intubation without sequelae, while all other events resolved with therapy. Interestingly the presence of preoperative respiratory problems or face/neck burns did not predict intraoperative respiratory problems. These authors suggest that, in patients with upper airway mucosal injury, laryngeal mask airway management may help avoid further

Fig. 13.9 An oral endotracheal tube can be secured to a loop created by a red rubber catheter (or similar device) passed through the nose and brought out the mouth. When the endotracheal tube is fastened to this loop there are no ties surrounding the head and neck which can irritate burn wounds and disrupt grafts. Note also the nasal pulse oximeter probe, which has undergone significant improvements recently. Other sites for pulse oximetry, such as ears and fingers, are frequently unavailable in patients with large burns.

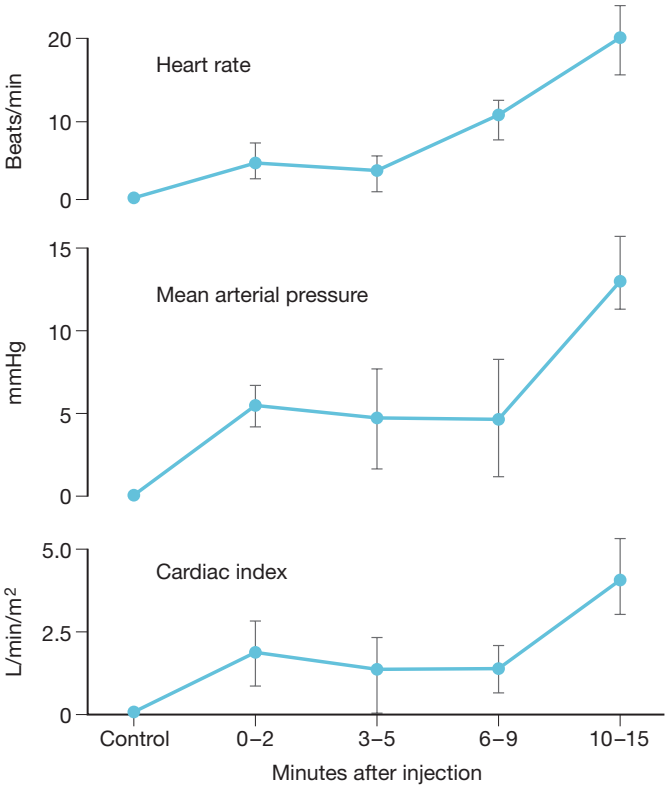

Fig. 13.10 Heart rate, mean arterial pressure, and cardiac index changes during a 15-min period of ketamine administration to critically ill patients. (From Nolan JP. Intravenous agents. In Grande CM, et al., eds. *Textbook of trauma anesthesia and critical care.* St. Louis: Mosby Yearbook; 1993.)

laryngeal injury that might occur with intubation of the trachea.

Hagberg et al. published a case report describing the successful use of an esophageal tracheal Combitube in a patient undergoing elective surgery for burn scars involving the mouth.[146] The patient had a class IV oral airway by Samsoon and Young's modification of the Mallampati airway classification and limited mouth opening. A translaryngeal endotracheal tube was undesirable because tracheostomy had resulted in subglottic stenosis that could have been exacerbated by an endotracheal tube. After induction with fentanyl and propofol, the Combitube was placed and the patient was relaxed with rocuronium and mechanically ventilated during the 60 min procedure.

Monitors

As with any critically ill patient suffering from multiorgan system involvement, the choice of monitors in a burned patient will depend on the extent of the patient's injuries, physiological state, and planned surgery. In addition to the preoperative pathophysiology associated with thermal injuries, perioperative monitoring must be adequate to assess rapid changes in blood pressure and tissue perfusion associated with the massive blood loss that can accompany excision of burn wounds. The minimum standards of the American Society of Anesthesiologists require monitoring of circulation, ventilation, and oxygenation. Standard monitors include electrocardiography (EKG), measurement of systemic blood pressure, pulse oximetry, capnography, and inspired oxygen concentration. The ability to measure body temperature should be readily available and is highly recommended for the burn patient.

Standard EKG gel electrodes usually will not adhere to burn patients because the skin is injured or covered with antibiotic ointment. For acute burn surgery, surgical staples and alligator clips are useful. Respiratory rate can be quantitated using bioimpedance from the EKG signal or from the capnogram. Pulse oximetry in burn patients can be difficult when transmission pulse oximetry sites are either burned or within the operative field. Reflectance pulse oximeter probes are now available, and nasal clip probes are much improved (Fig. 13.10 with oral red rubber).

If direct arterial pressure monitoring is not necessary, a blood pressure cuff can provide accurate measurements even if placed over bulky dressings applied to an extremity.[147] Systolic blood pressures obtained from the pressure at which the pulse oximetry signal returns during cuff deflation have also been found to be accurate.[148]

When vasoactive infusion is needed or blood loss is expected to be rapid and extensive, the blood pressure may change more rapidly than the interval between cycles of noninvasive blood pressure measurement. In this case an arterial catheter can provide direct and continuous measurement of blood pressure. This monitor can provide much more information regarding the patient's circulatory status than just systolic and diastolic blood pressure. The arterial pressure wave form is influenced by preload, contractility, and vascular tone. Perioperative variation in the rate of rise of arterial pressure, the area under the pressure wave, position of the dicrotic notch, and beat-to-beat alterations in systolic pressure related to respiration all reflect clinically significant hemodynamic changes.[149] With experience, trends in these variables can help guide volume and vasoactive therapy. Display of the beat-to-beat arterial pressure allows measurement of systolic pressure variation (SPV)

and other measures sensitive to variation in stroke volume. These dynamic measures of the interaction between preload and stroke volume have been used to predict the response to fluid volume administration. SPV is the difference between maximum and minimum systolic blood pressure during a single cycle of positive pressure mechanical ventilation. Several studies have correlated SPV with cardiac output response to volume infusion. Tavernier et al. reported that in septic patients on mechanical ventilation, SPV is a better predictor of left ventricular ejection volume response to volume loading than either pulmonary artery occlusion pressure or echocardiographic measurement of left ventricular end diastolic area.[150] When hemorrhage is brisk, the decision to administer volume is not difficult. In other cases during burn wound manipulation, hypotension and other evidence of poor perfusion can occur in the apparent absence of significant blood loss. Inappropriate fluid administration can cause hemodilution, increased cardiac filling pressure, and fluid overload. Measurement of central venous pressure (CVP) can indicate if there is room in the intravascular space for volume administration, and dynamic measures of fluid responsiveness can identify patients who will respond to fluid loading with an increase in cardiac output and tissue perfusion. The use of these dynamic measures of fluid responsiveness, as well as their limitations, have been reviewed recently.[151] However no single physiological variable can be relied on to correct all deficiencies in perfusion during burn wound debridement. Wound manipulation can release inflammatory mediators and bacterial products that alter myocardial compliance and contractility as well as vascular tone. During challenging cases with brisk bleeding volume replacement alone may not correct hemodynamic deficiencies. It is necessary to monitor blood gases, electrolyte changes, and urine output, as well as arterial and central venous pressures. Inadequate tissue perfusion may manifest as metabolic acidosis despite apparently adequate arterial and central venous blood pressures.

Arterial blood sampling for blood gas analysis can also provide valuable information regarding pulmonary function and ventilatory support, acid–base balance, and electrolyte abnormalities. Blood samples from a central vein are not truly mixed venous, but trends in central venous oxygen tension can help identify inadequate tissue perfusion. A CVC sutured into place also provides very secure intravenous access and is an ideal route for administration of vasoactive infusions. A pulmonary artery catheter is usually not required for burn surgery. In some cases, however, the ability to more closely monitor ventricular function and oxygen supply/demand relationships may be helpful in the presence of pre-existing disease or when large doses of inotropes or high PEEP is required.

Urine output is the most useful perioperative monitor of renal function. Urine output of 0.5–1.0 mL/kg per hour is often recommended as an end point for fluid management in acute burn patients. Adequate urine output is one measure of both renal and global perfusion. When intraoperative transfusion is planned, examination of the urine may be the only reliable indicator of a transfusion reaction since signs and symptoms other than hematuria are masked by general anesthesia or hemodynamic changes associated with burn surgery. Myoglobinuria may also occur after burn injury, and, in this case, a Foley catheter is necessary to monitor response to therapy. Diuretic therapy for myoglobinuria or any other indication will negate the usefulness of urine output as an index of global perfusion.

Vascular Access

Care of patients with major burn injury requires secure vascular access for resuscitation, blood sampling, hemodynamic monitoring, and intravenous medication. In patients with large burns a CVC can serve several functions. Extensive burns may preclude cannulation of peripheral veins. A CVC sutured in place can provide secure access longer than a peripheral catheter can be maintained. Multiport catheters can provide a monitor of CVP while infusing blood or other fluids and can allow simultaneous infusion of incompatible drugs.

Vascular cannulation of acutely burned patients can be one of the more technically challenging procedures facing the burn care team. Anesthesiologists are often involved in the management of vascular access for burn patients. In the pediatric age group the task can be even more difficult. Sites for percutaneous insertion of vascular catheters may be involved in the burn and nonburned sites are often distorted by burn wound, edema, or trauma. Early after burn injuries burn shock is associated with hypovolemia and vasoconstriction, which add to the difficulty. Later in the hospital course debridement and scarring further distort anatomy.

Because the systemic manifestations of wound infection and SIRS mimic those of catheter-related bloodstream infections, vascular catheters are changed to new sites more often than in nonburned patients. In addition, CVCs appropriate for ICU care are not always appropriate for rapid infusion of fluid and blood products during surgery, often necessitating placement of new catheters in the operating room. With hospitalization for major burns lasting weeks and months, patients may need multiple cannulations over a prolonged time period. With multiple technically difficult vascular cannulations over a prolonged period, risks of infectious and mechanical complications are significant. In addition to immediate mechanical complications of line insertion, repeated cannulation of vessels can result in thrombosis, which can be a source of embolic events, and the vessel can be obliterated, causing venous stasis and limiting future access. These considerations make it necessary to minimize the number of cannulations as much as possible, especially for patients expected to have a long hospital course. Infectious complications are as much a consideration as mechanical complications in burn patients. Open, possibly infected wounds near or at the insertion site as well as bacteremia that may occur during wound care increase the risk of line infection. Although it is commonly assumed that arterial catheters are less susceptible to infection, studies show that the rates are similar for arterial and central venous catheters.[152] However, since the risk of mechanical complications for femoral arterial cannulation is greater (see later discussion), the risk–benefit relationship of changing sites or exchanging over a wire is less favorable for arterial catheters than venous. There is no consensus, and a great deal of variation exists between burn centers regarding policies and procedures to minimize these risks.

Early complications of the placement of venous catheters include trauma, hematoma, bleeding, air embolus, pleural effusion, pneumothorax, or pericardial tamponade. Late complications include venous thrombosis, infection, and infiltration. Complications of arterial catheters include damage to adjacent structures, ischemia to distal tissues, and infection.

Ultrasound-guided placement of vascular catheters is now widely recommended.[153,154] This technique has been found to be faster and associated with fewer complications than cannulation with anatomical landmarks. Few studies, however, compare ultrasound-guided cannulation outcomes with other techniques in burn patients. The combination of massive edema, hypovolemia, vasoconstriction, and acoustic shadows from scars all degrade the ultrasound image. Practitioners should not rely solely on one technique but should be able to utilize multiple techniques including ultrasound, anatomical landmarks, a palpable pulse, and pencil Doppler signal to place vascular catheters.

When possible, if a percutaneous insertion site is involved in the burn wound, it is best to have surgical debridement accomplished before insertion. This facilitates both ease of placement and infection control. Catheter selection must take into account multiple clinical needs: blood sampling, hemodynamic monitoring, rapid infusion of large volumes of fluid and blood products, and infusion of medications that may be incompatible with each other. A lumen large enough to allow rapid infusion of volumes appropriate to the patient's size is necessary. When blood loss is expected to be extensive, it is helpful to monitor CVP. Although CVP correlates poorly with hemodynamic function in populations of patients, when hypotension or anemia occur, knowledge of whether the CVP is high or low can help decide if an inotrope is appropriate or if there is room in the vascular space to increase the hematocrit quickly. In addition, ICU management may require a different catheter. Some compromise or a change of catheters prior to transport to the ICU may be needed.

In recent years peripherally inserted central catheters (PICCs) have been used in burn patients. The advantages of these devices over conventional CVCs are the ease of insertion, reduced risk of some complications of CVCs, and reduced cost. At the time of this writing the largest study of complications associated with PICCs is by Austin and colleagues who described their clinical experience with 53 patients and reviewed the literature.[155] While the use of a PICC avoids some risk of a CVC, such as pneumothorax or hemothorax, the PICC carries its own unique risks. The incidence of catheter-related infections may be similar for PICCs and CVCs. Despite the use of antithrombotic prophylaxis upper extremity deep vein thrombosis (UEDVT) that can lead to fatal embolic events has been associated with PICC placement. Burn patients are often hypercoagulable and, as a result, are at risk for occlusive and embolic events. Austin et al. found symptomatic UEDVT in 5.5% of patients with PICC lines in place.[155] UEDVT associated with PICC lines appears to increase with duration longer than 7 days and with increasing diameter of the catheter. Austin and colleagues describe the PICC as an accepted standard of care for burn patients but not without risk. The decision of whether to use a PICC or a conventional CVC must balance the risks and benefits of these devices for each patient.

Table 13.3 Changes That Occur During Storage of Whole Blood in Citrate-Phosphate-Dextrose

	Days of Storage at 4°C			
	1	7	14	21
pH	7.1	7.0	7.0	6.9
P_{CO_2} (mm Hg)	48	80	110	140
Potassium (mEq/L)	3.9	12	17	21
2,3-Diphosphoglycerate (μmol/mL)	4.8	1.2	1	1
Viable platelets (%)	10	0	0	0
Factors V and VII (%)	70	50	40	20

Maintaining arterial catheters in burn patients presents an additional challenge. Radial artery catheters are problematic because the hands are often burned, and it is difficult to maintain them over prolonged periods in burn patients. As a result most burn centers rely on femoral artery catheters when arterial cannulation is indicated. Since the femoral artery is an end artery, mechanical injury can lead to the devastating complication of the loss of lower extremity tissue. For this reason it is essential to have a clear indication for arterial cannulation (Table 13.3). In many cases clinical decisions can be made with analysis of venous blood samples rather than arterial blood.

Studies in nonburned patients have compared rates of infection of different insertion sites. In nonburned patients it is recommended that cannulas not be changed over a wire to avoid infection.[156] It is also recommended that catheters not be changed in response to fever alone, and, when universal precautions are followed, catheters can be left in place for prolonged periods. However in burn patients requiring prolonged hospitalization it is often necessary to utilize all available sites as catheters are rotated to fresh sites. Also, the increased risk of line infection in patients with burns and the confounding signs and symptoms of systemic inflammation from the burn wounds that mimic catheter-related bloodstream infection make it difficult to follow guidelines established for nonburned patients. Lozano and colleagues found 9.36 catheter-related infections per 1000 catheter days when vascular catheter sites were changed only with signs of infection as per guidelines from the U.S. Centers for Disease Control and Prevention (CDC) but only 3.23 per 1000 catheter days when the sites were routinely changed every 5 days. As a result, in most burn centers, vascular insertion sites are changed more frequently than in ICUs caring for nonburn patients. Many centers will also change catheters over a wire and culture the catheter tip after a certain period of time. If the tip is colonized a new site can be cannulated. It is difficult to form universal protocols for vascular access in burn patients since they comprise such a heterogeneous group. Decisions regarding site of cannulation and when to change sites are influenced by multiple factors including which sites are available, previous complications, surgical scheduling, ICU management (e.g., need for total parenteral nutrition), and evidence of infection (wound- or catheter-related). Incidence of catheter infection increases when the insertion site

is in or near burn wounds.[157] With limited sites available it is tempting to leave catheters in unburned sites longer than in sites through burn wounds. Decisions are best guided by the general goals of minimizing infection and mechanical complications but should be individualized for each patient's immediate needs.

Although arterial catheters are generally considered less likely to be associated with infection, these catheters are infected with a frequency similar to CVCs.[152] There are fewer sites for arterial cannulation, however, and the risk of serious mechanical complications of femoral artery injury are potentially greater than with venous catheters. As a result, femoral arterial catheters are often left in place longer than venous cannulas.

Delayed complications include infection and thrombosis, which have been studied by many authors with often conflicting results. Many older studies recommend frequent catheter changes to decrease the incidence of infection, but several later studies show no increase in infection out to as many as 7–10 days. Three large randomized trials demonstrated no difference in the incidence of catheter-related infections among groups who had lines placed at a new site every 7 days and groups who had their lines changed over a guidewire every 7 days.[158–160] The incidence of mechanical complications is lower with guidewire exchange rather than changing to a new site.[161]

Vascular catheters that incorporate an antibiotic have been found effective in reducing the incidence of catheter-related bloodstream infections in burn patients. A prospective, randomized trial examined the efficacy of two types of CVCs that incorporate antibiotics: one catheter releases silver ions continuously, and the other is impregnated with two antibiotics with different mechanisms of action, rifampicin and minocycline. Both catheters were associated with low rates of catheter-related bloodstream infections.[162] If effective, these catheters can provide two significant clinical advantages. Reduced colonization of CVCs will reduce the risk of blood-borne infections, and reduced need for changes in vascular access sites for infection control will reduce the incidence of mechanical complications of catheter insertion. However, as with other clinical decisions with burn patients, the data from studies in burn patients make it difficult to form guidelines. Studies consistently show decreased rates of bloodstream infection, but the rates of infection between burn centers are greater than the effect of using antibiotic-impregnated catheters.[163,164] Moreover, since catheters are changed much more frequently in burn patients, often every 72 hours, and even earlier with signs of infection, the cost benefit in burn patients is not established.

When planning vascular access for perioperative anesthetic management it is important to be aware of and take into account the patient's hospital course. Choice of access site should avoid vessels previously involved in complications such as thrombosis or vascular injury. Note must be taken of when existing catheters were placed and what the local convention is with regard to timing of regular changes of access sites for infection control. The patient's hospital course must also be considered when choosing a catheter. The catheter should be large enough to transfuse appropriately for the case, but catheters much larger will increase risk without benefit.

Patient Transport

The safe transport of a critically ill burn patient to and from the operating room can be a formidable task. A methodical approach will help to ensure patient safety and the seamless maintenance of respiratory, hemodynamic, and general support. Hemodynamic status should be optimized prior to patient transport; pharmacological support may be required. The American Society of Anesthesiologists standards mandate evaluation, treatment, monitoring, and equipment appropriate to the patient's medical condition for any transport. Depending on the patient's condition, simple observation may be appropriate. Patients requiring supplemental oxygen should be monitored by pulse oximetry. Hemodynamic monitoring is guided by the patient's hemodynamic status. Sufficient battery power must be available for uninterrupted monitor and infusion pump function during transport.

Airway supplies should be readily available, including a full oxygen cylinder, a self-inflating Ambu bag with mask, and intubation equipment. The patient's airway and ventilation, as well as overall condition, must be continually observed by the anesthesia care team. Drugs for resuscitation should accompany the patient on any transport. As discussed earlier, hypothermia is poorly tolerated by patients with an acute burn injury. It is imperative that patients be kept warm during transport in order to avoid increasing oxygen consumption and taxing limited metabolic reserve

Selection of Anesthetic Agents

Many anesthetic agents have been used effectively for the induction and maintenance of anesthesia in burn patients. Intravenous agents can be used for both induction and maintenance, and the specific agent used will depend primarily on the patient's hemodynamic and pulmonary status as well as on the potential difficulty of securing the patient's airway. Ketamine has many advantages for use in the burn patient for induction and maintenance of anesthesia. As an induction agent, ketamine can be administered at a dose of 0.5–2.0 mg/kg. Except in patients who are catecholamine depleted, ketamine generally preserves hemodynamic stability (Fig. 13.10). In addition, ketamine preserves hypoxic and hypercapnic ventilatory responses and reduces airway resistance.[165] Compared to other IV anesthetics, airway reflexes remain more intact after ketamine administration. Patients who do not require ventilatory support can be allowed to breathe spontaneously, which provides an additional margin of safety should inadvertent extubation occur. In fact, some clinicians have reported the use of ketamine anesthesia without instrumentation of the airway.[166,167] Patients were allowed to breathe spontaneously, and the airway complication rate was comparable to that of intubated patients. The use of intramuscular ketamine can be beneficial in securing the airway of pediatric burn patients or uncooperative adults who do not have vascular access. Because ketamine preserves spontaneous ventilation and induces dissociative anesthesia, it provides good conditions for securing the airway by fiberoptic bronchoscopy. When using this

technique, the addition of potent volatile agents should be avoided until the airway is secured because these anesthetics depress respiratory drive and relax pharyngeal muscles, thus increasing the risk of apnea, upper airway obstruction, or laryngospasm. Ketamine can also be utilized, either alone or in combination with other anesthetics, for maintenance of anesthesia either by infusion or intermittent bolus. Ketamine has potent analgesic properties and is used extensively in the operating room as well as for painful dressing changes and procedures such as line insertion. A drying agent such as glycopyrrolate (2–5 μg/kg) may be given in combination with ketamine to reduce ketamine-induced secretions. Delirium during emergence from ketamine sedation is more common in adults. This is often treated with midazolam, but dexmedetomidine may be more effective and also attenuates hypertensive and tachycardic effects of ketamine.[168] Dexmedetomidine also reduces the dose of ketamine required.[169]

Propofol is the most common intravenous induction agent used in burn patients. Dose requirements for propofol will vary over time after the initial burn injury. Initially, with hypovolemia and reduced cardiac output, a lower dose may be required but as the hyperdynamic circulatory pattern develops the V_d and clearance rate for propofol are increased enough to increase dose requirements.[170]

Volatile anesthetics may be used for both induction and maintenance of anesthesia in burn patients. In pediatric patients, mask induction with sevoflurane is commonly used if the patient does not have injuries that may make airway manipulation difficult. In the acute setting, an anesthetic technique involving nasotracheal intubation after mask induction with halothane, nitrous oxide, and oxygen has been described.[171] The proponents particularly emphasize avoiding the potential problems associated with the ketamine-based technique. However volatile agents produce dose-dependent cardiac depression and vasodilation. In addition, hypoxic ventilatory drive is ablated by volatile anesthetics at low concentrations, and a dose-dependent depression of hypercapnic drive also occurs. However, as maintenance agents, volatile anesthetics have predictable wash-in and wash-out kinetics and provide a useful adjunct to other agents when titrated to hemodynamic and ventilatory parameters. Of the volatile agents, nitrous oxide has the least impact on cardiovascular and respiratory function and can serve as a useful component of a balanced anesthetic if the patient's oxygen requirements permit.

Opioids are important agents for providing analgesia for burn patients throughout the acute phase of injury and for providing postoperative analgesia in patients undergoing reconstructive procedures. The spectrum of opioids currently available provides a wide range of potencies, durations of action, and effects on the cardiopulmonary system. Burn patients experience intense pain even in the absence of movement or procedures, and opioids are the mainstay for providing analgesia in the acute phase of burn management. Selection of dosage must take into account the fact that acute burn patients usually become tolerant to opioids due to continuous and prolonged administration. Therefore opioids should be titrated to effect in the acute burn patient. Most opioids have little effect on cardiovascular function, but they are potent respiratory depressants. Therefore the ventilatory status of patients receiving opioids, particularly those with challenging airways, should be monitored closely.

Regional anesthesia can be used effectively in patients with small burns or those having reconstructive procedures. In pediatric or adult patients having procedures confined to the lower extremities, lumbar epidural or caudal anesthesia can provide a useful adjunct for control of postoperative pain. In cooperative adult patients with injuries confined to lower extremities, epidural or intrathecal anesthesia may be used if no contraindications exist. For upper extremity procedures, brachial plexus block may be considered as the primary anesthetic or as an adjunct for postoperative pain control.

Scalp donor sites are particularly painful. Sensory nerves to the scalp are superficial and easily blocked with injections of local anesthetic, and this technique has been used for awake craniotomy.[172] Scalp blocks have been used with success at our institution for donor sites in acute patients (unpublished observation) and for scalp procedures in reconstructive patients.[173]

Fluid Management

Fluid management and blood transfusion for burn wound excision can be quite challenging. Fluid administration should be guided not only by intraoperative events but previous hospital course and ICU treatment goals. If excision is performed during the first 24 hours, perioperative fluid management may involve acute resuscitation, and fluid needs will exceed replacement of shed blood. Even after this period insensible fluid requirements are increased by large open surfaces from excised wounds, hypermetabolic state, and hyperthermia. However, early in the patients' hospital course, patients are edematous from the large amounts of crystalloid solutions administered during resuscitation. At this time additional crystalloid administered during the perioperative period may be poorly tolerated and may result in complications of compartment syndrome in extremities or the abdomen. After the initial period of resuscitation ICU therapy may include vigorous attempts to reduce edema including the use of diuretics. If the ICU staff have been administering diuretics to the patients all week in order to reduce interstitial edema, it is not helpful when the patient receives several liters of fluid in the operating room. Perioperative fluid management must also take into account hypotonic clysis fluids that the surgeons may inject subcutaneously to facilitate donor skin harvest with the dermatome. In small children the volume of this fluid can be in excess of 50 mL/kg. State of hydration and electrolyte balance must be monitored carefully in order to maintain proper fluid balance. Although it is important to avoid overhydration, aggressive diuresis in the burn ICU may result in a patient who presents to the operating room intravascularly hypovolemic despite extensive peripheral edema.

Replacement of surgical blood loss during burn wound excision and grafting represents another challenge. Unlike most general surgical procedures, during burn surgery it is impossible to accurately estimate the amount of shed blood during the procedure. Shed blood is not collected in suction canisters where it can be measured. During burn surgery shed blood is concealed beneath the patient, in drapes, in

sponges, or may be washed down a drain on the operating table. As discussed earlier regarding the initial resuscitation, there is no one physiological end point to titrate volume replacement. Arterial pressure may be maintained by vasoconstriction despite significant hypovolemia, CVP is not a reliable index of preload, changes in urine output and hematocrit lag behind rapid reductions in blood volume, and metabolic acidosis may indicate deficient perfusion but does not identify the specific problem. All of these variables are useful, however, when evaluated together. Although systolic blood pressure may be within the normal range, alterations in the arterial wave form and changes with the respiratory cycle may indicate hypovolemia. Even though CVP correlates poorly with hemodynamic function, this variable is useful in determining if volume administration will be tolerated by the patient. If the perfusion appears inadequate and CVP is low or normal it is safe to give volume. If CVP is elevated, volume administration may cause pulmonary edema.

The concept of *transfusion trigger* with regard to burn care is discussed in the next section. It must be remembered, however, that during rapid blood loss the hematocrit may change more slowly than the blood loss, and often blood must be administered in anticipation of the hematocrit falling below a specific trigger.

BLOOD TRANSFUSION

The need for blood transfusion is usually not a major concern during the immediate resuscitation phase in acutely burned patients unless other coexisting trauma exists. In fact, when the resuscitation is inadequate, the hematocrit will be elevated. Nevertheless a fall in plasma hemoglobin concentration can occur during the acute resuscitative phase due to hemodilution and blood loss from escharotomies and other invasive procedures.[174] However major blood loss is common during excision and grafting of burn wounds. Desai and colleagues reported that the amount of blood loss during burn wound excision is determined by the age of the burn, the body surface area involved, and whether infection is present (see Table 13.1).[12] In general, more blood loss was observed as the time from initial injury increased and if wounds were infected. Transfusion requirements ranging from 0.45 to 1.25 mL of packed red blood cells (PRBCs) per cm^2 burn area were reported. In another study, Criswell and Gamelli reported an average transfusion rate of 0.89 mL PRBC/cm^2 burn area in a cohort of adult burn patients.[175] A study by O'Mara and colleagues showed an average transfusion rate of 0.65 mL PRBC/cm^2 in a heterogeneous group of burn patients.[176]

Controversy exists regarding transfusion triggers and targets. Some authors advocate allowing hematocrit to drop to 15–20% prior to transfusion in otherwise healthy patients undergoing limited excision and transfusing at a hematocrit of 25% in patients with pre-existing cardiovascular disease.[177] The same group proposed maintaining hematocrit near 25% in patients with more extensive burns and near 30% if the patients have pre-existing cardiovascular disease. A small study by Sittig and Deitch showed fewer transfused units and no increase in adverse hemodynamic or metabolic effects in patients transfused at a hemoglobin of 6–6.5 g/dL compared to patients maintained at a hemoglobin near 10 g/dL.[178] However, in general, few outcome data exist regarding the optimum transfusion trigger for blood transfusion during burn wound excision. Assessment of blood transfusion needs is best determined by evaluating the clinical status of the patient; specifically, assessment of ongoing blood losses, preoperative hemoglobin levels, vital signs, and urine output. Metabolic evidence of inadequate oxygen delivery such as acidemia and decreasing mixed venous oxygen tension provide important information regarding the oxygen balance in the patient. Patients with coexisting cardiac and pulmonary disease generally require higher oxygen-carrying capacity. Oxygen requirements will be determined by the type and severity of coexisting conditions. Overall American Society of Anesthesiologists guidelines indicate that blood transfusion is rarely required at a hemoglobin of 10 g/dL or above and is almost always indicated at a hemoglobin of less than 6 g/dL.[179]

During excision of large burn wounds, patients may require one or more blood volumes of transfused blood to replace intraoperative blood losses. Massive blood transfusion can be associated with a variety of complications, and the use of blood products is associated with significant financial costs.[175] Several means of decreasing surgical blood loss during burn wound excision may be employed, such as the use of tourniquets on limbs and compression dressings at sites of burn wound excision or skin graft harvesting.[180] Tourniquets have been shown to be an effective strategy for decreasing blood loss during burn wound excision.[176] The drawbacks of tourniquet use are that their effectiveness is limited to surgery on the extremities and they may interfere with the surgical field. Pharmacological interventions that may decrease blood loss include the use of epinephrine-soaked dressings or topical epinephrine spray to induce local vasoconstriction. Alternatively subcutaneous tissues may be infiltrated with epinephrine-containing fluids. The use of epinephrine may be associated with tachycardia and hypertension if significant amounts are absorbed into the systemic circulation. However some studies have reported that the use of topical or subcutaneous epinephrine in burn patients is not associated with an increased incidence of side effects or complications.[181]

The effectiveness of this approach is, however, unclear. A recent study showed that the use of topical epinephrine spray or subcutaneous epinephrine infiltration did not result in decreased blood loss during burn wound excision.[182] However the data were quite variable, and the patients also received topical thrombin. A larger study examining the effects of subcutaneous epinephrine and topical thrombin might clarify this issue. In a more recent study, Mzezewa and colleagues reported that treatment with systemic terlipressin, a vasopressin analog, decreased blood loss and transfusion requirements in a cohort of pediatric and adult burn patients.[183] The authors did not report significant complications associated with this approach.

BLOOD COMPONENTS

Several blood components are available for replacement of losses incurred during burn wound excision. These components include whole blood, PRBCs, fresh frozen plasma (FFP), platelets, and cryoprecipitates.

Box 13.6 Indications for Arterial Cannulation

1. Expected blood pressure changes more rapid than the interval between noninvasive measurements
2. Patient's fragility and reduced physiological reserve (e.g., ischemic or valvular heart disease)
3. Requirement for vasoactive infusions (other than dobutamine)
4. Need for measurement of Pa_{O_2} for management of respiratory support
5. Extremities unavailable for blood pressure cuff

Table 13.4 Comparison of Whole Blood and Packed Red Blood Cells

Value	Whole Blood	Packed Red Blood Cells
Volume (mL)	517	300
Erythrocyte mass (mL)	200	200
Hematocrit (%)	40	70
Albumin (g)	12.5	4
Globulin (g)	6.25	2
Total protein (g)	48.8	36
Plasma sodium (mEq)	45	15
Plasma potassium (mEq)	15	4
Plasma acid (citric/lactic) (mEq)	80	25
Donor/recipient ratio	1 unit per patient	1 unit every 4–6 patients

Whole Blood

Whole blood consists of unfractionated blood and contains all of the components of blood including red blood cells (RBCs), plasma, platelets, and white blood cells. However whole blood stored for more than 24 hours does not contain functional white blood cells or platelets (Box 13.6). One unit of whole blood contains approximately 200 mL of red blood cells and 250 mL of plasma. Whole blood is available in some hospitals for large-volume blood transfusions (trauma, liver transplantation, burns) and treatment of hypovolemic shock. However, because of the scarcity of blood products in most communities, whole blood is not readily available. Fractionation of whole blood into its individual components is a much more efficient and cost-effective means of maximizing blood usage. When available, however, whole blood provides an excellent means of volume expansion and to provide oxygen-carrying capacity in patients requiring large-volume blood transfusion.

Packed Red Blood Cells

PRBCs are the most common means of replacing RBC loss during surgical procedures. Most of the plasma and platelets are removed during processing so that PRBCs provide few plasma components, clotting factors, or platelets. A unit of PRBCs contains approximately 200 mL of red cells and 50 mL of residual plasma. A comparison of PRBC composition with whole blood is shown in Table 13.4. PRBCs provide oxygen-carrying capacity and, when reconstituted with crystalloid or plasma, volume resuscitation.

Fresh Frozen Plasma

In the setting of burn injury, FFP is most commonly used to replace clotting factors during massive blood transfusion. FFP will replace clotting factors as well as protein S and protein C by a factor of 2–3% per unit. The initial recommended volume is 10–15 mL/kg. The use of FFP varies among different burn centers. Plasma is frozen within 6 hours of collection, and each unit provides approximately 250 mL of plasma containing normal levels of all coagulation factors. In the setting of massive blood transfusion, FFP administration is indicated if active bleeding exists and laboratory evidence of coagulation factor depletion is shown. A volume of 2–6 units is generally used depending on the severity of the coagulopathy. Some practitioners argue that the use of FFP rather than crystalloid to reconstitute PRBCs results in less interstitial edema during the postoperative period and may enhance skin graft survival.

In the past, guidelines recommended the use of FFP to replace shed blood only for documented coagulopathy due to reduced coagulation factors. Recent experiences with both civilian and military trauma have led to more liberal use of FFP, and, as a result, early and aggressive use of FFP to treat massive hemorrhage has been associated with decreased mortality.[184,185] As a result, massive transfusion protocols including early use of blood products other than PRBCs to support coagulation (e.g., FFP, platelets, and cryoglobulin) are now activated for trauma patients requiring massive transfusion.[186,187] Blood loss during extensive burn wound excision often meets criteria for the diagnosis of massive transfusion. The physiological status of trauma patients presenting with hypovolemic shock, acidemia, hypothermia, and coagulopathy, however, is different from the post-resuscitation burn patient. Except in certain emergencies burn patients should have their wounds debrided when resuscitation is effective or in the post-resuscitation period. Under these circumstances the patient is warm, has adequate preload and oxygen-carrying capacity, adequate or increased cardiac output, and no coagulation dysfunction. As a result, all features of the massive transfusion protocol are not necessary initially. At our institution (Shriners Hospital for Children, Galveston) shed blood is initially replaced with colloid (2.5% albumin), and the HCt is allowed to diminish to a target value appropriate for the patient before PRBCs are administered. As a result of dilution, shed blood contains a smaller mass of RBCs. When shed blood reaches 50% of estimated total blood volume, it is then replaced with PRBCs mixed with FFP. Transfusion of reconstituted whole blood in burned children has been shown to be safe and efficacious.[188] Only if microvascular bleeding occurs along with thrombocytopenia and/or hypofibrinogenemia are other blood products administered.

Platelets

Platelets are stored at room temperature to maximize viability. The incidence of bacterial contamination increases exponentially after 4 days. However refrigerated platelets remain viable for only 24–48 hours. Platelets are obtained from either units of whole blood or by apheresis from a

single donor. ABO-compatible platelets, particularly if from a single donor, should be used when possible because post-transfusion viability is improved. One unit of whole blood platelets contains approximately 5×10^{10} platelets in 50 mL of plasma. Most commonly, 6 units of platelets are combined into a single bag and transfused. A unit of single-donor platelets contains about 30×10^{10} platelets suspended in 200–400 mL of plasma. Therefore, 1 unit of single-donor platelets is equal to about 6 units of whole blood platelets. One unit of whole blood platelets will increase the platelet count by 5000–10,000/μL.

Cryoprecipitate

Cryoprecipitate is prepared by thawing FFP at 4°C and collecting the precipitate. Cryoprecipitate is rich in factors VIII and XIII, fibrinogen, and von Willebrand's factor. In the setting of massive blood transfusion, it is used primarily to treat hypofibrinogenemia. Generally cryoprecipitate is administered when plasma fibrinogen levels fall below 100 mg/dL. One unit of cryoprecipitate will increase plasma fibrinogen levels by 5–7 mg/dL.

COMPLICATIONS OF MASSIVE BLOOD TRANSFUSION

Coagulopathy

Coagulopathy associated with massive blood transfusion is due to thrombocytopenia or depletion of coagulation factors. PRBCs are essentially devoid of platelets, and whole blood stored for more than 24 hours does not possess significant numbers of viable platelets.[189] Whole blood contains essentially normal levels of coagulation factors with the exception of the volatile factors V and VIII. Because most plasma is removed from PRBCs, they provide a poor source of coagulation factors. Massive blood loss and transfusion results in dilutional losses of platelets and factors V and VIII, particularly when PRBCs alone are utilized.

Thrombocytopenia is the most common cause of nonsurgical bleeding after massive blood transfusion.[190] In general, 15–20 units, or 2–4 blood volumes of blood or PRBCs, must be transfused before bleeding due to thrombocytopenia will develop (Fig. 13.11). Observed platelet counts usually remain higher than calculated values due to the release of platelets from sites of sequestration. Bleeding due to thrombocytopenia usually develops when the platelet count drops below 50,000–100,000 platelets/μL. Replacement of platelets usually requires transfusion of 6 units of whole blood platelets or 1 unit of single-donor platelets as described earlier in this chapter.

Development of coagulopathy due to depletion of coagulation factors is also possible during massive blood transfusion. Significant prolongation of the prothrombin (PT) and partial thromboplastin time (PTT) can result after transfusion of 10–12 units of PRBCs in adults. It has been recommended that FFP be given to correct dilutional coagulopathy if the PT and PTT exceed 1.5 times normal levels.[191] It is also important to know the fibrinogen level in massively transfused patients since hypofibrinogenemia can also result in prolongation of the PT and PTT. Fibrinogen may be replaced using cryoprecipitate.

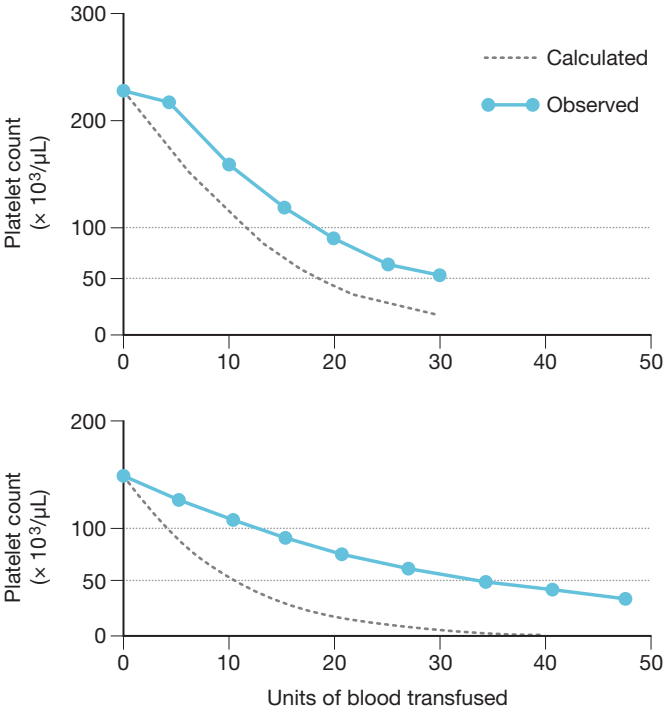

Fig. 13.11 Calculated versus observed mean platelet counts in two studies of platelet count after massive blood transfusion. (From Reed RL, et al. Prophylactic platelet administration during massive transfusion. *Ann Surg.* 1986;203:46.)

Citrate Toxicity

Citrate is universally used as an anticoagulant in the storage of blood because of its ability to bind calcium that is required for activation of the coagulation cascade. Citrate is metabolized by the liver and excreted by the kidneys. Patients with normal liver and kidney function are able to respond to a large citrate load much better than patients with hepatic or renal insufficiency. During massive blood transfusion, citrate can accumulate in the circulation, resulting in a fall in ionized calcium.[192] Hypocalcemia can result in hypotension, reduced cardiac function, and cardiac arrhythmias. Severe hypocalcemia can also result in clotting abnormalities. However, the level of calcium required for adequate coagulation is much lower than that necessary to maintain cardiovascular stability. Therefore hypotension and decreased cardiac contractility occur long before coagulation abnormalities are seen. During massive blood transfusion it is generally prudent to monitor ionized calcium, especially if hemodynamic instability is present in the hypocalcemic patient.

Potassium Abnormalities

During the storage of whole blood or packed red cells, potassium leaks from erythrocytes into the extracellular fluid and can accumulate to concentrations of 40–80 mEq/L. Once the RBCs are returned to the in vivo environment, the potassium quickly reenters RBCs. However, during rapid blood transfusion, transient hyperkalemia may result, particularly in patients with renal insufficiency.[193] The transient hyperkalemia, particularly in the presence of hypocalcemia, can lead to cardiac dysfunction and arrhythmias. In

patients with renal insufficiency, potassium load can be minimized by the use of either freshly obtained blood or washed packed RBCs. Hypokalemia can also result from massive blood transfusion due to reentry of potassium into RBCs and other cells during stress, alkalosis, or massive catecholamine release associated with large-volume blood loss. Therefore potassium levels should be monitored routinely during large-volume blood transfusions.

Acid–Base Abnormalities

During the storage of whole blood, an acidic environment develops due to the accumulation of lactate and citrate with a pH in the range of 6.5–6.7. Rapid transfusion of this acidic fluid can contribute to the metabolic acidosis observed during massive blood transfusion. However metabolic acidosis in this setting is more commonly due to relative tissue hypoxia and anaerobic metabolism resulting from an imbalance of oxygen consumption and delivery. The anaerobic metabolism that occurs during states of hypovolemia and poor tissue perfusion results in lactic acidosis.[186] Generally, administration of sodium bicarbonate is not indicated. The re-establishment of tissue perfusion and homeostasis is a much more important factor in re-establishing acid–base balance. In contrast, many patients receiving massive blood transfusion will develop a metabolic alkalosis during the post-transfusion phase. This is due to the conversion of citrate to sodium bicarbonate by the liver and is an additional reason to avoid sodium bicarbonate administration during massive blood transfusion except in cases of severe metabolic acidosis (base deficit >12).

Altered Oxygen Transport

During the storage of blood, red blood cell 2,3-diphosphoglycerate (DPG) levels decline. This results in a shift in the oxyhemoglobin dissociation curve to the left. Under these conditions, oxygen has a higher affinity for hemoglobin, and oxygen release at the tissue level is theoretically diminished. In clinical practice, this alteration in oxygen affinity has not been shown to be functionally significant.

Hypothermia

Rapid infusion of large volumes of cold (4°C) blood can result in significant hypothermia.[194] When added to the already impaired thermoregulatory mechanisms in burn patients this can result in clinically significant hypothermia. Potential complications of hypothermia include altered citrate metabolism, coagulopathy, and cardiac dysfunction. During large-volume blood transfusion in burn patients, fluids should be actively warmed with systems designed to effectively warm large volumes of rapidly transfused blood. In addition, the room temperature should be elevated and the patient's extremities and head covered to minimize heat loss. Body temperature should be maintained at or above 37°C in burn patients.

Pulmonary Complications

Pulmonary edema is a potential complication of massive blood transfusion. This may result from volume overload and/or pulmonary capillary leak due to inflammation and microaggregates present in transfused blood. Some studies have indicated that the incidence of pulmonary edema is more related to the patient's underlying injury than to blood transfusion per se. However volume status should be monitored closely during large-volume blood transfusion so that volume overload may be avoided.

Table 13.5 Blood Groups and Cross-Match

Blood Group	Antigen on Erythrocyte	Plasma Antibodies	Incidence (%)	
			Whites	African-Americans
A	A	Anti-B	0.40	27
B	B	Anti-A	11	20
AB	AB	None	4	4
O	None	Anti-A	45	49
Anti-B				
Rh	Rh	42	17	

Transfusion-associated acute lung injury (TRALI) is a relatively rare complication characterized by acute hypoxemia and noncardiogenic pulmonary edema occurring within 6 hours of blood transfusion.[195] Although relatively uncommon, TRALI is among the most common causes of transfusion-related mortality.[196] The pathogenesis is not well understood but is thought to be related to transfusion-associated inflammatory responses. Although the incidence is higher in critically ill patients, specific risk factors are difficult to identify and treatment is supportive. In cases of transfusion-related lung injury, it is important to rule out other causes of ARDS and the presence of transfusion-associated volume overload (TACO).

Transfusion Reactions

Hemolytic transfusion reactions are a relatively rare but devastating complication of blood transfusion. The incidence of transfusion reactions is approximately 1 : 5000 units transfused, and fatal transfusion reactions occur at a rate of 1 : 100,000 units transfused. Most severe reactions result from ABO incompatibility. The most common cause of transfusing ABO-incompatible blood is clerical error. Therefore most hospitals have developed policies that require multiple checks of the blood prior to transfusion. A list of blood types and associated circulating antibodies is shown in Table 13.5. Massive hemolytic transfusion reactions result from destruction of transfused erythrocytes by circulating antibodies and complement. Many of the common signs and symptoms of transfusion reactions, such as chills, chest pain, and nausea, cannot be detected in a patient under general anesthesia. The most commonly recognized signs of transfusion reaction in the anesthetized patient are fever, hypotension, hemoglobinuria, and coagulopathy. The cornerstones of treatment are to stop the transfusion, protect the kidneys with aggressive hydration and alkalization of urine, and treat existing coagulopathy.[197]

Delayed hemolytic transfusion reactions can occur in patients who have received prior blood transfusions and result from a secondary immune response with production of antibodies to blood antigens. This reaction can occur from 2 to 21 days after transfusion and should be suspected in patients with unexplained decreases in hematocrit during the postoperative period. Renal injury is less common than in acute hemolytic reactions, but adequate hydration and

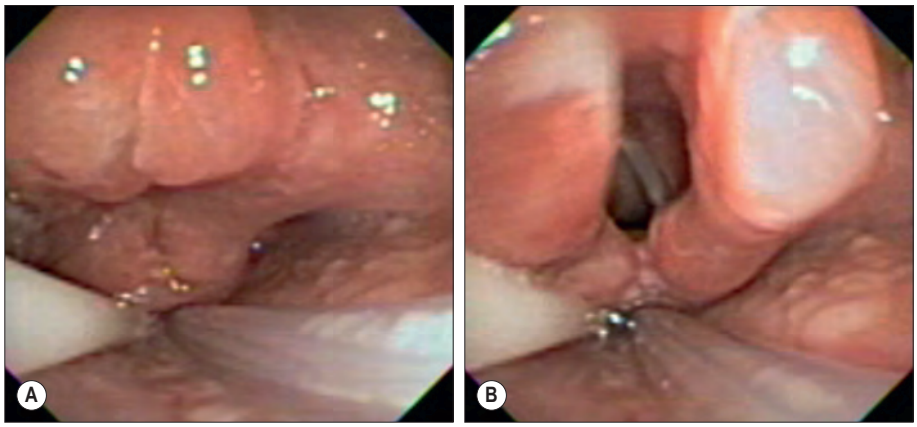

Fig. 13.12 Dynamic obstruction of the upper airway in a pediatric patient with thermal injury of the larynx. Edematous tissues collapse and obstruct during inhalation (A) but expand and allow exhalation (B).

alkalization of urine are usually indicated. Febrile reactions are common following blood transfusion and are generally due to contaminating leukocytes and leukocyte antigens present in transfused blood. Pure febrile reactions usually do not require termination of the transfusion, but the patient should be monitored closely to assure that a more severe transfusion reaction is not developing.

Infection

Infection is a major problem in burn patients due to disruption of the cutaneous barrier and immunosuppression. Blood transfusion adds to the infection risk. Graves and colleagues showed a significant correlation between the number of blood transfusions and infectious complications in burn patients.[198] The most common source of major infection from blood products is hepatitis. Hepatitis C is the most common offender, followed by hepatitis B. The incidence of hepatitis C is approximately 3 in 10,000 units transfused. The development of rigorous screening mechanisms has markedly decreased the incidence of HIV infection to 1 in 200,000–500,000 units transfused. Cytomegalovirus (CMV) has been identified in blood products and could cause clinically significant problems in immunocompromised burn patients. However the incidence of clinically important CMV infection is low in burn patients.

Postoperative Care

Decisions regarding postoperative airway management and support of ventilation depend on several factors. Extubation is desirable as soon as it is indicated, but, in burn patients, for a number of reasons it often may be even more important not to extubate when it is not indicated. If the patient came to the operating room intubated, the indication for intubation must be determined. If the initial indication has resolved, the decision to extubate depends on perioperative events. Some patients with neck and facial burns are intubated to protect the airway from obstruction by edema. The airway must be examined to be sure edematous pharyngeal tissues will not cause obstruction of the airway when the endotracheal tube is removed. Air leaking around a deflated endotracheal tube cuff during positive pressure ventilation is an encouraging sign that the airway may remain patent after extubation. The upper airway can also be examined by direct laryngoscopy or with an endoscope. In marginal cases the endotracheal tube can be removed while an exchanger is left in the trachea. Another technique is to extubate under direct vision with a bronchoscope with an endotracheal tube already loaded on the bronchoscope. Especially in small pediatric patients a common reason for post-extubation stridor and failed extubation is edematous and redundant mucosa over the arytenoid eminences that obstruct the glottic inlet during inspiration (Fig. 13.12A, video). This condition can be exacerbated by an endotracheal tube that is too large, excessive patient motion due to inadequate sedation and analgesia, reflux of acidic gastric contents, and mechanical irritation due to compression of the posterior laryngeal structures between the endotracheal tube and gastric tubes. These irritants can also cause laryngomalacia in pediatric patients (Fig. 13.12B). If laryngeal obstruction persists despite attention to all these details a short course of steroids is often effective as long as concerns regarding burn wound infection do not preclude the use of steroids (unpublished observations.) Heliox has also been used successfully in this situation.[199]

The decision to extubate must also take into consideration the metabolic state and the burn-related decrease in strength of the patient. Increased generation of CO_2 must be matched by increased minute ventilation and respiratory effort. Work of breathing is often also increased by poor pulmonary compliance and diaphragmatic elevation due to hepatomegaly.[200] At the same time skeletal muscle wasting and decreased strength are also products of the catabolic state.[98] If the patient's physiological reserve was marginal preoperatively, it may be best to continue mechanical ventilation until extubation criteria can be assessed objectively in the ICU.

After transfer of monitors and ventilatory support in the ICU, a full report of the intraoperative anesthetic course is given, along with information about the patient's current condition and therapy. A chest radiograph may be needed for vascular catheters placed in the OR to check the position of an endotracheal tube if the patient will be ventilated postoperatively. Laboratory studies, including arterial blood gas, blood chemistries, renal function tests, hematocrit,

platelet count, and coagulation studies, are sent soon after patient arrival to the ICU. These studies are particularly important if massive transfusion was required in the operating room.

One of the most important issues in the immediate postoperative period for burn patients is adequate analgesia and sedation, particularly for the intubated and mechanically ventilated patient. Debridement of burned tissue and the harvesting of skin grafts are painful procedures that merit ample analgesic doses in order to ensure patient comfort. It is not uncommon for burn patients to be quite tolerant to narcotic analgesics, especially after they have had several operative procedures, and, in this case, larger doses than normal are required.

Ongoing blood loss is unfortunately a common problem after the excision and grafting of a large burn wound, even when strict attention is placed on intraoperative hemostasis by surgical personnel. The burn wounds are necessarily excised down to bleeding tissue before skin grafts are applied. Massive intraoperative transfusion adds to the problem with dilutional thrombocytopenia and coagulopathy. Diligent postoperative care is needed to continually assess ongoing blood loss and to transfuse additional blood products as they are indicated by clinical course and laboratory studies. Postoperative bleeding can be concealed by bulky burn dressings. Such bleeding may manifest as hypovolemia and hypotension even in the brief period of transport from the operating room to the ICU. Monitoring of CVP and urine output also help in guiding postoperative blood and fluid therapy.

Adequate ventilation is essential in the postoperative period in order to minimize hypoxemia and hypercarbia. Blood gases and oxygen saturation can be used as guides to ventilator management. Patients with inhalation injury benefit not only from rational ventilator management but also from a program of inhaled bronchodilators and mucolytics combined with judicious airway suctioning. Extubated patients require supplemental oxygen for at least the first few hours postoperatively in order to maintain adequate oxygen saturation. Airway support may also be necessary initially in these patients until they are more alert and responsive.

Finally, burn patients must be recovered in a warm environment. Postoperative hypothermia can result in vasoconstriction, hypoperfusion, and metabolic acidosis and exaggeration of the hyperdynamic and catabolic metabolic response to their injury. Radiant heaters, blood and fluid warmers, warm blankets, heated humidifiers for gas delivery, and high room temperature are all useful in the postoperative period to provide warmth to the recovering patient.

Conclusion

Anesthetic management of the burn patient presents numerous challenges. Anatomical distortions make airway management and vascular access difficult. Pathophysiological changes in cardiovascular function range from initial hypovolemia and impaired perfusion to a hyperdynamic and hypermetabolic state that develops after the resuscitative stage. These and other changes profoundly alter response to anesthetic drugs. Effective anesthetic management will depend on knowledge of the continuum of pathophysiological changes, technical skills, proper planning, and availability of proper resources. A team approach is necessary, keeping in mind that perioperative management should be compatible with ICU management and goals. This requires close communication with other members of the burn care team, which is one of the most important principles of effective anesthetic management of these challenging patients.

14 The Skin Bank

CHARLES D. VOIGT, STEVE WILLIAMSON, RICHARD J. KAGAN, and LUDWIK K. BRANSKI

History

The first skin autograft was described by Reverdin[1] in 1871, and the use of allograft skin as a clinical method for wound coverage soon followed.[2] In 1874, Thiersch published a report about a small series of patients on whom he had used partial-thickness skin grafts.[3] This led to extensive trials of harvesting extremely thin grafts, leaving some of the surface epithelium behind to aid in donor site healing. Results from the use of these small, thin grafts, known as "Thiersch grafts," "pinch grafts," "epidermis grafts," or "razor grafts" were generally so unsatisfactory for resurfacing large areas that they were typically limited to the treatment of small ulcerated wounds. The first successful use of allogeneic skin for burn wound coverage was reported by Girdner[4] in 1881. Five years later, Thiersch described the histologic anatomy of skin engraftment which popularized the clinical use of split-thickness skin grafts.[3]

Storage of human skin did not begin until the early 1900s, when Wentscher[5] reported his experience with the transplantation of human skin that had been refrigerated for 3–14 days; however it was not until the 1930s that blood and tissue banking took their place in the clinical practice of medicine. The clinical utility of allograft skin in burn wound coverage was first described in 1938, when Bettman[6] reported his success in the treatment of children with extensive full-thickness burn injuries. Webster[7] and Matthews[8] later described the successful healing of skin autografts stored for 3 weeks at 4–7°C; however it was not until 1949, following the establishment of the United States Navy tissue bank, that modern-day skin banking began.

The establishment of skin banking signaled the beginning of significant research related to the processing, preservation, and storage of human tissues. Baxter[9] explored the histologic effects of freezing on human skin and discovered that the formation of ice crystals caused the destruction of skin architecture. This was followed in 1952 by the pioneering research of Billingham and Medawar[10] who demonstrated that skin could be effectively cryopreserved using glycerol. Soon afterward, Taylor[11] was able to demonstrate that the addition of glycerol to storage solutions decreased ice crystal formation in frozen tissues. These advancements permitted Brown[12] and Jackson[13] to popularize the use of allogeneic human skin grafts as biologic dressings for extensive burns and denuded tissue. By 1966, Zaroff[14] had reported the 10-year experience using allograft skin in the treatment of thermally injured patients at the Brooke Army Medical Center. In this report, he described the mechanical and physiologic advantages of allograft skin as a biologic dressing. In 1966, Cochrane[15] reported the first successful use of frozen autologous skin grafts following controlled-rate freezing in 15% glycerol and rapid rewarming prior to implantation. This was followed by Morris's[16] report demonstrating the beneficial effects of using allogeneic skin in the treatment of infected ulcers and other contaminated wounds and Shuck et al.'s[17] report suggesting the potential use of allogeneic skin in the treatment of traumatic wounds based on their Vietnam War experience. These increased uses of allograft skin led to further research into the beneficial effects of allograft skin on wound healing, including its association with a reduced incidence of bacterial infections[18,19] and the stimulation of wound bed neovascularization.[20]

Bondoc and Burke[21] are credited with the establishment of the first functional skin bank in 1971. Their experience with allograft skin led to a report of successful burn wound excision and allografting with temporary immunosuppression in children with extensive injuries.[22] Today allograft skin remains an ideal temporary cover for extensive or excised cutaneous or soft tissue wounds, particularly when sufficient autograft skin is not available or when temporary wound coverage is desired.

Another biologic dressing with a long history in the treatment of burned patients is amniotic membrane, with the first use for the purpose taking place in 1912 by Sabella a few short years after it was originally used in skin transplantation by Davis in 1910.[23,24] During the immediate period following these reports, the use of amniotic membranes was attempted as permanent skin replacements, although the grafts were rejected. In 1952, Douglas was the first to report the use of amniotic membrane as a temporary burn wound covering. Since that time, amnion has been one of the tools available in the treatment of partial-thickness burns.[25–30] Amnion has been shown to alleviate pain, prevent infection,[23,28,31,32] reduce pruritus,[30] and accelerate wound healing.[24,26,31] Our institution has used amniotic membrane for temporary total ocular surface coverage in the treatment of toxic epidermal necrolysis, which has shown improvements in corneal clarity, conjunctival scaring, and dry eye symptoms at 3-month follow-up as compared to a historical group that received maximal medical treatment.[33] The preparation and storage of amnion has been a role in many skin banks around the world.

The Growth of Skin Banking

The widespread use of allograft skin in the management of patients with extensive burn, traumatic, and soft tissue injuries has had a major impact on the number of skin banking facilities over the past two decades or so. Consequently the majority of skin banks have been founded in close proximity to regional burn centers or within the burn center hospitals themselves. Skin banks must therefore maintain a close working relationship with regional burn

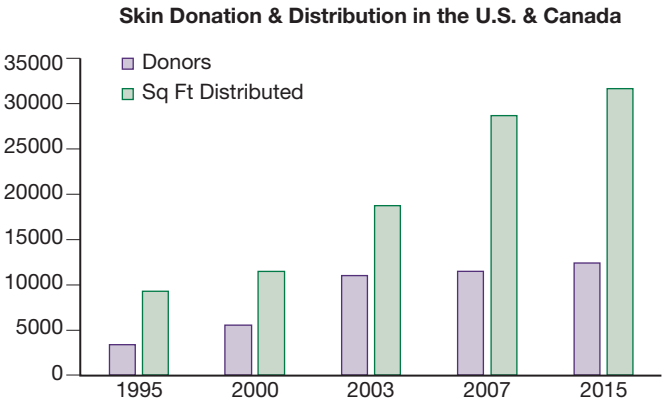

Fig. 14.1 Skin donation and distribution in the United States and Canada from 1995 through 2015.

centers not only to meet the specific needs of the burn surgeon but also to help generate community support for skin donation through combined educational outreach programs.

From 1969 to 1988, there was a steady growth in the number of skin banks; however this number declined, reaching its nadir in 2002. Since that time, however, there has been a steady increase in the number of skin banking facilities to its current total of 81 American Association of Tissue Banks (AATB)-accredited tissue banks that recover, process, store, and/or distribute skin for transplantation. In 1983, DeClement and May estimated that as much as 32,000 square feet of skin might be needed in burn and wound care centers.[34] Fig. 14.1 shows the total number of skin donors as well as total number of square feet of skin distributed by skin banks throughout the United States and Canada from 1995 through 2015.

Role of the American Association of Tissue Banks

As skin banking facilities grew in number, it became apparent that policies and procedures required standardization. This was quite difficult initially because there was insufficient data to develop a consensus regarding standards of practice. As early as 1976, the AATB had begun to address this issue by the formation of a Skin Council. This provided a forum for the discussion of skin banking practices and was complemented by the activities of the American Burn Association's Skin Banking Special Interest Group. The Standards and Procedures Committees were created in 1977 and produced the first guidelines for tissue banking in 1979. The first Standards for Tissue Banking were published in 1984, and tissue-specific technical manuals (including skin) were developed in 1987. Since that time, the Standards have been modified and refined based on consensus and, where available, supportive scientific research, with the latest edition, the 14th, released in 2016. In addition, shortly after the development and promulgation of its Standards for Tissue Banking, the AATB created an inspection and accreditation committee in 1982 and began conducting voluntary inspections in 1986. This program continues today and is important in ensuring that tissue banks adhere not only to AATB Standards but also the U.S. Food and Drug Administration (FDA) regulations governing all aspects of human tissue banking. In 1992, the AATB presented its Year 2000 Plan, outlining the institution's goals of supporting tissue and cell banks and ensuring the safety and quality of tissues, as well as advancing and strengthening the AATB.[35] The AATB has worked with many organizations, such as the FDA, the Centers for Disease Control (CDC), and the American Burn Association, to update standards and quickly respond when necessary, such as through the timely creation of instructions and methods to screen potential donors for emerging infectious diseases, including West Nile, Ebola, and Zika viruses in order to reduce risk of infection.

Box 14.1 Indications for Allograft Skin Use in Wound Management.

- Coverage of extensive wounds where autologous tissue is not available
- Coverage of widely meshed skin autografts
- Extensive partial-thickness burns
- Extensive epidermal slough
  - Stevens-Johnson syndrome
  - Toxic epidermal necrolysis
  - Staphylococcal scalded skin syndrome
- Testing the wound bed's ability to accept autograft
- Template for the delayed application of keratinocytes.

Clinical Uses of Allograft Skin

COVERAGE OF EXTENSIVE FULL-THICKNESS WOUNDS

The increasing use of allograft skin in specialized burn care centers has been one of the driving forces behind the growth and development of skin banks in the United States. The general indications for its use in wound management are listed in Box 14.1. Allograft skin possesses many of the ideal properties of biologic dressings and plays a major role in the surgical management of extensive wounds when autologous tissue may not be immediately available (Box 14.2). It reduces evaporative water loss and the exudation of protein-rich fluids, prevents wound desiccation, and suppresses microbial proliferation. Wound pain is lessened, and this is associated with better patient compliance with occupational and physical therapy. By restoring the physiologic barrier at the wound surface, the allografts reduce heat loss through the wound and mitigate the hypermetabolic response to burn injury. The frequent and unpredictable demand for allograft skin in specialized burn care centers has prompted the growth and development of local and regional skin banks throughout the world.

Fresh allograft skin represents the gold standard for all biologic dressings employed for temporary wound closure based on a number of its distinctive properties compared to cryopreserved skin (Box 14.3). Its availability is critically important for the surgeon faced with the need to provide immediate coverage of large excised burn wounds. Fresh allografts become well-vascularized,

Box 14.2 Advantages of Human Allograft Skin Use.

- Reduce water, electrolyte, and protein loss
- Prevent desiccation of tissue
- Suppress bacterial proliferation
- Reduce wound pain
- Reduce energy requirements
- Promote epithelialization
- Prepare wounds for definitive closure
- Provide dermal template for epidermal grafts.

Box 14.3 Advantages of Fresh Allograft Skin.

- Rapidity and strength of adherence to the wound
- Control of microbial growth
- Rapidity of revascularization
- Reproducible clinical results

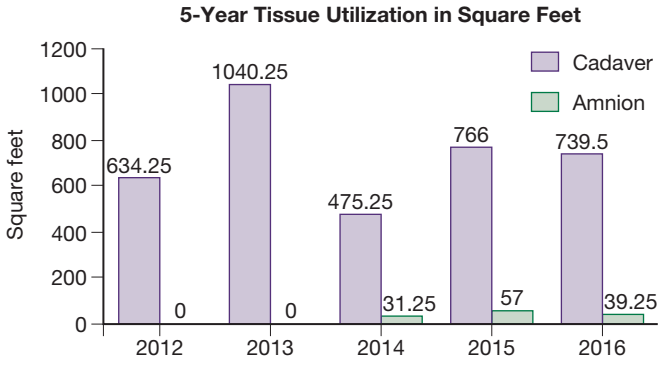

Fig. 14.2 Allograft and amnion skin usage at the Shriners Hospitals for Children – Galveston, Texas.

stimulate neovascularization in the underlying wound bed, and prepare the recipient sites for permanent coverage with autologous skin. In addition, fresh allografts tolerate modest wound contamination and adhere better to the freshly excised subcutaneous fat than do cryopreserved grafts. The allogeneic skin is usually removed once the patient's donor sites have healed sufficiently for reharvesting or once autologous cultured skin is available for permanent wound closure.

The use of fresh allografts has become extremely limited in recent years, however, due to increased FDA regulations put in place to reduce risk of disease transmission. When fresh allograft is not available, cryopreserved skin is an excellent alternative for temporary wound coverage. Although frozen cryopreserved skin generally has less measurable viability than fresh skin, it is currently difficult to maintain continuous and ample stores of fresh skin beyond 14 days. It has therefore been standard skin banking practice to cryopreserve allograft skin within 7–10 days of recovery if it is not going to be utilized within the time period that viability can be maintained. Fig. 14.2 depicts the quantitative use of allograft skin and amnion in thermally injured children treated at the Shriners Hospital for Children in Galveston, Texas, since 2012.

Alternative wound coverings such as Integra dermal regeneration template have provided alternatives to allograft skin for the treatment of excised burn wounds in patients with extensive full-thickness burn injuries. When compared with artificial dermis, fresh, refrigerated allograft has been shown to have a better rate of engraftment than the dermal regeneration template.[36] A study performed at our institution in 2007 indicated that Integra can safely be used for wound coverage in children with burns of more than 50% total body surface area (TBSA) burned with an associated attenuation of post-burn hypermetabolism with no increased risk of infection.[37]

COVERAGE OF WIDELY MESHED ZSKIN AUTOGRAFTS AND PARTIAL-THICKNESS WOUNDS

Another use of allograft skin has been its application as an overlay on top of widely expanded, meshed autologous skin grafts (Fig. 14.3). This technique was originally described utilizing meshed allograft[38] and provides immediate, as well as both temporary and permanent, wound closure. Our institution utilizes 2:1 meshed cadaver skin for the coverage of widely expanded autografts (with a ratio greater than 2:1). Because it is usually less viable than fresh skin, it functions more as a biologic dressing than as a temporary skin replacement. Its adherence to the underlying wound bed results in the relief of pain and the limitation of exudative and water losses, and it reduces the need for frequent dressing changes. As the underlying wound bed reepithelializes, the allograft slowly separates without disturbing the delicate underlying epithelium. These properties of frozen allograft are also utilized in the coverage of partial-thickness wounds. Studies by Rose[39] and Naoum[40] demonstrated more rapid healing times and shorter hospital stays for children with extensive partial-thickness burns when treated with early wound débridement and allografting compared to conventional topical antimicrobial therapy. However due to lower costs and ease of use, Shriners Hospitals for Children – Galveston primarily uses xenograft for partial thickness burns.

There has been some concern that allografts may induce an inflammatory rejection response resulting in delayed reepithelialization of underlying autografts; therefore the use of lyophilized tissue has been suggested because the lyophilization process destroys cellular components and results in a diminished immunologic response from the graft recipient.[41,42] A 2013 study of 11 patients treated with lyophilized allograft showed no evidence of immunologic reactions due to the administration of allograft.[42]

TEMPLATE FOR DELAYED APPLICATION OF KERATINOCYTES

The clinical use of cultured epidermal autografts (CEA) in the care of burn patients was first described by O'Connor et al.[43] in 1981. Since that time, there have been numerous reports supporting its use as a permanent skin replacement for patients with extensive full-thickness burn injuries. This methodology has not been without problems, however, with many authors describing variable take rates and instability of the grafts. Cuono first advocated the use of

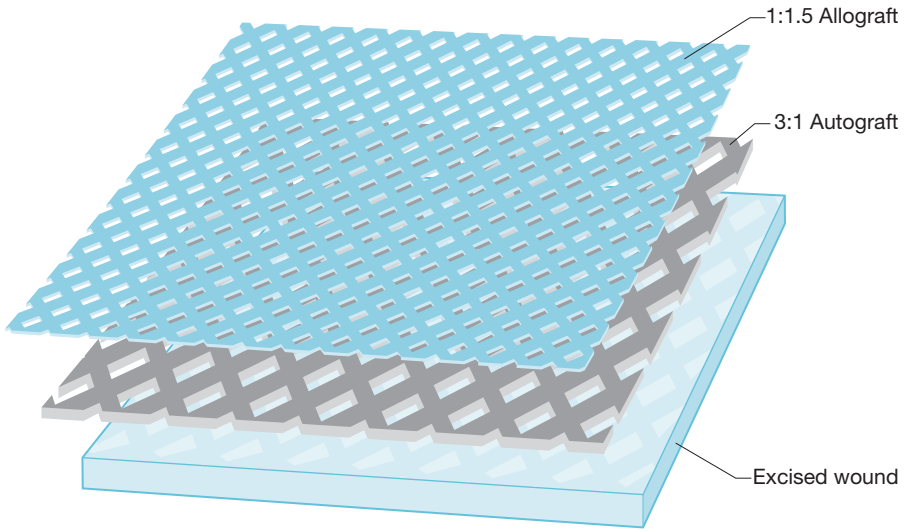

Fig. 14.3 Diagrammatic illustration of meshed allograft overlay technique (as described by Alexander et al.). The allograft is generally meshed 1.5:1 or 2:1 while the underlying autograft may be meshed 3: 1 or greater. (From Alexander JW, MacMillan BG, Law E, et al. Treatment of severe burns with widely meshed skin autograft and widely meshed skin allograft overlay. *J Trauma.* 1981; 21:433–438.)

allogeneic skin with CEA, allowing the allograft skin to vascularize before removing the antigenic epidermal layer by dermabrasion.[44] Hickerson et al. reported results on five burn patients demonstrating more than 90% CEA take on the allogeneic dermis and supple, durable grafts up to 4 years postoperatively.[45] A recent multicenter randomized trial compared patients with full-thickness burns who were treated with split-thickness skin autografts to those who were additionally treated with CEA. The application of CEA resulted in faster wound epithelialization, improved perception of scarring, and improved pigmentation and elasticity of the skin at follow-up.[46]

ACELLULAR DERMAL MATRIX

The past decade or so has also witnessed the development of an acellular allogeneic dermal matrix (AlloDerm) as a template for the simultaneous application of thin split-thickness autografts.[47] The potential advantage of the dermal template is reasoned to be the use of a thinner autologous skin graft resulting in more rapid donor site healing and reduced morbidity. A multicenter clinical trial demonstrated equivalence of this technique with a standard split-thickness meshed autograft; however autograft take rates were somewhat lower than that for controls and varied from center to center.[48] In addition, the allogeneic dermal grafts measured only 36–116 cm^2 and were only evaluated up to 180 days post-grafting. AlloDerm has also been used as a template for CEA; however there have been only a few anecdotal reports related to this potential application.

Potential Disadvantages of Allograft Use

INFECTION

Allograft skin has been reported to cause bacterial infection.[49] It is therefore imperative that skin banks perform microbial cultures prior to releasing the tissue for transplantation. In fact, the AATB Standards[50] require that skin be discarded if pathogenic bacteria or fungi are present. This is particularly important given the immunocompromised status of the potential recipient and the potential for developing wound sepsis following such contamination.

There have also been reports of viral disease transmission by skin allografts. In 1987, Clarke reported what was thought to be the transmission of HIV-1 to a burn patient from an HIV-positive donor[51]; however, the results of donor testing were not known prior to skin use. Moreover, the recipient, who had a number of risk factors for HIV, had not been tested prior to receiving the allograft. To date, there have been no other reported cases of HIV or hepatitis transmission from skin allografts.

Kealey et al. have reported the transmission of cytomegalovirus (CMV) from cadaver skin allografts.[52] Because nearly 23% of the CMV-negative patients seroconverted, they recommended the use of CMV-negative allograft skin for seronegative burn patients. Plessinger et al. reviewed 479 consecutive skin donors and found 63% of this predominantly adult donor pool to be CMV-positive.[53] They reasoned that while tissue from seronegative donors would be ideal for use in seronegative patients, such a practice would significantly limit the availability of fresh allograft skin for most thermally injured patients. In addition, while there is good evidence to support the transmission of CMV by allograft in burn patients, there is little evidence that CMV seroconversion is clinically significant or affects outcome in thermally injured patients.[54,55] Furthermore Herndon and Rose[54] reiterated that the benefits of using cadaver allograft skin for the treatment of burn patients clearly outweigh the small risks associated with CMV seroconversion. At present, most burn surgeons and skin banks recommend that the decision regarding the use of allograft skin from CMV-positive donors should be made by the burn/transplanting surgeon.

REJECTION

While demonstrating many characteristics of an ideal wound covering, allograft skin contains Langerhans cells that express class II antigens on their surface. These cells reside in the epidermis of the skin and are ultimately rejected as the result of an immunologic rejection response. This typically results in an acute inflammatory reaction and can lead to wound infection. Vascularized allogeneic skin grafts typically remain intact on the wound of a burn patient for 2–3 weeks, although there have been reports of allograft skin survival for up to 67 days due to the inherent immunosuppression of extensive burn injury.[56] Recent improvements in immunonutrition, critical care management, and a more aggressive surgical approach to definitive wound closure, however, have made the persistence of allografts less predictable.

Efforts to prevent rejection have included methods that might reduce antigen expression by controlling the activity of the Langerhans cells in the allograft skin. Treatment of the allografts with ultraviolet light irradiation and incubation of the skin in glucocorticoids has been reported to result in a modest prolongation of allograft survival compared to nontreated skin; however the utility of this methodology has not been substantiated. Other investigators have studied the effects of pharmacologic agents to induce immunosuppression in patients with major burn injuries. Initial clinical trials reported an improvement in both allograft and patient survival when children were treated with azathioprine and antithymocyte globulin[57]; however this regimen was associated with azathioprine-induced neutropenia, and the clinical outcomes were not corroborated by others. More recently, the use of cyclosporin A was demonstrated to prolong skin allograft survival in patients with extensive full-thickness burns.[58,59] In these studies, allograft rejection was generally observed within a few days of discontinuing treatment; however there were instances where engraftment persisted after the completion of therapy. Further studies of these and newer immunosuppressive agents may be warranted.

Technical Aspects of Skin Banking

DONOR SCREENING

It is vitally important that complete and accurate medical information about the potential tissue donor be obtained to ensure the safety of the tissue for transplantation. The AATB and the FDA require a comprehensive medical and social history of the donor. In this regard, the AATB developed a Donor Risk Assessment Interview (DRAI) with the cooperation and assistance of other organ and tissue recovery organizations and the FDA.

A panel of serologic screening tests for transmissible diseases is required.[50] These include:

- Antibodies to human immunodeficiency virus, types 1 and 2 (anti-HIV-1 and anti-HIV-2)
- Nucleic acid test (NAT) for HIV-1
- Hepatitis B surface antigen
- Total antibodies to hepatitis core antigen (including both IgG and IgM)
- Antibodies to hepatitis C virus (anti-HCV)
- Nucleic acid test (NAT) for HCV
- Syphilis (a non-treponemal or treponemal-specific assay may be performed)
- Nucleic acid test (NAT) for the hepatitis B virus (HBV)

Test kits should be FDA-licensed, approved, or cleared for donor screening and, ideally, should be approved for cadaveric specimens. Barnett et al. reported their 2-year experience with cadaveric skin donor discards due to positive serologic tests. In that report, they noted that 61 of 813 donors (7.5%) required tissue discard due to positive serologic tests. A positive hepatitis B core antibody test accounted for 52.3% of the serology-based discards, whereas hepatitis B surface antigen testing accounted for 18.1%, and hepatitis C, HIV-1/2, HTLV-1, and syphilis tests accounted for 14.3%, 4.9%, 4.9%, and 5.5%, respectively.[60] This finding was substantiated by Plessinger et al. in their 5-year review of 1235 donors, of whom 93 7.5%) were deferred based on positive serologic tests.[61]

Although it is also necessary for the tissue bank medical director to review the results of an autopsy (if one was performed), a 10-month follow-up study of 264 donors recovered following the 1998 changes in the AATB Standards revealed that none of the donors required deferral based on autopsy findings alone.[61] A review of 468 consecutive skin donors and 457 consecutive amnion donors recovered by our tissue bank from February of 2014 through September of 2016 indicated that 50 skin donors (10.7%) and 32 amnion donors (7.0%) required discard as a result of the autopsy, serology, DRAI, or physical exam findings. [62]

SKIN RECOVERY

Once donor screening is complete and proper authorization has been obtained, the recovery team must arrange the time and location for skin recovery in an appropriate facility (i.e., hospital morgue or operating room, medical examiner's office, or the tissue bank). It is extremely important that the time of death and body storage conditions be accurately documented because these have a significant bearing on skin viability and microbial contamination, as can the time from skin recovery to banking.[62] Current AATB Standards require that skin prep begin within 24 hours of asystole, provided the donor's body was cooled (e.g., application of sufficient amounts of wet ice or a cooling blanket, cold weather conditions) or refrigerated within 12 hours of asystole. The skin prep shall begin within 15 hours of death if the deceased donor's body has not been cooled or refrigerated. If the donor's body is cooled for a period of time then not cooled for a period of time, the time period the donor's body is not cooled cannot exceed 15 cumulative hours.[50]

In brief, the skin is recovered under aseptic conditions but first a thorough physical assessment is necessary to determine if the donor should be deferred for other medical reasons as well as to determine the quality of the skin and the technical feasibility of skin recovery by evaluating the donor's size and skin condition. Box 14.4 lists disease states that are commonly associated with deferral of a potential skin donor. Blood samples are also obtained for the required infectious disease testing. The areas from which the skin is

Box 14.4 Disease States Commonly Associated With Potential Skin Donor Deferral.

- Extensive dermatitis
- Acute burn injuries
- Cutaneous malignancy
- Poor skin quality
- Extensive tattoos
- Collagen vascular disease
- Toxic chemical exposure
- Skin infections
- Extensive skin lesions
- Extensive skin or soft tissue trauma.

taken are shaved of hair and cleansed with an antimicrobial agent approved for use in operative procedures (i.e., povidone-iodine, chlorhexidine). The tissue recovery technician wears the appropriate personal protective equipment (PPE; i.e., surgical cap, mask with face shield, shoe covers), performs a surgical scrub, and dons a sterile gown and gloves while the circulating technician completes the required documentation of the tissue recovery as well as prepares the tissue and transport containers. This is usually followed by a chlorhexidine prep surgical scrub of the tissue donor, rinsing with 70% isopropyl alcohol after the required contact time of the surgical scrub and allowing the skin surface to dry. A back table with all the required supplies for skin recovery is set up, and the donor is then surgically draped. Split-thickness skin grafts are then removed using a dermatome at a thickness of 0.012–0.018 inches. The width of the grafts generally should range from 3 to 4 inches but ideally should be determined by the preference of the transplanting surgeon(s). Skin retrieval sites are usually limited to the torso, hips, thighs, and upper calves. The amount of skin obtained may vary depending on body habitus, skin defects or lesions, and body geometry; however an average yield of 4–6 square feet per donor is not unusual for an experienced tissue recovery technician. After tissue is obtained from the posterior surfaces, the donor is turned to expose the anterior surface, reprepped, and draped prior to completing the recovery process. The skin is then placed in tissue culture medium and maintained at wet ice temperatures (above freezing to −10°C) during transport to the skin bank for processing.[63]

SKIN PROCESSING

Processing Environment

Skin should be processed under aseptic conditions in a bacteriologically and climate-controlled environment (Fig. 14.4). While current AATB Standards mandate the processing of cardiovascular tissues in a class 100 laminar flow environment, no such requirement exists for human skin banking. In fact, a study performed by Plessinger et al. failed to demonstrate any statistically significant quantitative or qualitative difference in microbial growth whether the skin was processed and packaged in a class 100 laminar flow hood or a class 10 000 clean room.[64]

Fig. 14.4 Aseptic tissue processing environment.

Microbiologic Testing

After returning to the skin bank, the tissue recovery team should obtain cultures for aerobic and anaerobic bacteria, yeast, and fungi. Tissue cultures can be obtained by swabbing, destructive testing of companion tissue, or by fluid elution.[65] Cultures from representative anatomical areas shall be obtained prior to processing. Culture methods shall be validated to ensure the suitability of the culture method selected. Inhibitory substances (e.g., skin prep solution(s), transport media, antibiotics, etc.) that may be added to unprocessed skin during recovery or for transport must not interfere with culture results (i.e., produce false-negative results). Testing should be conducted in accordance with adherence to relevant standards (e.g., CAP, ISO, ASTM, AAMI, USP), and the skin should not be used for transplantation if it contains any of the following microorganisms[50]:

- Staphylococcus aureus
- Group A, β-hemolytic Streptococci
- *Enterococcus* spp.
- Gram-negative bacilli
- *Clostridium* spp.
- Fungi (yeasts or molds).

While AATB Standards require that microbiology culture results should not be reported before 7 days of incubation before releasing the tissues for transplantation, when fresh, non-cryopreserved allograft skin is used for transplantation within days of tissue recovery, the results of the microbial cultures are frequently unavailable. Plessinger et al. reviewed the results of the microbiologic skin cultures from 219 consecutive skin donors whose tissues were released for transplantation prior to the availability of culture results. Although 14.3% of the cultures were positive for microbial growth, only 1.8% of the cultures identified organisms that required subsequent notification of the transplanting surgeon. In each of these instances, there was no adverse outcomes in any of the patients who received the skin transplants.[66] These findings were substantiated by Britton-Byrd et al.[67] in their review of tissue donors whose skin was used after only 3 days of incubation. They reported

three cases resulting in tissue recall due to positive microbiological cultures and concluded that 3-day culture results do not result in significant microbiologic contamination of allograft skin. White et al.[68] have suggested that cadaver allograft containing less than 10^3 organisms per gram of tissue can be safely used for temporary wound coverage. Despite the results of these studies, it is strongly recommended that the tissue bank communicate all available information regarding donor and tissue suitability to the transplanting surgeon so that he or she can adequately assess the potential risks and benefits for the recipient.

Maintenance of Viability

Maintenance of cell viability and structural integrity are vital for the engraftment and neovascularization of allograft skin yet there have been no studies that have quantified the degree of viability necessary to ensure allograft take. Postmortem time lapse appears to have the single greatest effect on skin viability, as May demonstrated that the functional metabolic activity of the skin rapidly declined if the donor was not refrigerated within 18 hours of death.[69,70] The ideal nutrient tissue culture medium also has not yet been identified. Eagle's MEM and RPMI-1640 continue to be generally accepted; however, Cuono demonstrated the potential benefits of University of Wisconsin (UW) solution.[71] To date, it remains unclear which cryoprotectants offer the greatest preservation of cell viability and structural integrity. Glycerol (10%–20%) and dimethylsulfoxide (10%–15%) have been reported to maintain skin viability following incubation times ranging from 30 minutes to 2 hours; however the optimal concentrations of these cryoprotectants have not been identified nor have these agents been compared for efficacy. Last, factors such as age and gender do not appear to influence skin viability.

REFRIGERATION

Refrigeration slows the metabolic rate of the viable cells, and nutrient tissue culture medium supports cellular metabolic activity. "Fresh" allograft skin is typically stored at 4°C in tissue culture medium with or without antibiotics. The skin should be free-floating in a sterile container with approximately 300 mL of medium per square foot of skin. Recent studies suggest that skin viability can be maintained for up to 2 weeks at 4°C if the nutrient medium is changed every 3 days.[72,73]

It has been common practice to cryopreserve the skin within 10 days of tissue recovery. This has been based on the work of May et al., who demonstrated that glucose metabolism declined at a rate of 10%–15% each day during refrigerated storage.[70] Recently demonstrated has been the benefit of a two-layer storage method utilizing 95% oxygen-enriched perfluorocarbon (O_2PFC) combined with changing the nutrient medium every 3 days in an effort to prolong the viability of refrigerated skin. This method results in maintenance of skin viability for up to 41–63 days, as well as maintenance of normal skin anatomy.[74]

CRYOPRESERVATION

When skin is frozen for long-term storage, it is important that the methods utilized maintain cell viability and structural integrity. AATB Standards dictate that refrigerated skin should not be stored for longer than 14 days; however if the skin is not to be used "fresh," it should be cryopreserved within 10 days of recovery if the nutrient medium is changed every 72 hours. If the medium is not utilized or changed in this manner, AATB Standards dictate that the skin must be frozen within 96 hours of recovery.[50] The skin is generally incubated in cryoprotectant solution for 30 minutes at 4°C. Skin that is to be frozen may be meshed (Fig. 14.5) or kept as a sheet, and it should be folded with fine mesh gauze or bridal veil covering the dermal surface prior to placement in a flat packet (Fig. 14.6) to ensure uniformity of the cooling process.[75] This is followed by slow-rate cooling at a rate of approximately −1°C/min. Although computer-assisted, control-rate freezing is thought to be optimal, studies have demonstrated that cooling in a heat sink box at less than −2°C/min is equally effective and does not compromise the metabolic activity of the skin.[76] The skin is frozen to a temperature of −70 to −100°C prior to placement in either a mechanical freezer

Fig. 14.5 Processed tissue after being run through a 2:1 mesher.

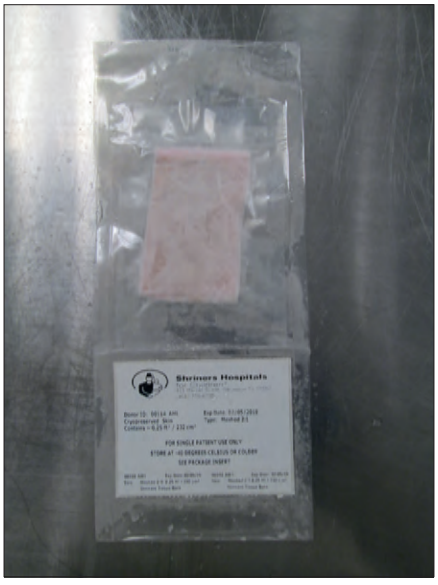

Fig. 14.6 Completed, frozen, packaged tissue.

or liquid nitrogen. Skin stored in a mechanical freezer (below −40°C) can be maintained for up to 5 years. Although this methodology has been reported to result in 85% retention of viability, there is a need for research to determine the optimal technology for skin preservation.[77]

LYOPHILIZATION

Skin can also be lyophilized by freeze-drying or incubation in glycerol.[78] This process has been reported to decrease biologic degradation and antigenicity; however this also results in epidermal cell destruction, the loss of barrier function, and resulting poor adherence to the wound bed and less effective control of microbial growth. Its clinical use has been further limited by its high cost of production compared to conventional allograft.

IRRADIATION

Human allograft skin can also be treated with γ-irradiation to significantly reduce and possibly eliminate the risk for viral disease transmission. The preservative and sterilizing effects of this treatment allow it to be stored at room temperature for up to 2 years. One such product, GammaGraft, has been successfully utilized to treat partial-thickness burn injuries and skin graft donor sites; however it is not often utilized to provide temporary coverage for excised full-thickness burn wounds. Its most common indications, however, are for the management of chronic wounds/ulcers and exposed soft tissues.[79]

Transport

Refrigerated skin should be transported in tissue culture medium at wet ice temperatures (above 0–10°C) in an insulated container. Frozen allograft skin is transported on dry ice in an insulated container to prevent the skin temperature from rising to greater than −40°C. If the frozen skin is thawed at the tissue bank, it should be transported at wet ice temperatures.

Rewarming

Rewarming of frozen cryopreserved allograft skin must be performed in such a manner as to minimize cryodamage and preserve the structural integrity and viability of the skin. Early studies demonstrated that warming rates of 50–70°C/min resulted in 80%–95% graft survival. Subsequent research[75] has revealed that warming should be performed in 2–4 minutes or less at a temperature of 10–37°C (127–470°C/min). Rewarming in a microwave oven is not recommended due to uneven heating and excessive intracellular temperatures.

FDA Regulation of Human Skin Banking

Concerns related to the potential transmission of disease from tissue donors triggered concern within Congress and the FDA, which resulted in the FDA's publication of an interim rule for the regulation of human tissues intended for transplantation in 1993.[80] The interim rule required that all donors have an accurately recorded medical and social history to assure freedom from risk factors for or clinical evidence of hepatitis B, hepatitis C, and HIV infection. Since then, the FDA has published its proposed final rules concerning establishment registration and listing, donor eligibility, and good tissue practices [81]. Numerous guidance documents are also posted on its website (http://www.fda.gov/BiologicsBloodVaccines/TissueTissueProducts/default.htm). Burn centers should only obtain allograft skin from tissue banks that comply with these regulations and preferably from those facilities accredited by the AATB. Obtaining tissue that complies with FDA regulations is required for burn center verification by the American Burn Association.

AMNION PROCESSING

The methods for processing amniotic membranes are remarkably similar to that of cadaveric skin, with only a few important differences. First, amniotic membranes are collected from living donors, so first-person consent is obtained from the donor prior to caesarean section. Following consent, the medical chart is reviewed for exclusionary criteria, and recent physical exam by a physician may be examined in lieu of direct physical examination. The donor completes a DRAI form, and blood is collected for serology as described in the processing of cadaveric skin, with the addition of testing for West Nile virus. During the caesarean section, the amnion is aseptically collected into a specimen container and refrigerated at 0–10°C until the tissue can be delivered to the skin bank within hours. From this point, the processing of the amnion is identical to cadaveric skin, with the exception that amnion must be frozen within 5 days of processing instead of 10 days.

The Future of Skin Banking

Skin banking must continue to evolve as engineered skin substitutes enter the clinical arena for the temporary and permanent coverage of partial- and full-thickness wounds. Allograft skin has the potential to play a major role in permanent skin reconstruction after extensive thermal injury; however this will require interactive research with the burn centers caring for these patients.

Moving forward, tissue banks have the opportunity to play a major role in continued research into regenerative medicine, stem cell therapies, and decellularized tissue that may provide novel uses for human tissue in the treatment of burns and many other conditions. Application of mesenchymal stem cells has been shown to result in faster healing of burn wounds, decreased inflammation, and improved scar quality, as well as improved corneal wound healing.[82–84] Decellularized tissue is an important area of research for tissue banking due to the improved compatibility of using these products in patients. In burn care, decellularized human allografts (AlloDerm) and porcine xenografts (Permacol) are already in use, although they are under continuing research scrutiny. In addition, research into methods to

preserve tissue will continue to be an important avenue of investigation. Tools such as glycerolization and irradiation of tissue produce nonviable tissue, which are useful as temporary wound coverage, as they result in decreased rejection and reduced risk of infectious disease transmission.[85] It will become increasingly important for skin banks to perform basic science and clinical research (in conjunction with burn and wound healing centers) to demonstrate the clinical indications and efficacy of allograft skin products in various clinical applications.

Skin banks must also identify ways of increasing cadaveric skin donation, ensuring recipient safety from potential disease transmission, and reducing costs of tissue recovery and processing while optimizing allograft viability. This will become increasingly difficult as it becomes necessary to perform additional infectious disease testing procedures to ensure recipient safety. To accomplish these goals, it has recently become necessary for many skin banking operations to consolidate, and tissue banks may even begin to expand internationally. Such an undertaking could enhance tissue supplies and availability and result in increased clinical use by surgeons.

15 Skin Substitutes and 'the next level'

ESTHER MIDDELKOOP and ROBERT L. SHERIDAN

Introduction

STRUCTURE AND FUNCTION OF THE SKIN

Skin, the body's largest organ, is incredibly complex. Functionally, there are two layers with a highly specialized and effective bonding mechanism. Numerous appendages traverse the skin, and a rich and reactive capillary network provides nutrient flow while controlling temperature. The epidermis, consisting of the strata basale, spinosum, granulosum, and corneum, provides a vapor and bacterial barrier. The dermis provides strength, mechanical resistance, and elasticity. The thin epidermal layer is constantly refreshing itself from its basal layer, with new keratinocytes undergoing terminal differentiation over approximately 4 weeks to anuclear keratin-filled cells that make up the stratum corneum, which provides much of the barrier function of the epidermis. The basal layer of the epidermis is firmly attached to the dermis by a complex bonding mechanism containing among others collagen types IV and VII. When this bond fails, serious morbidity results, as demonstrated by the disease processes of toxic epidermal necrolysis (TEN) (Fig. 15.1)[1] and epidermolysis bullosa.[2]

CONSEQUENCES OF LOSS OF BARRIER FUNCTION

Loss of the epidermal barrier has serious adverse physiologic effects. Direct and evaporative fluid losses are immediately seen. If wounds are large, this quickly leads to dehydration and shock. Protein losses are also substantial, leading to loss of colloid oncotic pressure and secondary edema. Microorganisms have unimpeded access to the microcirculation with resulting systemic infection. Deep tissues become desiccated with secondary cell death and progression of wound depth.

Open wounds present a high risk of fluid loss, high inflammation, bacterial colonization, infection, and sepsis, which can lead to a poor prognosis in terms of prolonged healing times and scarring. Timely wound closure is therefore one of the key objectives in modern burn care.

An increasingly effective group of temporary and permanent wound coverings is available.

The objective of this chapter is to review the currently available strategies for temporary and (semi-) permanent skin substitutes in terms of origin of the material (tissue, biological, or synthetic material) and wound indication (partial-thickness vs full-thickness wounds).

Temporary Skin Substitutes and Dressings

Partial-thickness wounds remain confined to the dermal part of the skin. Usually, these wounds have a good healing potential because epidermal cells present in (remnants of) sebaceous glands, sweat glands, and hair follicles are available to close the wound.

In these wounds, the main demands to reach pain reduction and high-quality wound healing without scarring is to warrant undisturbed wound healing. A moist environment and protection against bacterial invasion are the most important qualities that need to be provided.

Wound dressings for partial-thickness wounds should:

- Provide a moist environment (migration of cells is more difficult if when there is a dry scab on the wound).[3]
- Protect the wound from excessive fluid loss and bacterial invasion.
- Require a limited number of dressing changes (pain reduction).

Modern wound dressing are able to fulfil these requirements. Generally, membranous dressings such as hydrocolloids and hydrofibers fulfill these requirements better than topical antimicrobial creams such as silver sulfadiazine (SSD) cream.[4-6] The main indication for temporary skin substitutes is partial-thickness wounds, of which donor sites are a special category, but essentially are similar wounds.

We can classify temporary skin substitute materials by their tissue origin into:

1. Biological tissues, such as allograft, xenograft, and amnion (keratinocyte sheets and cells)
2. Synthetic materials such as hydrocolloids and hydrofibers

BIOLOGICAL TISSUES

Allograft

The first type of membranous wound coverage used was human allograft skin. Human allograft is generally used as a split-thickness graft after being procured from organ donors. When used in a viable fresh or cryopreserved state, it vascularizes and remains the "gold standard" of temporary wound closures.[7-9] It can be refrigerated for up to 7 days, but it can be stored for extended periods when cryopreserved. It is also used in a nonviable state after

Fig. 15.1 Patient with toxic epidermal necrolysis.

Fig. 15.2 Glycerolized allograft on a partial-thickness scald burn.

preservation in glycerol or after lyophilization. Viable split-thickness allograft provides durable biologic cover until it is rejected by the host, usually within 3 or 4 weeks. Prolongation of allograft survival, through the use of antirejection drugs, has been advocated[10] but is not generally practiced for fear that antirejection drugs will increase the risk of infection.[11]

A frequently used application of glycerolized allograft skin is as a membranous dressing on partial-thickness burns, especially scald burns in children (Fig. 15.2).[12] Modern banking techniques and regulations warrant the safety and quality of banked skin.[13] Allograft is also effectively used in combination with meshed autograft in patients with large burns, the interstices of the meshed graft being immediately closed by the overlying unexpanded allograft, possibly reducing metabolic stress and local wound inflammation.

Human Amnion

Human amniotic membrane is used in many parts of the world as a relatively cheap temporary dressing for superficial wounds.[14,15] Amniotic membrane is generally procured fresh and used after brief refrigerated storage.[16,17] It can also be used in a nonviable state after preservation with glycerol.

Beneficial effects have been described in a randomized controlled trial comparing amnion membrane with SSD by Mostaque et al on partial-thickness burns, with a better outcome using amnion membrane on time to epithelialization, length of stay (LOS), pain, and frequency of dressing changes.[18]

The principal concern with amnion is the difficulty in screening the material for viral diseases unless preservation methods can eliminate potential viral contamination. Without the ability to screen the material in this way, the risks of disease transmission must be balanced against the clinical need and the known characteristics of the donor.

Xenograft

Although various animal skins have been used for many years to provide temporary coverage of wounds,[19] only porcine xenograft is widely used today. It has been used as primary temporary cover and as a scaffold for dermal regeneration efforts.[20] Porcine xenograft is commonly distributed as a reconstituted product consisting of homogenized porcine dermis that is fashioned into sheets and meshed.[21] Split-thickness porcine skin is also used fresh, after brief refrigeration, after cryopreservation, or after glycerol preservation. It effectively provides temporary coverage of clean wounds such as superficial partial-thickness burns and donor sites[22] and has been used in patients with TEN.[1,23] Porcine xenograft has been combined with silver to suppress wound colonization.[24,25] Porcine xenograft does not vascularize, but it adheres to clean superficial wounds and can provide excellent pain control while the underlying wound heals.

SYNTHETIC MATERIALS

Nowadays, synthetic membranous dressings are increasingly capable of replacing biological membranous dressings. Next to protection against bacteria and fluid loss, pain reduction and mechanical protection, they provide a moist environment in which wound healing can proceed undisturbed. A number of semipermeable membrane dressings can provide a vapor and bacterial barrier and control pain while the underlying superficial wound or donor sites heal. These typically consist of a single semipermeable layer that provides a mechanical barrier to bacteria and has physiologic vapor transmission characteristics.[26]

The main advantages of synthetic membranes over biological ones are their constant composition, sterility, and availability. Disadvantages include their higher costs.

Nevertheless, in a number of recent studies, superiority of synthetic membranes over topical creams and ointments has been shown, especially with regard to healing time, LOS, and pain management.[4]

Some examples are mentioned here:

Biobrane (Smith & Nephew, Andover, MA) is a two-layer membrane constructed of an inner layer of nylon mesh that allows fibrovascular ingrowth and an outer layer of silastic that serves as a vapor and bacterial barrier.[27] It is widely used to provide temporary closure of superficial burns and donor sites.[28] All synthetic membranes

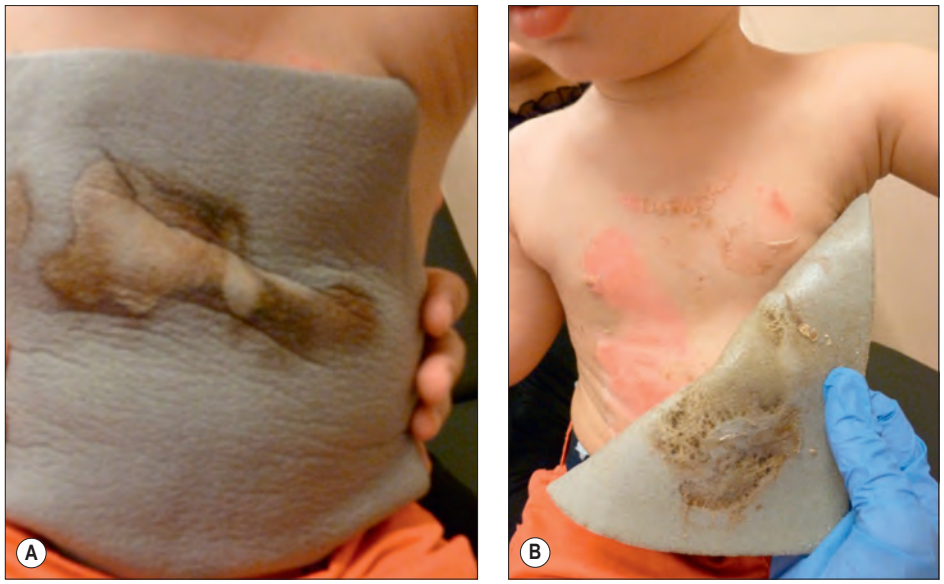

Fig. 15.3 Mepilex Ag for partial-thickness burn treatment, 7 days after burn.

are occlusive and can foster infection if placed over contaminated wounds, especially in the presence of necrotic tissue.[29] Appropriate monitoring is essential to their proper use.

Another category of silicone containing dressings is formed by the silicone-coated dressings such as Mepitel and Mepilex (Mölnlycke, Göteborg, Sweden) (Fig. 15.3) of which advantages are reported in terms of time to healing, pain reduction, and number of dressing changes.[30,31]

Hydrocolloid dressings are generally designed with a three-layer structure: a porous, gently adherent inner layer; a methyl cellulose absorbent middle layer; and a semipermeable outer layer. They foster a moist wound environment while absorbing exudate. A moist wound environment has been found to favor wound healing.[32] A variety of pastes and powders made from hydrocolloid materials are also widely available. These can be applied to superficial or deeper chronic wounds to absorb wound exudate while maintaining a moist wound environment.

Hydrofiber dressings absorb wound exudate and have been used as temporary wound membranes. When combined with ionic silver (Aquacel-Ag; ConvaTec, Flintshire, UK), additional antimicrobial activity is seen. This membrane has been used successfully in some burn programs as an adjunct in the management of partial-thickness burns and donor sites (Fig. 15.4).[33]

Alginate dressings (e.g., Kaltostat, ConvaTec; Comfeel, Coloplast, Humlebaek, Denmark) are fibrous dressings derived from seaweed. They have a high absorption capacity because of strong hydrophilic gel formation.[34] Their use in burns is mainly as dressing for donor sites. Not many comparative prospective trials are available.

Other synthetic wound dressings include Suprathel (a polylactic acid membrane; Polymedics, Denkendorff, Germany), Urgotul (polyester mesh impregnated with hydrocolloid and petroleum jelly; Urgo Medical, Chenove, France), and Allevyn (a polyurethane foam dressing) (Smith & Nephew), and new materials appear on the market very frequently.

Fig. 15.4 Aquacel Burn hydrofiber dressing, 2 days after application on a partial-thickness burn.

Permanent Skin Substitutes

In contrast to partial-thickness wounds, full-thickness skin lesions lack the availability of enough viable epidermal cells that could close the wound within a reasonable time frame. Therefore, for deep wounds, surgical intervention is indicated. The main purpose of the surgery is to bring a new source of epidermal cells to the wound to speed up wound closure. This can be done in different ways, such as a

split-skin graft, cultured epithelial sheets, carriers or sprays, or skin substitutes.[35] Furthermore, full-thickness grafts or flaps are also used for treatment of full-thickness wounds of limited size.

In addition to providing epidermal coverage, replacement of dermal tissue is also important. From the early studies on treatments with cultured epithelial sheets, it is now known that even after a prolonged time, the dermal–epidermal junction is not fully regenerated, which leaves a rather vulnerable skin that is prone to mechanical damage.[36] Healing of full-thickness wounds is generally accompanied by scar formation. The use of dermal substitutes in full-thickness skin defects may contribute to a better quality of healing with reduced scarring.[37,38]

EPIDERMAL CELLS AND CONSTRUCTS

For more than 40 years, it has been possible to culture vast numbers of epithelial cells from a small skin biopsy,[39,40] and this has led to the widespread clinical use of cultured epithelial grafts to cover burn wounds. Originally, epithelial cells were procured from a full-thickness skin biopsy, the cells were cultured in medium containing fetal calf serum, insulin, transferrin, hydrocortisone, epidermal growth factor, and cholera toxin, overlying a layer of murine fibroblasts that had been treated with a nonlethal dose of radiation that prevented them from multiplying. After some weeks, epithelial sheets were removed from the dishes after treatment with Dispase.

When epithelial cultures were first used in patients with large burns, it was hoped that they would provide the definitive answer to the clinical problem of the massive wound.[41-43] With more frequent use of epithelial grafts, specific liabilities have become apparent, including suboptimal engraftment rates and long-term durability.[44,45] However, when faced with a very large wound and minimal donor sites, epithelial cell wound closure is a useful adjunct to split-thickness autograft, their liabilities and expense becoming more acceptable as wound size increases.

The elimination of risks of transmission of animal derived disease components such as viruses or prions to the patient nowadays represent serious regulatory and safety issues because from a regulatory point of view, these defined xenobiotic materials and cells should not be used for clinical treatment of a patient.

Many of the imperfections associated with epithelial cell wound closure may be attributed to the absence of a dermal element. Epithelial grafts are now commercially available, although several early biotech startup companies providing these services frequently experienced problems to reach an acceptable level of funding. The limited commercial volume of the products, high production costs, and increasing demands in terms of regulatory issues represent some of the challenges for small biotechnology companies.[35]

New developments in this line are found in eliminating the murine fibroblasts and (most of) the animal derived products in culture media, reducing culture time by transplanting subconfluent (proliferating) cells rather than confluent sheets (Fig. 15.5) and by applying spray techniques (Fig. 15.6) (Recell, Avita Medical, Northridge, CA; Keraheal, MCTTBio, Seoul, South Korea) to deliver either freshly isolated or proliferating epidermal cells to the wound bed.[46-48]

DERMAL CONSTRUCTS

Tissues

Virtually all of the characteristics of normal skin that are not related to barrier function are provided by the dermis. These characteristics include flexibility, strength, heat dissipation and conservation, lubrication, and sensation.

A dermal analog that is—in structure at least—closest to the original dermis is based on freeze-dried allogenic dermis. This material is intended to be combined with a thin epithelial autograft at the time of initial wound closure. It is marketed as AlloDerm (LifeCell Corporation, now Acelity, San Antonio, TX).[49,50] Split-thickness allograft skin is obtained from cadaver donors through tissue banks after proper screening for transmissible diseases. Using hypertonic saline, the epithelial elements of the grafts are removed and the remaining dermis is treated in a detergent to inactivate any viruses and the device is freeze-dried. The process is

intended to provide a nonantigenic dermal scaffold, leaving basement membrane proteins (particularly laminin and type IV and VII collagen) intact. The material is rehydrated immediately before placement on wounds with overlying ultrathin epithelial autograft. Clinical experience with this material in burn surgery is limited,[51] but early experiences have been favorable.[52,53] Nevertheless, these products now seem to be used more in breast reconstructive surgery than in acute burns.[54] A similar product, based on allogeneic dermis preserved in glycerol, is Glyaderm (Euro Tissue Bank, Beverwijk, The Netherlands). Also here, antigenicity is reduced by washing out the cells and preserving the original extracellular matrix. Initial studies on burn patients have been performed and reported favorable results.[55]

Dermal Scaffolds

The first dermal substitute used clinically was "artificial skin," also called Integra (IntegraLife, Plainsboro, NJ); it has been used worldwide for several years now for burns as well as reconstructive purposes. This material was developed in the early 1980s by a biomaterials research team from the Massachusetts General Hospital and Massachusetts Institute of Technology.[56] The research team, led by surgeon John Burke from the Massachusetts General Hospital and materials scientist Ionnas Yannas from the Massachusetts Institute of Technology, had the goal of developing a wound covering that would both provide a temporary vapor and bacterial barrier while providing a scaffold for later dermal regeneration. The material was intended to be placed on excised burn wounds. The silicone outer layer serves as a temporary epidermis and is removed after vascular ingrowth into the dermal replacement is completed (usually within 2–3 weeks). The inner layer of this material is a 1- to 2-mm-thick combination of fibers of collagen isolated from bovine tissue and the glycosaminoglycan chondroitin-6-sulfate. To manufacture the device, glycosaminoglycan and collagen fibers are precipitated and then freeze dried and cross-linked by glutaraldehyde. The outer layer of the membrane is 0.009-inch (0.23-mm) -thick polysiloxane polymer with vapor transmission characteristics similar to normal epithelium. This membrane is intended to be placed on freshly excised full-thickness burns and the outer silicone membrane replaced with a thin epithelial autograft 2–3 weeks later.[57] Clinical reports in patients with large burns have been generally favorable,[58-60] although submembrane infection must be watched for. Integra has also been found to be useful in selected burn reconstruction operations (Fig. 15.7).[61]

Whereas Integra is applied in a two-stage operation—first debridement and application of the substitute and 2–3 weeks later removal of the silicone layer and grafting of a split-thickness skin graft—some substitutes can be applied in a one-step procedure. The first dermal substitute that was applied in this way was Matriderm (Medskin Solutions, Billerbeck, Germany). Matriderm consist of bovine collagen fibers mixed with 3% elastin hydrolysate, purified and freeze dried into a dry scaffold that can be placed on the wound in this form immediately or can be prewetted with a saline solution. Clinical results indicate a somewhat retarded take of the graft, reflecting the interpositioning of the unvascularized scaffold between the wound bed and the graft; however, this was compensated by a better outcome in terms of scar quality even after as long as 12 years later (Fig. 15.8).[38] Other scaffolds in this same category are Permacol (a porcine dermal collagen implant, mainly indicated for hernia and abdominal wall repair; Tissue Science Laboratories, Hampshire, UK), Renoskin (Symatèse, Chaponost, France), Pelnac (Smith & Nephew) (both Renoskin and Pelnac are similar to Integra, consisting of a bilayer of collagen with a silicone top layer), and Novomaix (freeze-dried collagen scaffold with elastin fibers; (Matricel, Herzogenrath, Germany). Hyalomatrix (Fidia Advanced Biopolymers, Italy) consists of a bilayer of an esterified hyaluronan beneath a silicone membrane. The scaffold delivers hyaluronan to the wound bed, and the silicone membrane acts as a temporary epidermal barrier.

Fig. 15.7 Scar revision using Integra.

CELLULAR DERMAL SUBSTITUTES

Although some cellular constructs are or were (Dermagraft for chronic wound healing, Transcyte for partial-thickness burns; both Smith & Nephew) on the market using dermal cells in a scaffold for improving wound healing, most of these developments are still in the experimental stage. In vivo studies are described using adipose-derived regenerative cells in Integra,[62] and attempts were made to design a new generation of skin substitutes based on nanotechnology using nanocomposite polymers.[63] However, clinical safety and effectivity still need to be demonstrated for this technology.

A limited number of burn patients was already treated with a construct of native horse collagen with cells from a fetal skin bank.[64] Nevertheless, this is not a commercially available product yet. Furthermore, an experimental study Akershoek and colleagues found superior effects of autologous dermal cells over fetal cells when used in a dermal substitute (Novomaix).[65]

The fact that at present cell seeded skin replacement constructs fall into the category of advanced technology medicinal products (ATMPs) made it more difficult to proceed with these developments into clinical application. Production of these constructs should be strictly controlled,

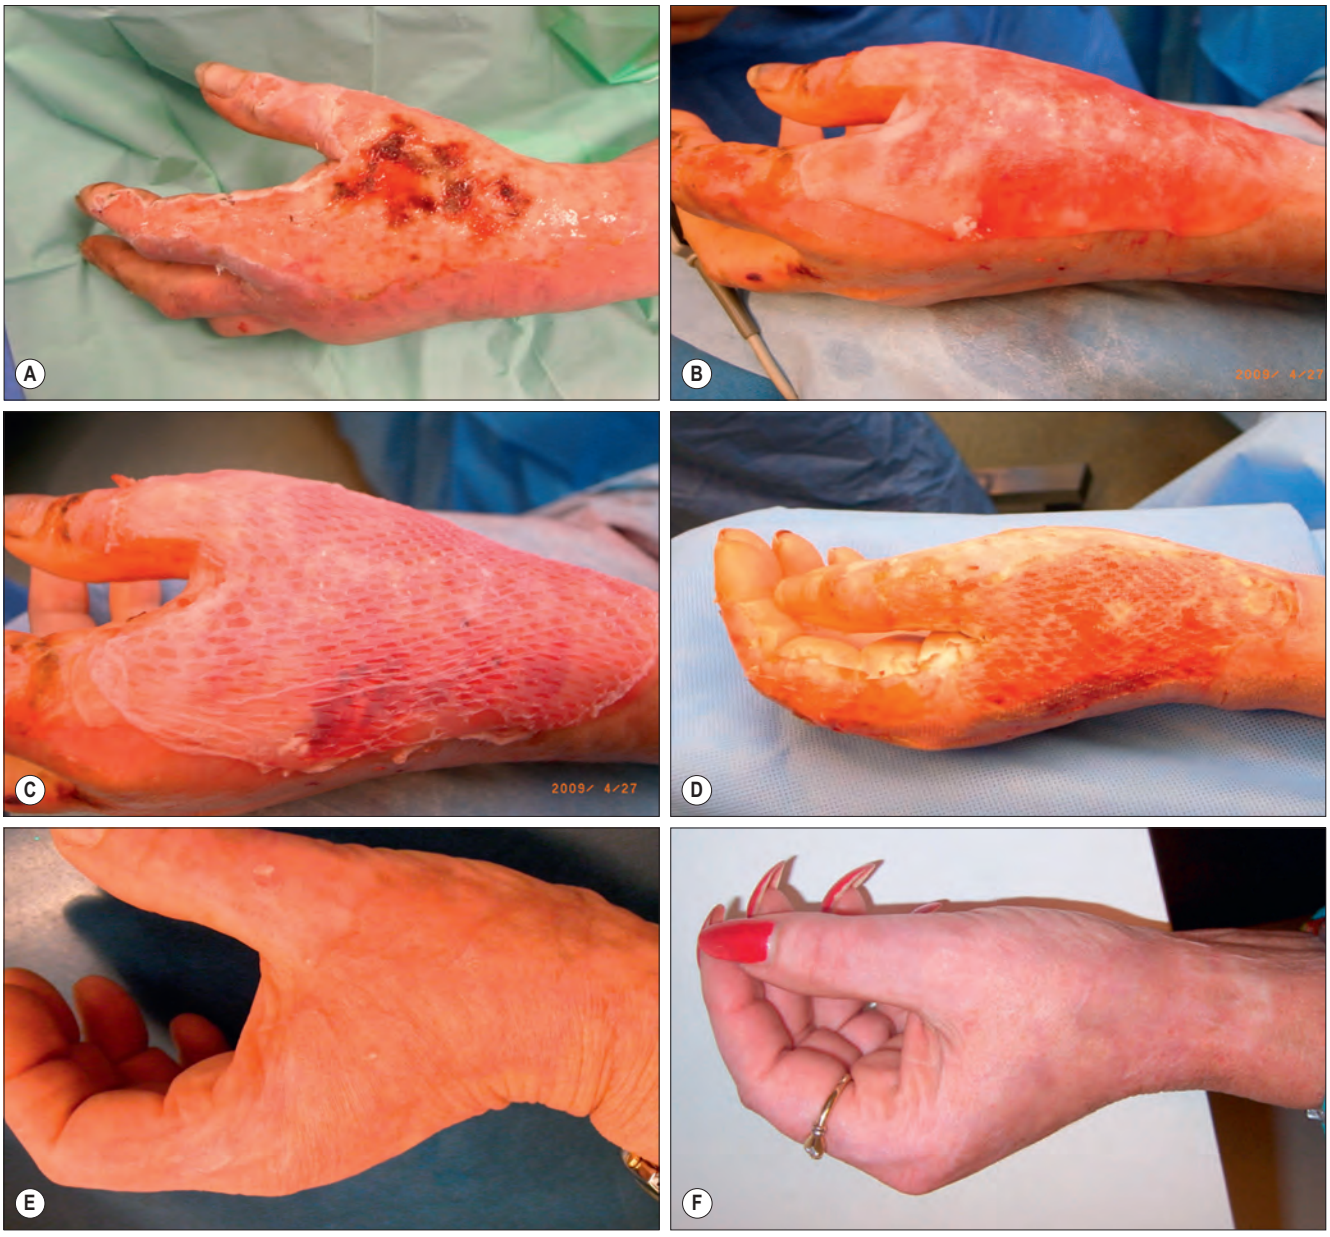

Fig. 15.8 Application and long-term results of Matriderm application. **A,** Full-thickness burn at postburn day (PBD) 3. **B,** Application of Matriderm during surgery, PBD 15. **C,** Application of split-skin mesh graft over Matriderm in a single stage procedure, PBD 15. **D,** Five days after grafting. **E,** Five months postoperatively. **F,** Eighteen months postoperatively.

with clinical-grade ingredients for cell culture media. This aspect stimulated investing in full skin equivalents rather than designing an ATMP for dermal replacement only. For developments in full skin equivalents, see the later discussion.

SUBCUTANEOUS FAT

Although mostly skin is defined as consisting of dermis and epidermis, in recent years, the subcutis has been noted as important for skin function as well. Especially in reconstructive areas, it has become more clear that subcutaneous fat—or the lack of it—plays an essential role in the gliding function of the skin. This is especially important on anatomical locations where the skin is relatively thin, such as the back of the hand and the tibia. In these areas, a scar can easily become attached to underlying tendons or bone if subcutaneous fat is also missing. Recent studies have noted beneficial effects on scar quality of lipo-injection with the patient's own fat, harvested by liposuction.[66–68] Although there is not enough solid clinical evidence yet, the data gathered so far indicate that fat grafting could become a new technique in improving scar quality and outcome after burns. Further research should aim at elucidating the best indications, timing and techniques, and frequencies of application.

Full Skin Substitutes

Ideally, a skin replacement technique would provide immediate replacement of both the dermal and epidermal layers. Combining epithelial cells with a dermal analog in the laboratory seems logical. A completely biological composite skin substitute, culturing human fibroblasts in a dermal matrix, and then growing keratinocytes on this, has been developed by several research groups.[69,70]

The first full composite skin construct to appear on the market was Apligraf (Organogenesis, Canton, MA). It consists of cultured human foreskin–derived neonatal fibroblasts in a bovine type I collagen matrix over which human foreskin–derived neonatal epidermal keratinocytes are then cultured and allowed to stratify. Because the cells are allogeneic, ultimately, the keratinocytes are rejected; therefore, for definite wound closure, an autologous source of keratinocytes needs to be present. Apligraf is therefore mainly used in chronic wound healing and not so much for healing of full-thickness burns.[71]

Another bilayered cellular skin substitute is Orcel (Fortcell Bioscience, Englewood Cliffs, NJ),[72] which contains a layer of cultured human allogeneic neonatal dermal fibroblasts and a layer of cultured human allogeneic neonatal epidermal keratinocytes into a type 1 bovine collagen sponge. Also here, the cells are of allogeneic origin and do not survive for more than 2–3 weeks in a wound. Its working mechanism is thought to be predominantly through the excretion of physiological levels and mix of growth factors and cytokines.

Full skin substitutes that make use of autologous (patient-own) cells have also been described in recent papers.[73-76] Apart from regulatory issues (see later discussion), major problems in the application of these constructs are the long culture times; high costs; and in some cases, the lack of pigment cells. Nevertheless, these are important developments because e in the end, they may lead to novel, clinically applicable truly regenerative full skin analogs, comprising not only dermal and epidermal structures but also vasculature, skin appendages, and even nerves.[77,78]

Regulatory Issues

New developments in regenerative medicine have indicated that the use of living cells in tissue engineered products might prove clinical benefit in terms of promoting wound healing and reducing scar formation.[79] During the past decade, however, new regulations have become effective, designating cell-based therapy as ATMPs. The European Medicines Agency (an agency of the European Union) is dedicated to the scientific evaluation and supervision of market access of medicines. Also, ATMPs fall into this category. Regulation (EC) No. 1394/2007 provides the overall framework on production and use of ATMPs in Europe.[80] In the United States, similar tasks are entrusted to the Food and Drug Administration), where the Office of Cellular, Tissue and Gene Therapies exerts the tasks to evaluate and supervise market access of ATMP products.

According to the EU Regulation No 1394/2007 definition, an ATMP is a "medicine for human use that is based on genes, cells or tissue engineering." A tissue-engineered product may contain or consist of engineered cells or tissues, with the purpose to regenerate, repair, or replace a human tissue, and it may contain viable or nonviable cells or tissues of human or animal origin. Therefore, skin substitutes containing living autologous cells, of dermal, adipose, or epidermal origin are considered as ATMPs and fall under the regulatory issues associated with these. One of the main features of these regulations is that production of ATMPs for human use must take place under good manufacturing practice conditions. For many research laboratories, such conditions are not feasible. Furthermore, a considerable administrative burden is represented by import and export procedures over international borders. Yet given the fact that commercial exploitation of this type of high technological wound treatment is only possible in an international context, these hurdles need to be overcome to allow a successful market position for these products.

Conclusion

Over the past decade, important clinical evidence has been gathered on dermal substitutes, and improvement were achieved in epidermal analogs, both in culture techniques and in application methods. Based on recent reports in preclinical research, we can expect to see further improvements in the next decade in the refinement of full skin equivalents, in incorporation of skin appendages, vasculature, and nerves.

Another area of improvement has been the development of the field of temporary dressings. More synthetic," well-controlled dressings were tested in clinical application. The incorporation of "actives" in these dressings, which was expected previously, was not realized, however. Rather than the addition of single growth factors in wound dressings, the technology of genetic modification might be one of the new clinical developments in the years to come. Cells (e.g., keratinocytes) can be engineered to overexpress platelet-derived growth factor, human growth hormone, insulinlike growth factor 1, and other growth factors.[81,82] On the other hand, mesenchymal stem cells are another tool that could likely lead to innovative technology in burn care.[83] When these can be developed into a readily applicable source for epidermal coverage, the dependence on autologous epidermal cells for wound closure will end.

Nevertheless, there is also an ongoing need for more evidence in clinical science, such as on the comparison of various temporary or permanent scaffolds in promoting wound healing, on the use of growth factors to stimulate the healing process, or on the optimal timing of physical techniques during scar management. Standardized and validated outcome measures should definitely receive more attention and development in clinical evaluation. Patient-reported outcomes can be considered an indispensable part of clinical evaluation. Clinical treatment should therefore focus not only on the treatment itself but also on adequate outcome evaluation of therapy.

16 The Pathophysiology of Inhalation Injury

PERENLEI ENKHBAATAR, LINDA E. SOUSSE, ROBERT A. COX, and DAVID N. HERNDON

Introduction and Epidemiology

It has been more than three decades since Herndon and colleagues' first manuscript on inhalation injury was published.[1] It was initially reported in 1985 that inhalation injury was a major determinant of mortality in severely burned patients.[2]. The standard of care has evolved over time, but inhalation injury still remains a major problem.[3]. Although sepsis is reportedly the most frequent cause of death among burned children,[4], roughly two-thirds of burned patients who have died at the Shriners Hospitals for Children suffer from inhalation injuries.[5] Based on data from 506,628 admissions to burn units from 1988 to 2008, burn patients with inhalation injury are more likely to die than those without inhalation injury (P <0.001).[6] Furthermore when 791 burned patients from 44 hospitals were retrospectively reviewed in 2014, the mortality rate of patients with inhalation injury was 17.9% compared to 0.7% in patients without inhalation injury (P <0.05).[7]

Smoke inhalation causes 5000 to 10,000 deaths annually in the United States and more than 23,000 injuries, including approximately 5000 firefighter injuries.[8] In fact, the United States has the tenth highest fire death rate per million people among industrialized countries.[9] Approximately 15% of burned individuals with over 80% total burned surface area (TBSA) who are admitted to burn centers in the United States have a concomitant smoke inhalation injury.[6] Greater percentages of fire victims who have sustained smoke inhalation are seen in several other countries.[10–13] The lung is a critical organ, and progressive respiratory failure associated with pulmonary edema is a pivotal determinant of mortality.[14–16] Although not as lethal, smoke inhalation alone is a serious problem. According to World Health Organization estimates, more than 4 million people die from household air pollution from cooking with solid fuels (Fig. 16.1).[17]

The inhalation of toxic materials has been of interest for a number of years, particularly because of the use of toxic gases in civilian mass casualty events. In the 1940s, two very large fires focused attention on smoke inhalation in fire accidents. The first was a fire at the Cocoanut Grove nightclub in Boston, Massachusetts, where a large number of people were trapped in a burning building and consequently sustained severe inhalation injury.[18,19] The second disaster occurred in 1947, in Texas City, Texas.[20] A ship loaded with ammonium nitrate fertilizer exploded in the harbor and set off a chain of explosions and fires among 50 refineries and chemical plants, resulting in more than 2000 hospital admissions. Many of the victims were burned and simultaneously inhaled smoke, while many others suffered from smoke inhalation alone. Disasters like those in Boston and Texas led to the establishment of centers for the care of burn victims and research into the pathophysiology of burn injury.

In many ways, the September 11, 2001, disaster at the Pentagon was similar to these two earlier disasters since the burn and inhalation injuries involved combustion of petroleum products. Among the 790 injured survivors of the terrorist attack on the World Trade Center in New York on September 11, 49% suffered from inhalation injury. The situation was the same as in the Pentagon attack in that inhalation injury was seen in some patients who were not burned.[21]

Inhalation injury can be classified as follows: (1) upper airway injury, (2) lower airway injury, (3) pulmonary parenchyma injury, and (4) systemic toxicity. The extent of inhalation damage depends on the fire environment: the ignition source, temperature, and the concentration and solubility of the toxic gases generated. For instance, hot air and smoke chemical compounds usually cause upper airway injury. Water-soluble materials such as acrolein and the other aldehydes damage the proximal airways and set off reactions that inflame in the bronchi and parenchyma, whereas agents with lower water solubility such as chlorine, phosgene, nitrogen oxide, nitrogen dioxide (N_2O_3 or even N_2O_4) are more likely to cause insidious injury.[22]

Pathophysiology

INJURY TO THE OROPHARYNX

Many of the pathophysiological changes occurring after inhalation injury are related to edema formation in the oropharynx, bronchial areas, and parenchyma. This edema results from an increased transvascular fluid flux from vascular beds in these respective tissues. Before discussing the changes that occur in these structures following inhalation injury, a review of the forces responsible for the variables of the Starling-Landis equation should be reviewed[23,24]:

$$J_v = K_f[(P_c - P_{if}) - \sigma(COP_p - COP_{if})]$$

This equation describes the physical forces and physiologic mechanisms that govern fluid transfer between vascular and extravascular compartments. J_v, the transvascular fluid flux, is equal to lymph flow during equilibrium states. As transvascular fluid flux increases, interstitial volume also increases (edema formation) until a new equilibrium with lymph flow occurs. K_f is the filtration coefficient, an index of the total number of pores that are filtering. The number of pores could increase if a larger area of the microcirculation were perfused or if there were more pores per given

Fig. 16.1 An example of direct exposure to smoke as result of open fire using various materials as a fuel.

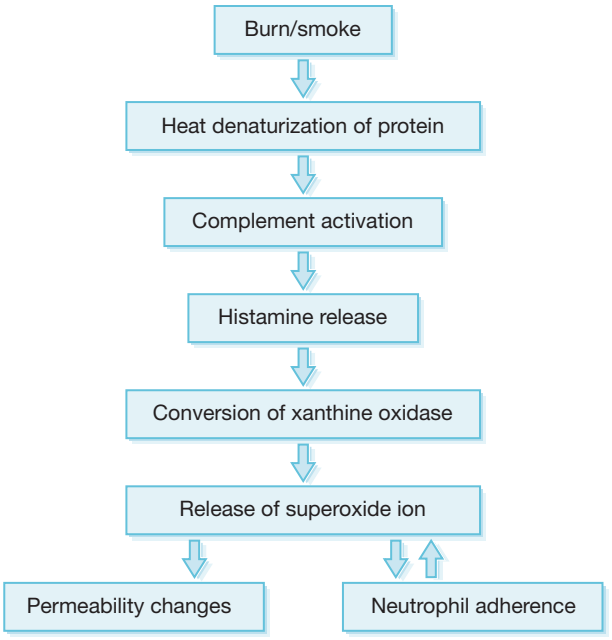

Fig. 16.2 Mechanism for edema formation in the oropharynx.

area of the microcirculation. These pores are the same size as water and electrolytes, as opposed to the larger pores associated with permeability to protein. P_c and P_{if} are the hydrostatic pressures in the microcirculation and interstitial space, respectively. The reflection coefficient, σ, is an index of microvascular permeability to protein. If σ is 1, the membrane is impermeable to protein; when σ is 0, the membrane is completely permeable to protein. COP_p and COP_{if} are the oncotic or colloid osmotic pressures in the plasma and interstitial spaces, respectively.

The major pathophysiology seen in the oropharynx following inhalation injury is induced by microvascular changes similar to those seen with thermal injury in other areas of the body. Heat denatures protein that, in turn, activates complement. Complement activation causes the release of histamine.[25,26] Histamine then causes the formation of xanthine oxidase, an enzyme involved in the breakdown of purines to uric acid.[27] During this conversion, reactive oxygen species (ROS) are released.[28,29] ROS combine with NO, constitutively formed in the endothelium, to form reactive nitrogen species (RNS).[30] The latter produce edema in the burned area by increasing the microvascular pressure and permeability to protein.[31,32] Eicosanoids and proinflammatory cytokines are also released.[33–35] These, along with oxygen free radicals and interleukin-8 (IL-8), attract polymorphonuclear cells to the area.[36] These neutrophils then amplify the release of oxygen radicals, proteases, and other materials into burned areas (Fig. 16.2).

The massive edema occurring in the soft tissue of the oropharynx following burns involves most variables in the Starling equation. There is a large increase in microvascular hydrostatic pressure,[37] a decrease in interstitial hydrostatic pressure,[38] a fall in the reflection coefficient,[37] and an increase in interstitial oncotic pressure.[38,39] The usual treatment for burn resuscitation calls for the administration of large amounts of crystalloid solutions, which has the effect of reducing the plasma oncotic pressure.[40,41] This reduction not only affects the oncotic pressure gradient in the microcirculation, but also has been reported to increase the filtration coefficient.[42,43] The result of this almost complete breakdown in control of the microvascular function and the insult of fluid administration is massive edema. This is probably nowhere more apparent than in soft tissues of the face and oropharynx. The danger to the patient is extreme. The edema may obstruct the airway, making it not only laborious or impossible to breath, but also difficult for the anesthesiologist to intubate the patient (Fig. 16.3A). To avoid this problem, many units prophylactically perform tracheostomies on patients who have evidence of thermal injury to the upper airway on admission. However tracheostomy itself may present problems. The tube may further damage injured areas, especially the larynx.[44] It may be time to reconsider some of these practices. Perhaps some consideration should be given to fluid resuscitation with colloids, which can prevent some of this soft tissue edema and reduce the volume of fluids required for resuscitation.[45,46]

INJURY TO THE TRACHEOBRONCHIAL AREA

With rare exceptions such as inhalation of steam, the injury to the airway is usually from chemicals in smoke. The heat capacity of air is low, and the bronchial circulation is very efficient in warming or cooling airway gases so that most gasses are at body temperature as they pass the glottis.[47] Flames must almost be in direct contact with the airway to induce thermal injury.[48] The chemicals in smoke depend on the materials that are being burned; however, for the most part, the host response is similar. In most instances biological materials such as cotton fabric, wood, grass, or products of these such as cattle feces (commonly used as fuel in developing countries) are the fuel for the fire. Burning of these materials produces ROS and RNS, organic acids, and aldehydes[49] that, upon inhalation, cause damage to the respiratory epithelium. The inhaled chemicals interact with the airway to induce an initial inflammatory response. In sheep that have inhaled cooled cotton smoke, there is

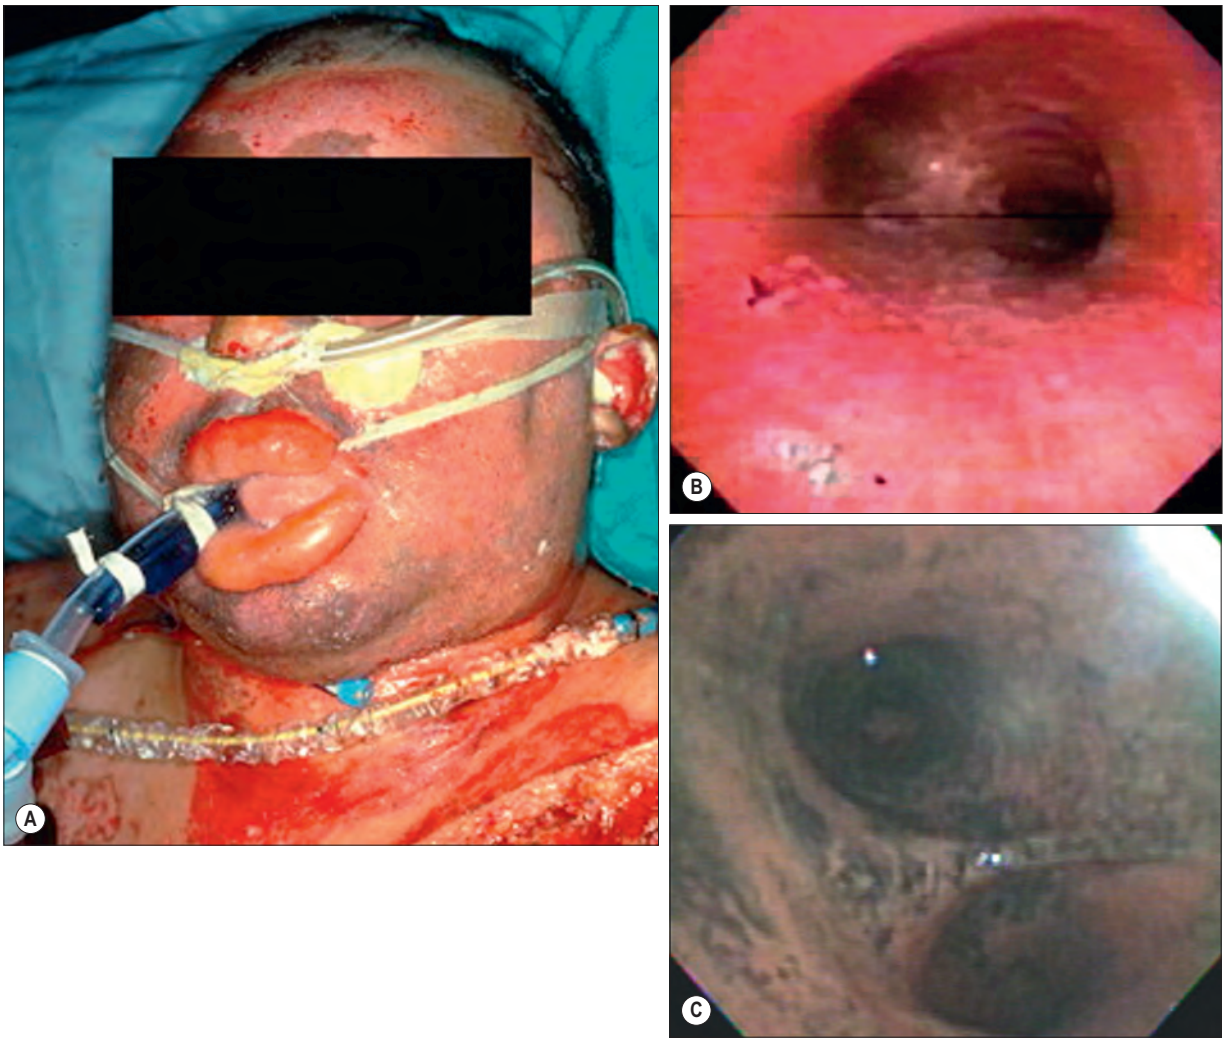

Fig. 16.3 Facial and airway injury after burn and smoke inhalation. **(A)** A facial burn is often associated with thermal injury to the upper airway. **(B)** Hyperemia of airway epithelium. **(C)** Formation of airway obstructive cast. (A is from Cancio LC. Airway management and smoke inhalation injury in the burn patient. *Clin Plast Surg*. 2009;36(4):555–567.)

damage to the tracheobronchial[50,51] and alveolar epithelium. Injury and loss of these cells lead to an intense inflammatory response.[35]

Many of the studies on bronchial circulation following smoke inhalation injury have been performed in sheep because these animals have a single bronchial artery[52] and a single lymphatic draining the lung, thus allowing measurement of pulmonary transvascular fluid flux.[53] In these animals, a 10-fold increase in bronchial blood flow occurs within 20 minutes of smoke inhalation.[54] These same animals demonstrate a sixfold increase in pulmonary transvascular fluid flux and a fall in Pao_2/Fio_2 to 200 or less, but these changes are delayed, occurring around 24 hours after injury. Similar findings have been reported in patients with smoke inhalation alone or a combination of large cutaneous thermal injury and smoke inhalation.[55]

Hyperemia of the airway is such a consistent finding in smoke inhalation that it is used to diagnose the injury.[56,57] Other variables that are used include injury in an enclosed space, singed nasal hair, and soot in sputum. However these latter injuries may be present but the subject may still not develop the signs of pulmonary edema characteristic of inhalation injury. Airway inflammation plays a major role in the overall response to inhalation injury (Fig. 16.3B and C).

As noted, there is a large sustained increase in blood flow in the airway following smoke inhalation.[58] These changes in blood flow are associated with increased bronchial microvascular permeability to protein and small particles[59] and pressure.[60] Simultaneous with changes in bronchial microvasculature function, there is a loss or shedding of the bronchial columnar epithelium.[35,50,61] These changes result in a perfuse transudate with a protein content similar to an ultrafiltrate of the plasma.[62] There are also copious secretions from the goblet cells of the lining and mucosal epithelium.[63] Early in the response, these secretions form a foam material in the airway that many have mistaken for severe pulmonary edema in patients.[64] After several hours the transudate/exudate, exfoliated epithelium, secreted mucus, and inflammatory cells form obstructive materials in the airways.[65] The degree of obstruction at this early stage statistically correlates with decreasing pulmonary function.

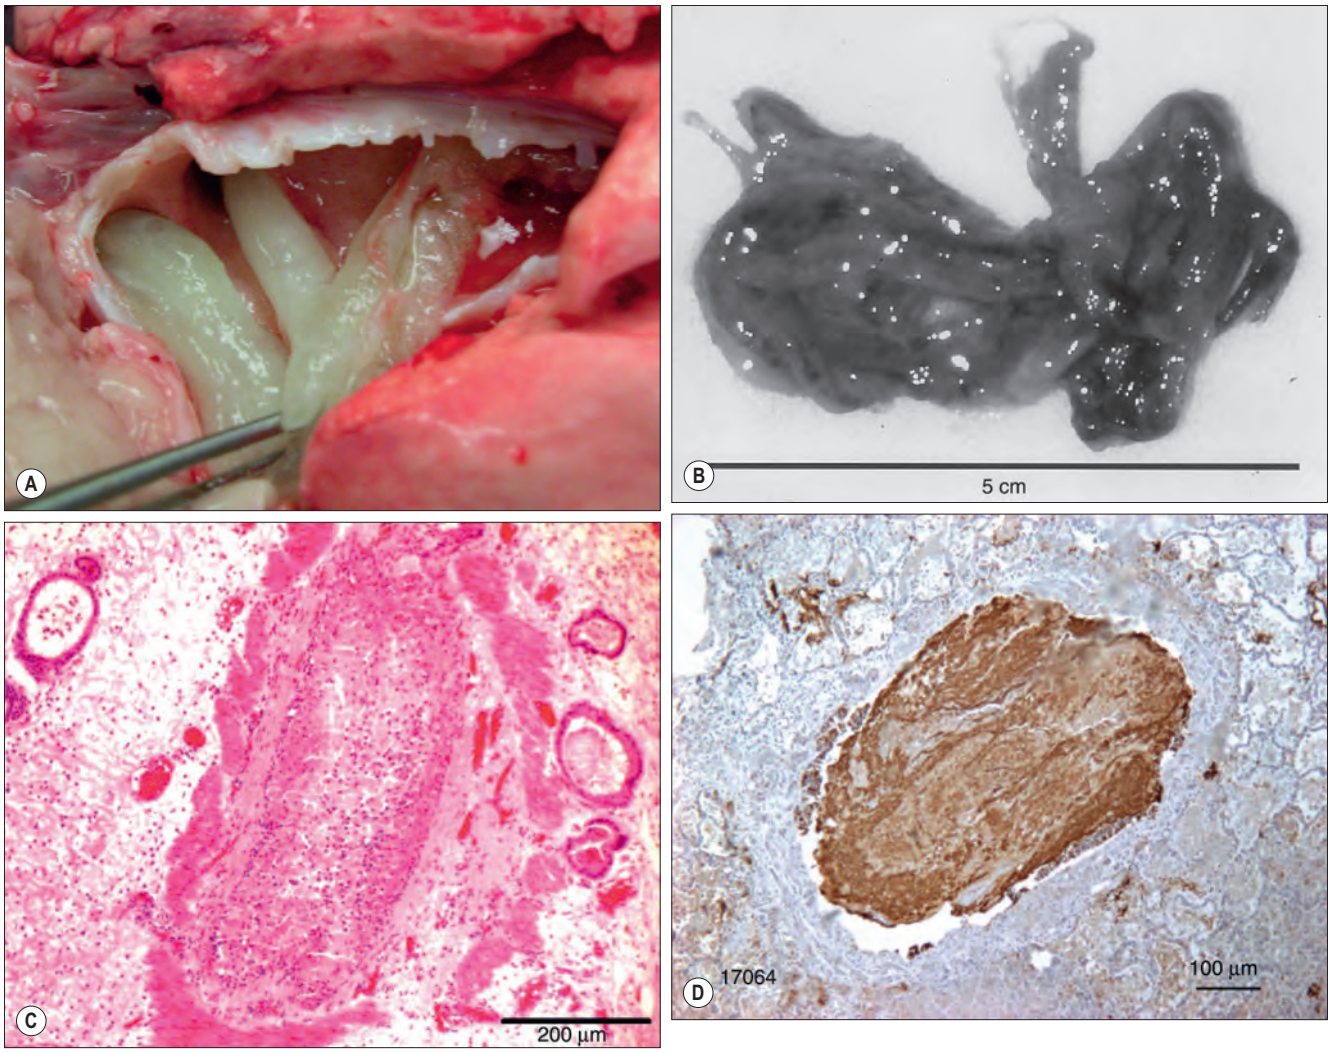

Fig. 16.4 Airway obstructive cast. **(A)** Macroscopic views of an airway obstructive cast in sheep 48 hours after burn and smoke inhalation injury. **(B)** Macroscopic views of an airway cast taken from a patient with burn and smoke inhalation injury by bronchoscope.[69] **(C)** Microscopic views of bronchi totally blocked by obstructive cast in sheep.[35] **(D)** Mucus totally obstructing a bronchiole in a patient after burn and smoke inhalation injury. The tissue had been immunostained for mucin 5B, an upper airway-specific mucin subtype.[66] (B is from Nakae H, Tanaka H, et al. Failure to clear casts and secretions following inhalation injury can be dangerous: report of a case. *Burns* 2001;27(2):189–191; C is from Cox RA, Burke AS, et al. Acute bronchial obstruction in sheep: histopathology and gland cytokine expression. *Exp Lung Res*. 2005;31(9–10):819–837; D is from Cox RA, Mlcak RP, et al. Upper airway mucus deposition in lung tissue of burn trauma victims. *Shock* 2008;29(3):356–361.)

With increasing time after injury, these obstructive materials formed in the upper airway may appear in the lower airway and alveoli.[63,66] This obstructive material is problematic from several stand-points. In some rare instances of severe airway injury these materials can induce total obstruction and are life-threatening (Fig. 16.4).[67–69] Occlusion of some of the bronchi or bronchioles in the setting of high NO production can lead to a loss of hypoxic pulmonary vasoconstriction and thus increased shunt fraction. Loss of hypoxic pulmonary vasoconstriction has been reported with inhalation injury. If single bronchi are occluded while the patient is on a volume-limited ventilator, there may be overstretch, and barotrauma to the alveoli of the nonoccluded portion of the lung can occur. Nebulized anticoagulants have been used to combat the upper airway obstruction that can occur with severe inhalation injury. These are beneficial in reducing cast formation and improving pulmonary performance,[70,71] although their use in the clinical environment has not yet been reported. Airway mucosal edema and luminal obstruction following an inhalation injury occur alongside airway smooth muscle hyperreactivity. Adrenergic[72,73] and antimuscarinic bronchodilator[74] therapies have been shown to be beneficial in reducing ventilatory peak pressure and improving pulmonary function. The initial hyperreactive response of the airways to injury and inflammation is followed by a more long-term pathogenesis of inhalation injury that includes bronchopneumonia.[2] Pneumonia is the leading complication in the critical care of burn victims,[75] with the incidence of pneumonia in a burn patient with inhalation injury being two- to fourfold greater than that seen in burn patients without inhalation injury.[15,76] Conceptually the high incidence of pneumonia in burn patients with inhalation injury is associated with the loss of airway epithelium and the essential properties of these cells in innate defense. Studies that have focused on the repair of the epithelium after burn injury are limited.

In an ovine model with a selected area of smoke injury to the tracheal epithelium, the epithelial repair process was completed at 18 days.[77] Further study by this team of investigators revealed that nebulization of cefazolin and growth factors[78] could improve the rate of airway healing. Because of the effects of pneumonia and inhalation injury on burn patient morbidity and mortality, further studies on the dynamics of airway damage and airway epithelial repair following toxic exposure are needed to improve critical burn care.

The airway is richly innervated with vasomotor and sensory nerve endings.[79] These fibers are known to release neuropeptides that can engender inflammatory responses.[80] Neuropeptides in the upper airway are also involved in mucus secretion, thus their release and interaction with the mucosal gland epithelium can increase the early obstructive pathology that occurs with inhalation injury.[81,82] Neuroinflammation is responsible for pathophysiological changes associated with a number of clinical conditions including tissue injury induced by chemicals.[83,84] Lange and colleagues reported that antagonists to substance P and calcitonin gene-related peptide had a marked effect on this response when administered to sheep and mice that were injured with both burn and smoke inhalation.[51,85] In an ovine model, the combination of burn and smoke inhalation injury caused a 10-fold increase in pulmonary transvascular fluid flux and a reduction of Pa_{O_2}/Fi_{O_2} to 200 or less. These changes were reversed by neuropeptide receptor blocking agents.[85] Released neuropeptides can activate nitric oxide synthase (NOS), have chemokine activity, and change microvascular permeability.[86] The resultant activities lead to the formation of ROS and RNS.[87] Some of the latter are very potent oxidants that can damage DNA.[30] Damage to DNA triggers activation of a DNA repair enzyme, poly(ADP-ribose) polymerase (PARP).[88] This enzyme depletes the cell of high-energy phosphates and causes the activation of nuclear factor-κB (NF-κB)[89,90] NF-κB activation induces upregulation of inducible NOS (iNOS) and IL-8, thus accelerating production of ROS and RNS.[91] NO and 3-nitrotyrosine (an index of RNS), and iNOS mRNA and protein have been reported to be in the airway after smoke inhalation.[87,92] Compounds that catalyze the breakdown of peroxynitrite reduce the response to smoke inhalation. Poly(ADP-ribose) (PAR), the product of the constitutive enzyme PARP, is detectable in airway tissues following smoke inhalation.[87] PARP inhibition prevents PAR formation, NF-κB upregulation, and 3-nitrotyrosine formation.[93] Similarly, Lange and colleagues have reported that compounds that inhibit peroxynitrite by catalyzing its rapid breakdown likewise prevent the formation of these materials.[94] It is interesting to note that mice missing the PARP genes or given a PARP inhibitor will not show the typical inflammatory changes usually observed with asthma.[95] Thus, in many ways, inhalation of smoke may be similar to other forms of airway injury. The fact that the response to inhalation injury is driven by neuroinflammation suggests that the response to smoke from wood or cotton is similar.

INJURY TO THE LUNG PARENCHYMA

As noted earlier, burn and smoke inhalation induce delayed lung parenchymal changes as reflected by reduced Pa_{O_2}/Fi_{O_2}, decreased compliance, and increased edema formation.[96] The delay is dependent on the severity of the airway injury.[49,97] Lung injury is associated with an increased pulmonary transvascular fluid flux.[98] The degree of transvascular fluid is proportional to the duration of smoke exposure[49] and is not caused by carbon monoxide (CO) in the inhalant gas.[99] However the degree of arterial CO is related to severity of inhalation injury.[100] The factors responsible for fluid leak are codified in the Starling-Landis equation.[23,24] The variables of this equation relate fluid movement to pressure and permeability variations. With inhalation of smoke, there is a reduction in the reflection coefficient (permeability to protein), an increase in the filtration coefficient (permeability to small particles), and an increase in pulmonary microvascular pressure.[101,102] Animals exposed to smoke inhalation injury were also noted to have reduced Pa_{O_2}/Fi_{O_2}. These variables are more severely affected when the inhalation is combined with burn injury[103] and show a good relationship to histologic injury scores and changes in transvascular fluid flux.[93] In addition, there is a loss of hypoxic pulmonary vasoconstriction in the injured animals that may help to explain the loss of oxygenation.[104]

As in the oropharynx, injury to the lung parenchyma is associated with PARP activation and 3-nitrotyrosine, and it is markedly reduced by the administration of iNOS or PARP inhibitors.[92]

The venous outflow of the bronchial circulation drains into the pulmonary microcirculation at the precapillary level.[105] Given that initial damage to the airway appeared to drive the pathophysiology of the parenchyma, investigators hypothesized that bronchial blood might deliver cytotoxic materials or cells to the pulmonary microcirculation. To test this hypothesis, several investigators have tied off the bronchial artery of sheep and then exposed the animals to smoke.[59,96,106] Lung parenchymal changes are reduced by this approach, affirming the hypothesis. It has also been shown that increased bronchial blood flow following smoke inhalation injury carries inflammatory mediators to the parenchyma, augmenting the injury process.[107–109] Recent ovine studies demonstrate that nebulized epinephrine (nonspecific adrenergic agonist) has similar effects following smoke inhalation injury: reduced airway blood flow, attenuated pulmonary edema, and reduction in proinflammatory mediators to levels seen in sheep with ablated bronchial circulation.[73,110] The latter observation is of particular clinical importance because the ligation/ablation of bronchial artery is not feasible in clinical practice.

What could be the linkage among the airway, the bronchial venous drainage, and parenchymal injury to the lung? Neutrophils activated in the bronchial circulation flow out into the bronchial venous drainage. Activated polymorphonuclear cells (PMN), especially neutrophils, are stiff. The diameter of neutrophils that have been fixed is approximately 7 μm.[111] Since these cells have been dehydrated in alcohol as part of the fixation process, unfixed cells are much larger, on the order of 12 μm. The pulmonary capillary is small, with an average diameter of 6 μm.[111] Normally, large neutrophils can traverse the pulmonary capillary by changing shape. However, following injury, many of the neutrophils in the bronchial areas have their F-actin activated. As result, these cells are stiff and cannot

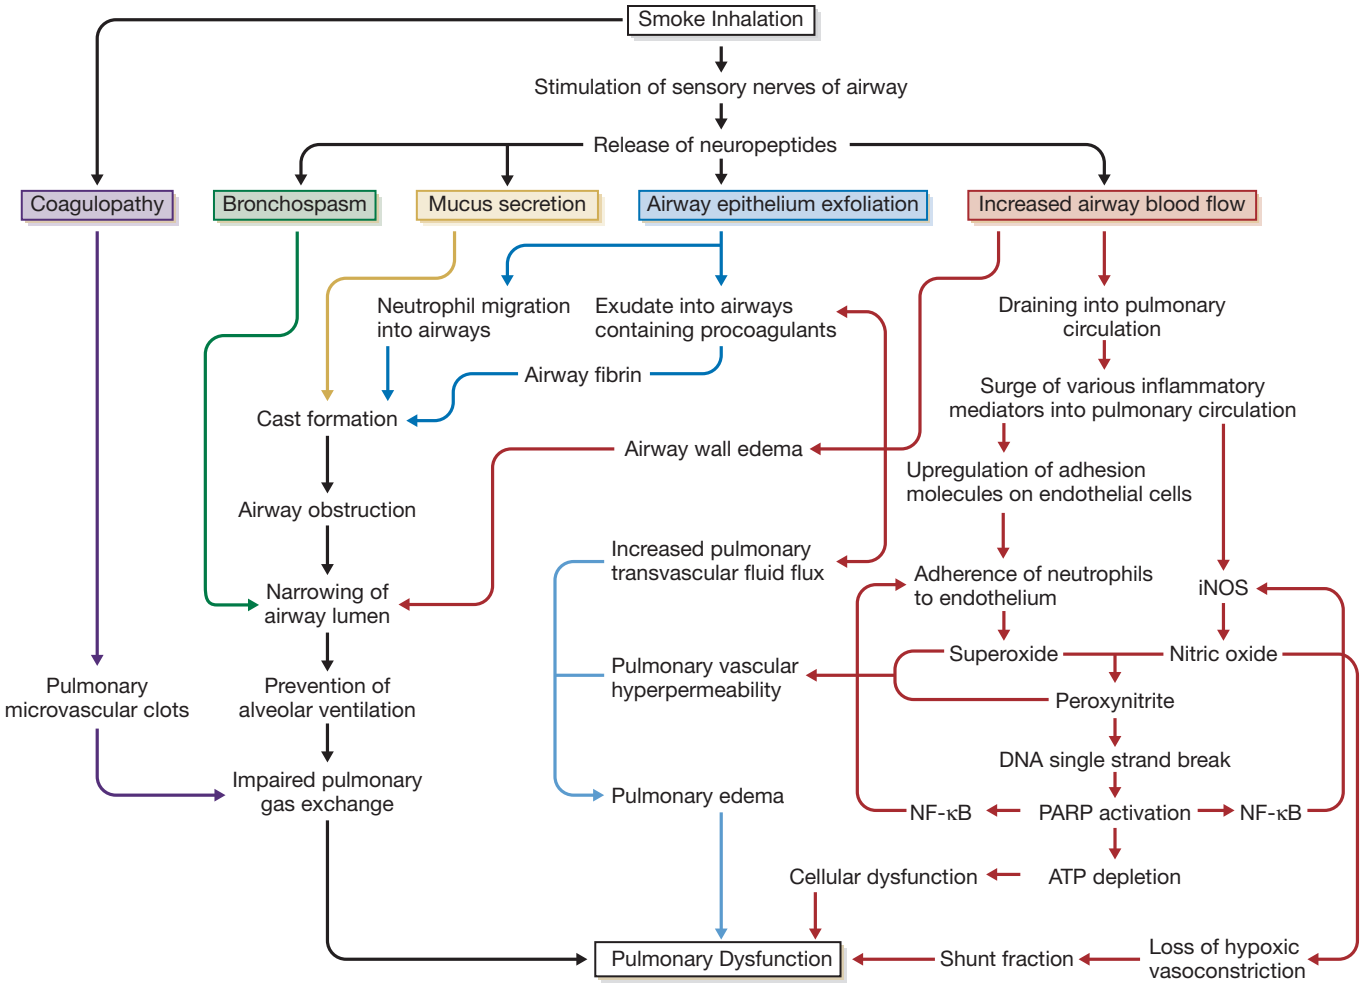

Fig. 16.5 Pathophysiology of burn and smoke inhalation induced acute lung injury. *iNOS*, inducible nitric oxide synthase; *PARP*, poly(ADP-ribose) polymerase. (From Fishman, ed. *Pulmonary diseases and disorders*, 5th edn., vol 2., McGraw-Hill Companies, China. ch. 94. 2015: 1428–1440.)

deform. These stiff cells are carried to the pulmonary microvasculature where they are captured by the narrow pulmonary capillaries. The activated neutrophils release ROS and proteases that damage the parenchyma. The following evidence supports this concept of neutrophil cytotoxicity. Oxidative processes are well established following inhalation injury, with lipid peroxidation and release of proteolytic enzymes following injury.[112–114] Moreover, administration of protease inhibitors or ROS scavengers will reduce the response to smoke inhalation[113,115–117] when activated PMNs lose L-selectin on their surfaces. This L-selectin shedding is prevented by treatment with an L-selectin antibody,[118] which prevents changes in transvascular fluid flux and other aspects of parenchymal damage.[119] Final proof of this hypothesis is provided by studies of how the response to inhalation injury is affected by depleting animals of neutrophils. In these studies of sheep depleted of their leukocytes, a large portion of the response to smoke inhalation was blocked.[120]

Coagulopathy has increasingly been described as a critical complication of burn and smoke inhalation injury. Following burn injury, there is a hypercoagulable state associated with severe deficiency of the potent endogenous anticoagulant antithrombin.[121] In preclinical studies, supplementation with recombinant human antithrombin has been shown to attenuate pulmonary edema, downregulate proinflammatory mediators, and improve pulmonary gas exchange.[71,122] In pilot clinical studies, antithrombin deficiency following cutaneous burn was correlated with TSBA, presence of smoke inhalation, length of ICU and hospital stay, morbidity severity, and mortality.[123–126] Recent unpublished observations showed that of six sheep exposed to smoke inhalation, all developed some degree of pulmonary vascular emboli (clot) observable by computed tomography scan. The pathophysiology of acute lung injury secondary to burn and smoke inhalation injury is summarized in Fig. 16.5.

In addition to exhibiting a depletion of antioxidants as discussed earlier, burn patients are depleted of arginine.[127] When arginine levels are low, NOS produces superoxide rather than NO.[128] Following smoke inhalation, arginase activity is also elevated.[129] This enzyme also depletes arginine by converting it to ornithine.[130] Administration of arginine may assist in reducing the oxidation that occurs with inhalation injury.[131] However the necessity of administering arginine as arginine hydrochloride (because of solubility) limits the amount that may be given intravenously without producing acidosis.

LONG-TERM EFFECTS OF INHALATION INJURY

When earlier editions of this book were published, mortality from inhalation injury was high and the acute inflammatory aspects of the injury were considered a major vector of mortality. Now 85% of our patients survive inhalation injury.[5] Thus the long-term aspects of this injury are of considerable interest. When patients are examined years after burn injury, they demonstrate symptoms of restrictive lung disease and reduced diffusion capacity, both of which are signs of lung fibrosis.[132] At autopsy, both patients and animals reportedly show hyaline membrane and deposition of collagen in their lungs, changes similar to those seen in other forms of acute lung injury.[61,129] As stated earlier, two enzymes compete for arginine: NOS and arginase.[134] NOS forms NO and RNS. Arginase forms ornithine, which is converted into polyamines and proline, leading to the formation of collagen.[135] When NOS is active, it forms N (omega)-hydroxy-nor-L-arginine (NOHA). NOHA is broken down into NO and citrulline. NOHA is a potent inhibitor of arginase.[136,137] Thus, as long as NOS activity is elevated, arginase is inhibited. It has recently been reported that the endogenous NOS inhibitor asymmetric dimethylarginine (ADMA) begins to rise in the lung of sheep following combined burn and smoke inhalation injury.[129] As ADMA increases, NO production falls and tissue levels of collagen increase. The increase in collagen results in hyaline membrane formation and thickening of the alveolar septum that interferes with the diffusion of oxygen into the lung. ADMA is formed in the lung on a regular basis but it is rapidly catabolized by dimethylarginine dimethylaminohydrolase (DDAH).[138,139] DDAH is inactivated by oxidation. Following burn and inhalation injury, lung levels of DDAH fall as markers of oxidation rise, and, as these events occur, levels of ADMA, arginase, and collagen increase.[129] We have previously determined that oxidation is such a serious problem that survival is dependent of the degree of oxidation.[115] In addition, it was recently reported that levels of γ- and α-tocopherol are markedly depleted in thermally injured children.[140] In sheep depleted of α- and γ-tocopherols following burn and smoke exposure, the administration of tocopherol, especially γ- tocopherol, either orally or through nebulization into the airways (more effective) restored not only lung levels of tocopherol, but also normal oxidation status and pulmonary function during the acute phase of injury.[140–146] Preliminary experiments using the long-term model reported by Sousse et al. indicate that the nebulization of γ-tocopherol also reduces collagen deposition; blocks elevation in arginase, proline, and ADMA levels; and restores DDAH levels.

Finally, recent preclinical ovine studies indicate that smoke inhalation causes structural damage in the brain as seen by neuronal and astrocyte death and microhemorrhage (unpublished data). It has previously been reported that smoke-induced oxidative DNA damage in the brain is extensive, and compromised fidelity of DNA repair may underlie neurotoxicity and contribute to delayed death of hippocampal neurons.[147] Furthermore, acute smoke exposure significantly compromises the respiratory capacity of hippocampal mitochondria.[148] These results suggest that fire victims, especially those with smoke inhalation injury, should carefully be monitored for possible nonpulmonary organ damage, including central nervous system (CNS) dysfunction.

The Fire Environment and Toxic Smoke Compounds

Smoke toxicity is an increasing concern because modern industrial products are changing from woods and natural materials toward lighter construction materials, synthetics, and petrochemical-based materials. These materials ignite and burn two to three time hotter and faster than conventional material and, when heated, emit a gas or smoke that is more toxic than natural biological materials. Consequently firefighters have less time to gain control of a fire, and victims are more likely to be incapacitated by breathing toxic gases and to sustain smoke inhalation because they have less time to escape from the burning area.[8] Inhalation injury is caused by steam or toxic inhalants such as fumes, gases, and mists. Fumes consist of small particles with various adherent irritants or cytotoxic chemicals that are dispersed in air. Mists consist of aerosolized irritant or cytotoxic liquids. Smoke consists of a combination of fumes, gases, mists, and hot air. Heat, toxic gases, and low oxygen levels are the most common causes of death in fires. A large variety of toxic gases and chemicals can be generated depending on the fire environment (Table 16.1).

Many of these compounds may act together to increase death, especially CO and hydrogen cyanide (CH).[149,150] A synergism between these compounds has been found to increase tissue hypoxia and acidosis[150] and may also decrease cerebral oxygen consumption and metabolism.[22,151] Hydrogen sulfide would also be predicted to synergize with CO since both cyanide and hydrogen sulfide are inhibitors of mitochondrial cytochrome oxidase. Victims may be incapacitated by the blinding and irritating effects of smoke, as well as by the decreasing oxygen concentration that occurs with combustion and results in progressive hypoxia.

Toxic gases such as CO and cyanide rarely damage the airway, but instead affect gas exchange and produce more systemic effects. Thus it is important to obtain information on the source of the fire and the combustion products generated when treating a fire victim (see Table 16.1). It is also important to know the duration of exposure and the extent to which the fire victim was in an enclosed area since this relates to the dose of toxic materials received.

CARBON MONOXIDE

CO is an odorless, colorless gas that is produced by incomplete combustion of many fuels, especially cellulolytic (cellulose) products such as wood, paper, and cotton.[152] CO toxicity remains one of the most frequent immediate causes of death following smoke-induced inhalation injury. The predominant toxic effect of CO is attributed to its binding to hemoglobin (Hb) to form carboxyhemoglobin (COHb). The affinity of CO for Hb is approximately 200 to 250 times higher than that of oxygen.[153] Inhalation of a 0.1% CO mixture may result in generation of a COHb level as high as 50% of the total Hb. The competitive binding of CO to Hb reduces delivery of oxygen to tissues, leading to severe

Table 16.1 Origin of Selected Toxic Compounds

Gases and Chemicals	Material	Source
Carbon monoxide	Polyvinyl chloride Cellulose	Upholstery, wire/pipe coating, wall, floor, furniture coverings Clothing, fabric Wood, paper, cotton
Cyanide	Wool, silk, cotton, paper, plastic, polymers Polyurethane Polyacrylonitrile Polyamide Melamine resins	Clothing, fabric, blankets, furniture Insulation, upholstery material Appliances, engineering, plastics Carpeting, clothing Household and kitchen goods
Hydrogen chloride	Polyvinyl chloride Polyester	Upholstery, wire/pipe coating, wall, floor, furniture coverings Clothing, fabric
Phosgene	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
Ammonia	Wool, silk Polyurethane Polyamide Melamine resins	Clothing, fabric, blankets, furniture Insulation, upholstery material Carpeting, clothing Household and kitchen goods
Sulfur dioxide	Rubber	Tires
Hydrogen sulfide	Wool, silk	Clothing, fabric, blankets, furniture
Acrolein	Cellulose Polypropylene Acrylics	Wood, paper, cotton, jute Upholstery, carpeting Aircraft windows, textiles, wall coverings
Formaldehyde	Melamine resins	Household and kitchen goods
Isocyanates	Polyurethane	Insulation, upholstery material
Acrylonitriles	Polyurethane	Insulation, upholstery material

From Prien T, Traber DL. Toxic smoke compounds and inhalation injury: a review. *Burns* 1988;14:451–460.

hypoxia, especially in the most vulnerable organs such as the brain and heart where oxygen extraction is considerably higher than that in most other organs. The oxygen–Hb dissociation curve loses its sigmoid shape and is shifted to the left, thus further impairing tissue oxygen availability.[149,154] In addition, the ability of CO to bind to intracellular cytochromes and to other metalloproteins contributes to CO toxicity. This competitive inhibition with cytochrome oxidase enzyme systems (most notably cytochromes a and P-450) results in an inability of cellular systems to use oxygen.[154,155] Shimazu and his colleagues have shown that extravascular binding of CO to cytochromes and other structures accounts for 10–15% of total body CO stores. This intracellular binding of CO explains the two-compartment elimination of CO from the circulation.[156] Miro and colleagues reported that CO inhibits cytochrome-c oxidase activity in lymphocytes.[157] The electron chain dysfunction induced by CO may cause electron leakage, leading to superoxide production and mitochondrial oxidative stress.[158]

Although smoke inhalation commonly affects the respiratory system, CNS disturbances can also develop. CNS signs can be classified as being related to either acute or delayed toxicity. The veterinary literature contains a few reports on the neurological consequences of smoke inhalation. In dogs, smoke inhalation produces lesions that are consistent with acute CO toxicity. Lesions are confined to the caudate nucleus, globus pallidus, and the substantia nigra bilaterally, as well as the cerebellum, cerebral cortex, and dorsal thalamus. A case report by Kent and colleagues describes the clinicopathological sequelae in acute CO toxicity.[159]

Symptoms and Diagnosis of Carbon Monoxide Poisoning

Symptoms of CO poisoning predominantly manifest in organs and systems with high oxygen utilization. The severity of clinical manifestations varies depending on CO concentration. For instance, CNS symptoms such as headache, confusion, and collapse may occur when the blood COHb level is 40–50%. Symptoms such as unconsciousness, intermittent convulsions, and respiratory failure may occur if the COHb level exceeds 60%, eventually leading to death if exposure continues. The cardiovascular manifestations may result in tachycardia, increase in cardiac output, dysrhythmias, myocardial ischemia, and hypotension depending on severity of poisoning. The correlation between clinical manifestation and severity of CO poisoning is summarized in Table 16.2.

Diagnosis should be based on direct measurement of COHb levels in arterial or venous blood by co-oximetry, taking into account that venous blood underestimates the arterial COHb content.[160] Diagnosis may be facilitated by use of on-site portable breath analyzers. The inability to differentiate oxyhemoglobin from COHb limits the use of a pulse oximeter. The use of blood gas analyzers that estimate sulfur dioxide (SO_2) based on measurement of dissolved PO_2 should also be avoided. Measuring acid–base balance, plasma lactate levels, and bicarbonate is helpful in

Table 16.2 Symptoms and Signs at Varying Concentrations of Carboxyhemoglobin (COHb)

COHb %	Symptoms
0–10	None
10–20	Tightness over forehead, slight headache, dilation of cutaneous blood vessels
20–30	Headache and throbbing in the temples
30–40	Severe headache, weakness, dizziness, dimness of vision, nausea, vomiting, collapse
40–50	As above; greater possibility of collapse, syncope, increased pulse and respiratory rate
50–60	Syncope, increased pulse and respiratory rate, coma, intermittent convulsions, Cheyne-Stokes respirations
60–70	Coma, intermittent convulsions, depressed cardiac and respiratory function, possible death
70–80	Weak pulse, slow respirations, death within hours
80–90	Death in less than 1 h
90–100	Death within minutes

From Einhorn IN. Physiological and toxicological aspects of smoke produced during the combustion of polymeric materials. *Environ Health Perspect*. 1975;11:163–189; and Schulte JH. Effects of mild carbon monoxide intoxication. *Arch Environ Health* 1963;7:524–530.

managing CO poisoning with accompanying lactic or metabolic acidosis. It is important to note that high oxygen concentrations are usually administered to the victim in transit to the hospital, and some delay from cessation of exposure to measurement of CO may limit evaluation of the true extent of exposure.[161] A nomogram has been developed that can relate the COHb levels of a patient to the values that may have been present at the time of smoke inhalation, and this can be used to estimate the true degree of inhalation injury.[100]

HYDROGEN CYANIDE

Hydrogen cyanide (CN), the gaseous form of cyanide, is generated by the combustion of nitrogen- and carbon-containing substances, such as wool, silk, cotton, and paper as well as synthetic substances like plastic and other polymers. Combustion of these materials may produce the rapid and lethal incapacitation of a victim at the fire source.[162] CN is a colorless gas with the odor of bitter almonds; however it is difficult to detect at the site of the fire. CN is cytotoxic mainly owing to its reversible inhibition of cytochrome c oxidase, the thermal oxidase of the respiratory chain, through interaction with the ferric ion of cytochrome a_3.[161] This suppresses cellular oxygenation and causes tissue anoxia. CN also adversely affects a number of other enzyme systems. CN is also toxic by virtue of its combination with essential metal ions, formation of cyanohydrins with carbonyl compounds, and sequestration of sulfur as a thiocyanate.

The importance of CN in smoke inhalation injuries is reflected by a study of residential fires in Paris, France, showing that mean blood CN concentrations in both fire victims who survived (21.6 mol/L) and those who died (116.4 mol/L) were significantly higher than those in control subjects (5.0 mol/L) and that levels in fire victims who died were significantly higher than those in survivors.[163] A study of 144 fire victims in Dallas County, Texas, showed results consistent with the Paris study.[164] Elevated CN concentrations are directly related to the probability of death, suggesting that CN poisoning rather than CO poisoning may be the predominant cause of death in some fire victims. CN also played a greater role in mortality following an aircraft fire at Manchester International Airport in the United Kingdom in 1985. These patients were not severely burned. The large majority (87%) of the 54 individuals who died had potentially lethal levels of CN in their blood, whereas only 21% of these fire victims had COHb levels exceeding 50%. This strongly suggests that, under certain conditions, CN can be a more important determinant of morbidity and mortality following smoke inhalation than CO, which is usually regarded as the primary toxic threat.[8] Smoke is also an often overlooked source of CN exposure in terrorist bombings. Following the first World Trade Center bombing in 1993, traces of CN were found in the vans where the explosion originated. The U.S. Centers for Disease Control and Prevention and the Department of Homeland Security consider CN among the most likely agents of chemical terrorism.[165] CN possesses all attributes of an ideal terrorist weapon: it is plentiful, readily available, and easily obtainable because of its widespread use in industry and laboratories. In addition the use of CN does not require any special knowledge. It is capable of causing mass incapacitation and casualties, and it can cause mass confusion, panic, and social disruption.[166]

Table 16.3 Symptoms of Cyanide Toxicity

Symptoms in Low or Moderate Inhaled Cyanide Concentrations	Symptoms in Moderate or High Inhaled Cyanide Concentrations
Faintness	Prostration
Flushing	Hypotension
Anxiety	Tremors
Excitement	Cardiac arrhythmia
Perspiration	Convulsions
Vertigo	Stupor
Headache	Paralysis
Drowsiness	Coma
Tachypnea	Respiratory depression
Dyspnea	Respiratory arrest
Tachycardia	Cardiovascular collapse

Symptoms and Diagnosis of Cyanide Poisoning

Diagnosis at the fire scene may be difficult. Poisoning may results in CNS, respiratory, and cardiovascular dysfunction due to inhibition of oxidative phosphorylation, depending on the concentration of CN inhalation (Table 16.3).

Electrocardiographic changes such as S-T segment elevation that mimic an acute myocardial infarction[167] may be suggestive. Laboratory findings of anion gap metabolic acidosis and lactic acidemia aid in confirming the diagnosis.[168] Lactic acidosis that is not rapidly responsive to oxygen therapy may be a good indicator for CN poisoning.[100,163] Also, an elevated mixed venous saturation is suggestive of

CN toxicity. CN increases ventilation through carotid body and peripheral chemoreceptor stimulation. Increasing ventilation may augment toxicity in the early stages. Low levels of CN are routinely found in the blood of healthy individuals at levels of 0.02 μg/mL in nonsmokers and 0.04 μg/mL in smokers. Toxicity occurs at a level of 0.1 μg/mL, and at 1.0 μg/mL death is likely.[169] Correlation of blood CN concentrations with clinical symptoms is summarized in Table 16.3.

OTHER TOXIC CHEMICALS

Other toxic chemicals may also substantially contribute to morbidity and mortality in a burn victim. Hydrogen chloride is produced by polyvinyl chloride degradation and causes severe respiratory tract damage and pulmonary edema. Nitrogen oxides may also cause pulmonary edema and a chemical pneumonitis, and they may contribute to cardiovascular depression and acidosis. Aldehydes such as acrolein and acetaldehyde, which are found in wood and kerosene, may further contribute to pulmonary edema and respiratory irritability. Toxic industrial chemicals such as chlorine, phosgene, hydrogen sulfide, and ammonia are of great importance. Because of their widespread availability and high toxicity, there is concern that these chemicals may be used as weapons by terrorists.[165,170]

Phosgene is a colorless, nonflammable, heavier-than-air gas at room temperature and has an odor of newly mown hay. At temperatures lower than 8°C phosgene is an odorless and fuming liquid. The inadequate warning properties of phosgene and the delayed nature of the symptoms that follow exposure make it a potential terrorist weapon.[171,172] Phosgene is only slightly soluble in water, hence its deeper penetration in the pulmonary system. On contact with water it hydrolyzes into carbon dioxide and hydrochloric acid, resulting in direct caustic damage. It also undergoes acylation reactions with amino-, hydroxyl-, and sulfhydryl-groups of cellular macromolecules, resulting in cellular damage and apoptosis.[171,173] Phosgene has delayed effects from 20 minutes up to 48 hours depending on the intensity of exposure. Phosgene inhalation produces severe pulmonary edema. Initially victims develop symptoms of upper airway irritation (eye irritation, rhinorrhea, cough) and then lower respiratory symptoms such as shortness of breath, substernal burning, and chest tightness. The development of overt pulmonary edema within 4 hours of exposure portends a poor prognosis (Table 16.4).

Chlorine is a greenish-yellow gas, an oxidizing agent, and very reactive with water. It has a pungent odor. Upon contact with water chlorine liberates hypochlorous acid, hydrochloric acid, and oxygen free radicals. It causes irritant effects throughout the respiratory tree but mostly in the nasal mucosa and upper airways. It induces cellular damage through its strong oxidizing ability.[174] Phosgene and chlorine gases were extensively used as weapons during World War I.

Ammonia is a colorless gas at room temperature with a very pungent odor. Ammonia readily dissolves in water to form ammonium hydroxide, a very caustic alkaline solution. It causes cutaneous, ocular, and pulmonary injuries. Inhaled ammonia can rapidly produce laryngeal injury and obstruction. It also causes upper tracheobronchial mucosal necrosis with sloughing and severe pulmonary edema.[174]

There are no specific antidotes to counter the toxicity of irritant gases (phosgene, chlorine, and ammonia). Depending on the severity of exposure, supportive therapy such as airway management and ventilation should be provided. Early intubation is required if any significant upper airway symptoms such as stridor are present (Table 16.5).

Table 16.4 Hydrogen Cyanide Concentrations in Air and Associated Symptoms in Humans

HCN Concentration ppm	Symptoms
0.2–5.0	Threshold of odor
10	(TLV-MAC)
18–36	Slight symptoms (headache) after several hours
45–54	Tolerated for 0.5–1 h without difficulty
100	Death in 1 h
110–135	Fatal in 0.5–1 h
181	Fatal in 10 min
280	Immediately fatal

17 Diagnosis and Treatment of Inhalation Injury

LEE C. WOODSON, LUDWIK K. BRANSKI, PERENLEI ENKHBAATAR, and MARK TALON

Introduction

Inhalation injury is a nonspecific term that refers to damage to the respiratory tract or pulmonary parenchyma by heat or chemical irritants carried into the airways during respiration.

Along with total body surface area (TBSA) burned and age, inhalation injury is one of the three features most associated with mortality following thermal insult.[1] Issues related to diagnosis and management of inhalation injury have been most recently reviewed by Walker et al.[2]

Inhalation injury may occur in conjunction with cutaneous burns or in isolation. The severity of injury varies depending on the chemical composition of the agent(s) inhaled, the intensity of exposure, and pre-existing comorbidities. There are three basic classes of inhalation injury: direct thermal injury, tissue damage due to inhalation of chemical irritants, and systemic effects of inhaled toxins. The upper airway serves as an efficient heat exchanger that protects lower structures from extremes of heat or cold. Reflex laryngeal closure also protects subglottic areas. As a result, direct thermal injury is generally restricted to the upper airway and rarely involves subglottic structures.[3] Exceptions are the inhalation of steam, due to the much higher specific heat of water vapor, and blast injuries that can force hot gases past the glottic opening. Inhaled irritants are generally present in smoke as a mixture of gases, fumes, and mists, and the chemical composition of smoke produced from various fuels has been described. Fumes consist of particles of various size dispersed in gases. Mists are aerosolized liquids. The intensity of exposure along with the size and chemical composition of these particles and droplets determines how far distally they will migrate in the respiratory tract and, thus, the nature of the tissue injury.[4] Large particles and droplets of lipid-soluble liquids are more likely to adhere to airway surfaces and do not reach as far distally as smaller particles and more water-soluble droplets. Systemic toxicity may occur when toxins such as carbon monoxide (CO) or cyanide are present in the inhaled gases.

The reported incidence of inhalation injuries has varied greatly over time and from region to region. Smith and others reported 19.6% incidence among burn patients in the United States.[5] In Israel Haik and colleagues found as few as 1.9% in association with burns,[6] whereas Luo and others found 8.01% in China.[7] Regional differences are to be expected as a result of differences in local customs, building materials, and other factors.

The presence of inhalation injury is clinically significant for a variety of reasons, as listed in Box 17.1. Inhalation injury has been found to be an independent risk factor for mortality.[8,9] It is also associated with hemodynamic instability because volume requirements for resuscitation may be increased by as much as 50% when cutaneous burns are accompanied by inhalation injury.[10,11] Parenchymal injury from inhaled irritants or hot gases can lead to impaired gas exchange, pneumonia, and acute respiratory distress syndrome (ARDS). When severe, these changes increase the risk of multiorgan failure and mortality. After recovery from inhalation injury pulmonary function disorders may persist due to pulmonary fibrosis or bronchiectasis.[12] Improvements in the survival of patients with inhalation injury have been attributed to better overall burn outcomes, improved ventilator management, and improved management of pneumonias.[7]

Improvements in the care of cutaneous burns have outpaced advancements in the treatment of inhalation injuries. There are several reasons for this disparity. The treatment of pulmonary parenchymal injury is inherently more complex than treatment for cutaneous burns. Necrotic skin can be excised and replaced with substitute materials or autografted skin, and healing can be observed directly. In contrast, treatment of injured lung involves measures to prevent further injury to allow host mechanisms to repair injured tissues. Healing of pulmonary injury is followed more indirectly by observations of blood gas exchange and radiographs. Inhalation injury results both from direct effects of heat and chemical irritants as well as from indirect effects from an inflammatory response to the initial insult. Despite extensive studies, these processes are incompletely understood and no specific therapies have been identified.

Because inhalation injury has such broad and critical clinical implications, it is important that it be diagnosed as early as possible. Early diagnosis can be accomplished by recognition of risk factors revealed by the history and physical examination and confirmed by diagnostic procedures.

Diagnosis

There is no consensus on the diagnostic criteria for inhalation injury. In the clinical setting the diagnosis is a relatively subjective judgment based on history and physical examination, often confirmed by additional diagnostic procedures such as bronchoscopy. One of the reasons for the lack of consensus for early diagnosis is that much of the impaired pulmonary function following inhalation injury results from obstruction of small airways and an inflammatory response to the initial direct injury. These changes develop over a period of days after injury. In addition, it is our clinical impression that progressive respiratory failure is not always proportional to the intensity of smoke exposure.[13] It is also possible for thermally injured patients to experience acute lung injury from the systemic effects of the

Box 17.1 Clinical Significance of Inhalation Injury

inflammatory response to severe cutaneous burns.[14] Thus it is not uncommon to see acute lung injury in children with large scald burns when inhalation of hot or caustic gases did not occur.[15] This makes it difficult to determine what component of respiratory failure is due to inhalation injury and what component is an effect of systemic inflammation associated with large cutaneous burns.

On initial presentation, patients with inhalation injury may have relatively normal gas exchange as evaluated by arterial blood gas analysis, and the chest radiograph is often normal.[16] In the absence of evidence of respiratory distress it is important to recognize features from the history and physical examination that reveal risk factors for inhalation injury. Normal gas exchange and chest radiograph on admission do not rule out significant inhalation injury. Early diagnosis is important to recognize the potential for airway compromise, manage fluid resuscitation, and to recognize systemic toxicity that may lead to permanent neurological deficits if not promptly treated.

History pertinent to the diagnosis of inhalation injury includes information regarding the mechanism of injury and the intensity of exposure. Mechanisms of injury that carry significant risk of inhalation injury include not only exposure to smoke from a fire, but blast injury that can force hot gases past the larynx, steam burns that can not only burn the upper airway but carry heat to structures below the larynx, and exposure to caustic fumes, as occurs in some industrial accidents. Information regarding the mechanism of injury also includes the source of combustion, which could identify specific chemical irritants. The history can also provide information regarding the intensity of exposure. Duration of exposure is an important determinant of intensity of exposure. When a victim's avoidance behavior is impaired, as when trapped in an enclosed space, intoxicated, unconscious, or in the case of extremes of age, exposure to injurious inhalants is increased.

History of the mechanism of injury is especially important in the case of scalds due to ingestion of hot liquids. Although patients may appear asymptomatic initially, oropharyngeal scalds have led to delayed fatal airway occlusion. Intraoral scalds can present in a manner similar to epiglottitis.[17] The larynx should be examined for evidence of compromise in all patients who present with significant risk (either by history or physical exam) of intraoral scald.

The physical examination can reveal additional risk factors for inhalation injury. We guard our face vigorously, and the presence of burns to the face or singed eyebrows or nasal hair implies a very intense exposure to heat. When gases hot enough to burn tissue are near the airway inlet it suggests that oropharyngeal or nasopharyngeal structures may also suffer thermal injury. Soot deposits on the face and carbonaceous sputum suggests inhalation of smoke. Physical examination may reveal signs and symptoms such as stridor, hoarseness, drooling, and dysphagia that are considered classic evidence of thermal injury to the oropharynx. Presence of these findings, however, does not always indicate that tracheal intubation is necessary.[18] However, as described below, when patients are considered at risk for upper airway thermal injury and occlusion, a priority is to evaluate the upper airway for impending occlusion that may be prevented by early tracheal intubation.

In addition to the history and physical examination, there are diagnostic tools that may be used to confirm a diagnosis of inhalation injury or to follow the progression of injury. Since manifestations of respiratory dysfunction may be delayed after inhalation injury, pulse oximetry and arterial blood gas analysis are insensitive indicators of lung injury during the initial stages. Despite this, it is important to employ these tools as soon as possible. Early impairment of gas exchange is an ominous sign of severe injury and requires early and aggressive intervention. Diagnosis of CO or cyanide toxicity may be facilitated by blood gas analysis. It is also important to have baseline values to judge progress.

Lee and O'Connel assessed the chest radiographs of 45 patients admitted to their hospital following injury in an enclosed space fire.[19] Of those patients, 33 had abnormal findings consistent with inhalation injury. They suggested that the initial radiograph is an important predictor of injury and need for mechanical support of respiration. However, Wittram and Kenny examined admission chest radiographs over a 3-year period for all patients requiring ventilatory support for inhalation injury.[16]. Out of 25 patients, 12 had normal initial chest radiographs despite ultimately requiring mechanical ventilation. The initial chest radiograph is considered an insensitive early indicator of parenchymal injury after smoke inhalation. Although an admission chest radiograph should be obtained in all patients suspected of inhalation injury a normal study does not rule out the possibility of significant pulmonary injury.[16]

Flexible fiberoptic bronchoscopy was early recognized as a powerful tool in the diagnosis of inhalation injury.[20] Fiberoptic bronchoscopy allows direct visualization of tissue damage to the upper airway and bronchi from heat and chemical irritants. This procedure can quickly and reliably identify patients with upper airway compromise who will benefit from intubation and, at the same time, avoid intubation of patients who will not benefit.[21] Bronchoscopic evidence of inhalation injury includes soot deposits, erythema, edema (as indistinct tracheal rings and/or blunting of the carina), mucosal blisters and erosions, hemorrhages, and bronchorrhea (Fig. 17.1). Flexible fiberoptic bronchoscopy has been considered the gold standard for diagnosis of inhalation injury and is often used to confirm the diagnosis of inhalation injury.[22] However, Hunt noted that, in some cases, bronchoscopy performed soon after injury may not show mucosal injury.[20] In addition, because acute lung injury and tracheobronchitis can be a result of systemic inflammation due to cutaneous burns,[14,23] endoscopic

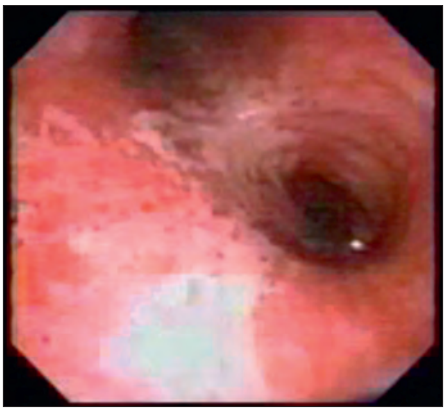

Fig. 17.1 Bronchoscopic view of the trachea from a patient with smoke inhalation injury. Note generalized inflammation and erythema. Edema is manifest as indistinct tracheal rings and blunting of the carina. There are patchy areas of denuded mucosa and a fibrinous exudate is forming at the carina

changes after 36–48 hours may be caused by mechanisms other than inhalation of chemical irritants. As an example, a small fraction of young pediatric patients with large scald injuries develop acute lung injury and require mechanical ventilation.[15] Bronchoscopic examination of these patients can reveal inflammatory changes characteristic of smoke inhalation. Moreover, although fiberoptic bronchoscopy can definitively identify tissue damage from inhalation injury, it has been recognized that the observed changes are relatively proximal and may be more severe than more peripheral parenchymal injuries.[24] As a result, a bronchoscopic diagnosis of inhalation injury does not always identify which patients will experience progressive respiratory dysfunction.

Numerous attempts have been made to grade severity of inhalation injury based on bronchoscopic findings in order to identify patients who may need increased levels of support regarding airway management, respiratory support, or increased volume of fluid during the initial resuscitation. In their retrospective study, Hassan et al. found that mortality among patients with inhalation injury correlated with severity of bronchoscopic findings.[25] However, Spano and colleagues also performed a retrospective review to evaluate the effectiveness of bronchoscopy to predict outcomes for patients with inhalation injuries.[26] They used an abbreviated injury score (AISD INH) introduced by Endorph and Gameli[27] that grades the severity of bronchoscopic findings associated with smoke inhalation injury. They also reviewed the three previous studies that specifically compared the AIS INH with clinical outcome.[27–29] All these studies found trends that were suggestive of poorer clinical outcome in patients with more severe bronchoscopic changes, but these trends were not statistically significant. Spano et al. suggested that further studies to allow refinement in descriptions of severity grades will be needed before bronchoscopic evaluation produces reliable prognostic information.[26]

It is generally accepted that patients with smoke inhalation injury require increased fluid volume for resuscitation of cutaneous burns.[10,11,30] Increases of up to 40–50% have been observed.[10] While this has been a fairly consistent observation, the value of bronchoscopy in predicting increased fluid needs has been inconsistent. Endorf and Gamelli found that an initial P:F ratio of less than 350 was a more reliable predictor of increased fluid requirements than was diagnosis of inhalation injury by bronchoscopy.[27] In their patients, fluid requirements during initial resuscitation were not correlated with severity of findings at initial bronchoscopy. Cancio and colleagues found that diagnosis of inhalation injury per se was not related to increased fluid needs but that mechanical ventilation was related.[30] They suggested that mechanical ventilation may be a surrogate variable for more severe inhalation injury, and this could explain its closer correlation with fluid needs. These observations reinforce the possibility that findings of bronchoscopy are relatively proximal and may not always reflect the severity of more distal parenchymal injury. Need for mechanical ventilation and decreased P:F are more dependent on parenchymal injury and therefore may be more accurate predictors of inhalation injury.

Mackie and colleagues have offered an alternative mechanism for increased fluid requirements in burn patients who also have inhalation injury.[31] They found that ventilated patients with burns but no inhalation injury required more fluid than did patients with similar burns but who did not receive mechanical ventilation. Fluid balance was not significantly affected in patients who also had burns, inhalation injury, and were mechanically ventilated. Mackie suggests that positive pressure ventilation increases intrathoracic pressure, which impairs venous return to the heart. More intravenous fluid is then required to maintain cardiac preload. These findings are consistent with a greater effect of mechanical ventilation on fluid balance than inhalation injury.[32]

Although bronchoscopy does not reliably predict respiratory failure, endoscopic assessment of the upper airway has been found to be highly useful in identifying patients with glottic or supraglottic changes who would benefit from early intubation. Just as important, this exam also helps avoid unnecessary intubations that expose patients to serious risk without benefit.[21]

Radionuclide studies represent an additional tool that has been used to provide evidence of pulmonary injury distal to the more proximal views permitted by flexible bronchoscopy. Intravenously administered xenon-133 is excreted by the lungs and exhaled. Delayed clearance of xenon-133 is a sensitive indicator of inhalation injury.[33] Lung scintigraphy using technetium-99 aerosol inhalation has also been used to identify areas of pulmonary dysfunction in patients with respiratory dysfunction after smoke inhalation. Delayed clearance and inhomogeneous lung distribution of radioactivity are evidence of injury.[34] These studies are sensitive indicators of inhalation injury, but interpretation can be confounded by pre-existing lung disease, and it may be difficult to perform these studies in critically ill burn patients.

The poor correlation of clinical outcome with severity of bronchoscopic findings in patients with smoke inhalation injury has led some clinicians to evaluate the possibility that chest computed tomography (CT) could provide more accurate prognostic information. CT can reveal regional differences in structural changes that impair pulmonary function, such as atelectasis, consolidation, and fibrosis, more effectively than chest radiographs. Yamamura and

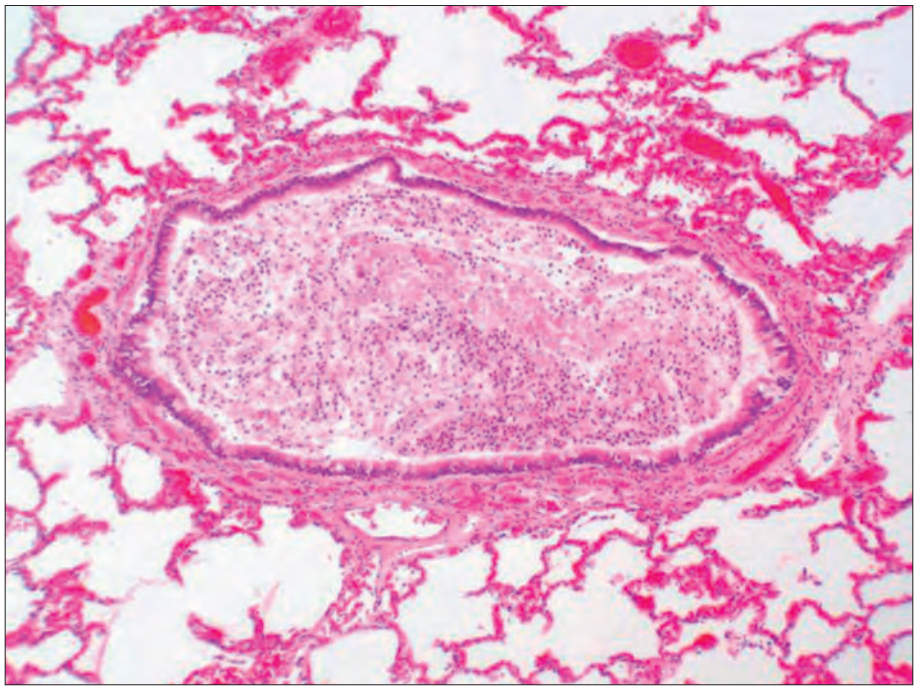

Fig. 17.2 Small airway occluded by inflammatory exudate in a patient who had a smoke inhalation injury.

others used admission chest CT to measure bronchial wall thickness in patients with suspected inhalation injury.[35] Increased bronchial wall thickness was associated with total number of ventilator days, ICU days, and pneumonia. Oh and colleagues obtained CT scans shortly after admission for patients at risk for smoke inhalation. A grading system was used to provide a score for each CT scan based on interstitial markings, ground-glass opacification, and consolidation. This score was compared with clinical outcomes described as a composite endpoint based on pneumonia, ALI/ARDS, and mortality. Injury detected by bronchoscopy alone was associated with an 8.3-fold increase in the composite score, while the combination of bronchoscopic evidence of inhalation injury and a high CT score was associated with a 12.7-fold increase in the composite endpoint. The authors were cautiously optimistic that with additional clinical experience and refinement of image analytical techniques, CT scans alone or in combination with bronchoscopic evaluation may provide more accurate early prognosis for patients with smoke inhalation injury. The risks of taking an acutely ill patient to the CT scanner were also acknowledged.

Pathophysiology of Pulmonary Insufficiency with Inhalation Injury

As stated earlier, except in special cases such as inhalation of steam, injury to airways below the larynx and pulmonary parenchyma nearly always results from chemical irritation rather than thermal injury. A number of reviews are available to describe the pathophysiology of pulmonary failure associated with smoke inhalation.[4,36,37] Chemicals inhaled with smoke, as well as carbon particles coated with irritants, are deposited in the airways. Aqueous secretions of the mucosa dissolve these irritants, and the respiratory mucosa is bathed in relatively concentrated caustic solutions. The initial response to this insult is direct injury to the respiratory epithelium, resulting in hyperemia, edema, increased mucous secretions, impaired ciliary clearance, and bronchoconstriction. Work in experimental animals has also demonstrated an early separation of ciliated respiratory epithelial cells from the basement membrane. This results in denuded areas of the airways and explains the copious formation of protein-rich exudate. Fibrin casts tenaciously adherent to the airway surfaces are formed from this exudate.

Much of the morbidity associated with smoke inhalation is also the result of the inflammatory response to the early direct effect of chemical irritants. The inflammatory response to smoke inhalation is similar to the injury produced by aspiration of acidic gastric contents. The direct injury to tissues from the initial insult causes local accumulation of inflammatory cells and initiation of a cascade of inflammatory mediators that exacerbate and sustain tissue damage (see later discussion). Airways become blocked by edema, bronchoconstriction, fibrin casts, necrotic debris, and inflammatory infiltrate (Fig. 17.2). Degraded surfactant causes alveolar instability and collapse. These changes result in impaired hypoxic pulmonary vasoconstriction and areas of atelectasis and in post-obstruction sequestration of material that provides a medium for bacterial growth and risk of pneumonia. Impaired function of alveolar macrophages slows the removal of these materials and facilitates the development of infection. Pulmonary compliance is reduced, which can greatly increase the work of breathing or require higher ventilator pressures and associated risk of ventilator-induced lung injury.

As a result of these changes pulmonary gas exchange is impaired. Atelectasis due to airway obstruction increases dead space and shunt to an extent, but the impaired gas exchange due to smoke inhalation appears to be primarily a ventilation–perfusion imbalance.[38] It has been suggested that this mechanism of pulmonary dysfunction is fundamentally different from other types of ARDS.[22] Other etiologies of ARDS, such as sepsis, involve disruption of the pulmonary capillary membrane and alveolar flooding, resulting primarily in true shunt. This distinction can influence the ventilator strategies employed. Patients with respiratory failure due to smoke inhalation injury have small airway obstruction, and care should focus on pulmonary toilet together with recruiting and stabilizing alveoli, which tend to collapse. By contrast, in ARDS due to other etiologies the strategy is to concentrate on avoiding ventilator-induced lung injury. In some burn centers this is a rationale for the use of high-frequency percussive ventilation. Just as the bronchi are the focus of the diagnosis of inhalation injury, it is also the focus of its pathology.[39] The hyperemia and edema that are seen in the airway and which are so important for the diagnosis of inhalation injury are the result of an almost 20-fold increase in bronchial blood flow.[40,41]

Following the airway injury, there are changes in the lung parenchyma. There is a release of the chemokine interleukin (IL)-8 and an influx of neutrophils into the airway and alveoli. Reactive oxygen (ROS) and nitrogen species (RNS) are formed.[42] One of the latter, peroxynitrite, damages DNA. DNA damage results in activation of poly-(ADP ribose) polymerase (PARP).[43] Poly-(ADP ribose) protects the damaged DNA but also activates the nuclear factor (NF)-κB.[44] This causes the formation of the inducible form of nitric oxide synthase (NOS) and additional release of IL-8, attracting and activating additional neutrophils and forming more reactive nitrogen and oxygen species.[45] The oxidation, nitration, and nitrosation of lung tissues results in membrane damage, edema formation, and impaired oxygen diffusion.[46,47] Alveoli that are not ventilated are not perfused with blood because alveolar hypoxia causes pulmonary vasoconstriction. NO released by NOS causes a loss of hypoxic pulmonary vasoconstriction, leading to perfusion of unventilated alveoli and thus a fall in arterial oxygen saturation.[48]

In experimental animals ablation of the bronchial blood flow will prevent most of the pathophysiology involved in inhalation injury to the pulmonary parenchyma.[39,49,50] These changes in bronchial blood flow are not associated with heat. They can be produced in experimental animals by smoke that has been cooled to body temperature.[41] As mentioned earlier, the blood flow to the airway is so effective in cooling or heating inhaled air that it is almost impossible for heat carried by dry gases to reach the bronchi.[3,51] These changes in blood flow also appear to be independent of the chemical composition of smoke because they are mediated by neuroinflammation. We have reported that, following insufflation of smoke into deeply anesthetized sheep, the airway blood flow increased 10-fold, but, after administration of an inhibitor of the neuropeptide calcitonin gene-related peptide (CGRP), the smoke-induced hyperemia was markedly reduced.[52] Neuropeptides (peptides released from nerves within the lung tissue) induce vasodilatation by causing activation of NOS, leading to the formation of NO. It has also been reported that an inhibitor of the neuro isoform of NOS would block the hyperemia and much of the pathophysiology mentioned earlier, including the loss of hypoxic pulmonary vasoconstriction.[53,54] These findings have led us to the following hypothesis: the chemicals in smoke activate sensory nerves to release neuropeptides that activate neuronal NOS1 to release NO and superoxide to form peroxynitrite, which damages DNA, activating PARP, which stimulates NF-κB, which in turn will up-regulate the inducible form of NOS (iNOS), leading to massive formation of ROS and RNS, tissue damage, and hypoxia and dyspnea. Some of the activated polymorphonuclear cells that escape from the pulmonary and bronchial circulation into the systemic circulation are carried to systemic organs, promoting multiorgan system damage.

Treatment

Currently there are no specific therapeutic interventions for inhalation injury, and treatment consists of supportive modalities. However, if systemic toxicity is suspected (i.e., cyanide or CO), there are specific interventions recommended. When mechanical ventilation is required, measures should be taken to minimize ventilator-induced lung injury. Surveillance cultures and other measures should be initiated to allow early recognition and treatment of pulmonary infection.

Treatment should begin at the scene of injury. Pulmonary function must be supported in coordination with care of cutaneous burns and other possible injuries. The history along with a rapid physical examination can identify victims at risk of inhalation injury as well as respiratory insufficiency and other indications for early intervention. Initially special attention must be given to the airway evaluation. There are many potential indications for early and even prophylactic intubation in victims of serious burn injury (Box 17.2). Early hypoxemia due to impaired gas exchange after inhalation injury is an ominous sign, and those with respiratory distress that is not corrected by supplemental oxygen may require intubation. Patients unable to protect their airway owing to diminished mental status due to injury or intoxication should be intubated to prevent aspiration. It is recommended that, even in the absence of inhalation injury, those with large full-thickness burns covering 30–40% or more of their total body surface area (TBSA) should be intubated because of the risk of associated hemodynamic instability.[55] Another indication for early prophylactic intubation is the risk of upper airway occlusion due

Box 17.2 Indications for Early Tracheal Intubation after Inhalation Injury

- Extensive burns over face and neck
- Overt signs and symptoms of airway obstruction by edema
- Inability to protect airway from aspiration
- Significant toxicity from carbon monoxide or cyanide
- Respiratory failure
- Hemodynamic instability

Box 17.3 Risks of Unnecessary Tracheal Intubation of Burned Patients

- Impairs communication with patient (impairs history and consent)
- Urgent attempts are more likely to fail or cause injury
- Facial burns make it difficult to secure the endotracheal tube, and unintended extubations are common
- Acute burn patients often require heavy sedation when intubated, which increases morbidity associated with unintended extubation
- A translaryngeal endotracheal tube can exacerbate a laryngeal injury

to edema from thermal injury. In some patients with burns to the face and neck or after inhalation of hot gases or steam, early intubation can be life-saving. Training supported by the American Burn Association has encouraged early tracheal intubation in patients at risk for airway occlusion. However, intubation is not a benign intervention, and there is growing recognition of the associated risks. Eastman and colleagues at the Parkland Burn Center published a retrospective study of pre-burn center intubations of burn victims.[56] This was in response to what may have been a preventable death of a burn victim intubated prior to hospitalization. Out of 879 burn patients intubated before admission to hospital, 11.9% were extubated on the day of admission. In addition, 41.1% were extubated within 48 hours of injury. It is unlikely that pathological changes requiring intubation would resolve so quickly. These findings suggest that many patients may have been exposed to the risks of intubation without commensurate benefit. Box 17.3 lists risks associated with unnecessary tracheal intubations. Intubation is especially dangerous during transportation outside a hospital. These patients require deep sedation to avoid unplanned extubation. With extubation during transport, impaired respiratory drive due to sedation may cause dangerous hypoventilation. The risk is even greater when muscle relaxants are used during transport.

Otolaryngologists at the Baltimore Regional Trauma Center used spirometry (flow–volume loops) and flexible fiberoptic bronchoscopy to prospectively evaluate indications for intubation in patients at risk of inhalation injury.[21] They reported that of 11 patients who were admitted to the emergency department with evidence of inhalation injury, six met their institutional criteria for intubation. However, when these patients were examined by fiberoptic bronchoscopy, no significant airway compromise was observed, and they were managed safely and effectively without intubation. The high negative predictive value of normal flow–volume loops for airway compromise in patients with inhalation injury that they also observed had been previously reported by Haponik et al.[57]

Madnani and colleagues have also demonstrated that the presence of signs and symptoms that have been considered classic evidence of inhalation injury does not always predict the need for tracheal intubation.[18] Further evaluation is needed to avoid morbidity associated with unnecessary intubations. When burn victims first present, the history and physical examination can identify those who are in significant respiratory distress or who have other indications for immediate endotracheal intubation. For other patients with risk factors for inhalation injury but who may only be experiencing mild distress, spirometry (flow–volume loops) and/or endoscopic evaluation can be used to identify those who have impending airway compromise and will more likely benefit from early prophylactic intubation. Those who do not require early intubation can be observed and repeat evaluations performed if their clinical condition changes. An algorithm for airway management in burn patients is illustrated in Fig. 17.3.

Another potential complication of inhalation injury requiring early attention is systemic toxicity from CO and/or cyanide. Intoxication should be considered in all patients suspected of significant exposure to smoke. The predominant toxic effect of CO is to prevent binding of oxygen to hemoglobin by the formation of carboxyhemoglobin (COHb). CO has an affinity for hemoglobin approximately 200 times that of oxygen. CO can also prevent cellular utilization of oxygen by binding to mitochondrial cytochromes. Early symptoms include headache, nausea, dizziness, and lowered mental status. Diagnosis requires direct measurement of COHb. Conventional pulse oximetry will not distinguish between oxyhemoglobin and COHb. COHb can be measured by arterial or venous CO oximetry or pulse CO oximetry.[58]

Increased oxygen partial pressure will speed elimination of CO. Oxygen supplementation by face mask is usually sufficient, but in more severe cases (COHb >15%) it may be necessary to provide 100% oxygen via an endotracheal tube. Hyperbaric oxygen has also been used to treat CO poisoning, but there is no consensus on the indications, treatment parameters, or outcome benefits.[59] Moreover, hyperbaric facilities are not widely available.

Cyanide is another toxic component of smoke, especially when the fuel is composed of certain plastic products. Cyanide causes cellular anoxia by binding to mitochondrial cytochromes and preventing intracellular oxygen utilization. Arterial oxygen partial pressures are not reduced by cyanide. Clinical signs of hypoxia despite adequate arterial oxygen tension or metabolic acidosis despite apparently adequate oxygen delivery suggest cyanide toxicity. The earlier treatment is initiated, the more likely it will be successful. Supplemental oxygen can cause nonenzymatic oxidation of reduced cytochromes, displace cytochrome oxidase, and potentiate the effects of administered antidotes. Pharmacological intervention includes methemoglobin generators such as nitrates (amyl nitrite 0.2 mL by inhalation, or sodium nitrite 10 mL of 3% solution intravenous for adults and 0.13–0.33 mL/kg of 3% solution for children) and dimethylaminophenol (3.25 mg/kg) to increase methemoglobin levels. Methemoglobin competes with cytochrome oxidase for cyanide. Caution is required because excessive levels of methemoglobin lead to decreased oxygen-carrying ability of hemoglobin and may cause toxicity. Some agents can bind cyanide directly. Dicobalt edetate (20 mL of 15% solution for adults or 0.3–0.5 mL/kg of 15% solution for pediatric patients) has a rapid effect but carries a risk of toxicity. Hydroxocobalamin (adults 5–10 g or children 70 mg/kg) is the precursor of vitamin B_{12} and has been shown to be safe, with few side effects. Sulfur donors such as sodium thiosulfate (adults 25 mL of 50% solution or children 1.65 mL/kg of 25% solution) accentuate the body's

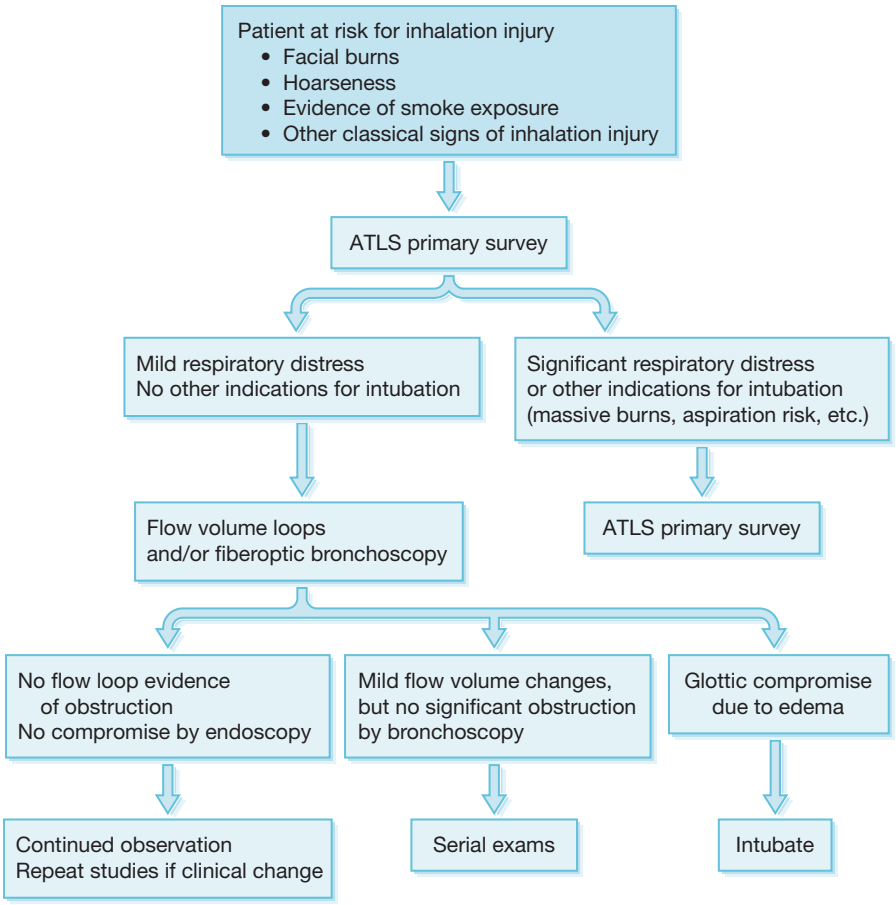

Fig. 17.3 An algorithm to assist airway management decisions in patients at risk for inhalation injury.

enzymatic conversion of cyanide to thiocyanate in the presence of the mitochondrial enzyme rhodanese, reducing its toxicity and increasing elimination.[60]

As mentioned earlier, inhalation injury has been consistently observed to significantly increase fluid requirements for resuscitation of patients with cutaneous burns.[10] The presence of an inhalation injury might intuitively be viewed as an indication to restrict fluids to avoid pulmonary edema. In fact, fluid restriction has been found to exacerbate pulmonary capillary leak and increase lung lymph formation in sheep that have sustained cutaneous burns and smoke inhalation injury.[61] Although it is important to avoid fluid overload in all patients, including those with inhalation injury, inadequate fluid resuscitation can also cause further injury to the lungs of patients with inhalation injury.[62] A combination of cutaneous burns and inhalation injury reduces the margin for error in managing fluid resuscitation. It becomes more difficult to reach a balance where sufficient volume is administered for resuscitation but not so much that it drives up filling pressures, which may increase transudation from pulmonary capillaries that already have increased permeability.

Supplemental humidified oxygen should be used for patients suspected of having inhalation injury. The humidification helps prevent inspissation of the airway secretions. The head of the bed should be placed at a 30- to 45-degree angle to reduce upper airway edema and limit the effect of pressure from abdominal contents on the diaphragm. Meticulous pulmonary hygiene is a vital component of the management of inhalation injury. Frequent airway suctioning, chest physiotherapy including percussive and coughing techniques, and early mobilization all help clear debris and prevent build-up of secretions, which can cause airway obstruction, atelectasis, and predispose to the development of pneumonia.[63,64] Care should be taken when suctioning to avoid hypoxia and bradycardia. Preoxygenation and suctioning for short periods of 10–15 sec can reduce the incidence of these problems. Postural drainage can be useful, although sometimes skin graft location and fragility impede use of this technique.[65] Percussive and vibratory techniques such as high-frequency chest wall oscillation also help clear mucoid secretions.[65,66] It is also important to maintain good nutritional status in these patients.

Inhalation of smoke produces damage to the airways resulting in sloughing of epithelial cells, increased microvascular permeability, and a dramatic increase in bronchial blood flow.[41] As a result, the airways are flooded with plasma exudate and cellular debris. This mix combines with mucus to form a fibrinocellular cast or pseudomembrane that partially or completely obstructs airways. This process is exacerbated by an intense inflammatory infiltrate. In an attempt to disrupt this sequence, Desai and colleagues administered

aerosolized heparin and N-acetylcysteine to slow formation of fibrin and thin mucous secretions in pediatric patients with smoke inhalation injury.[67] They observed a decrease in atelectasis, frequency of re-intubations, and mortality. Treatment with aerosolized heparin is utilized in many burn centers because it is intuitively attractive and does not affect systemic coagulation. The preclinical and clinical evidence of the effectiveness of inhaled anticoagulants for the treatment of smoke inhalation has been reviewed by Miller et al.[68] At the time of writing there were reports of improved survival in experimental animals and in patients, along with improved oxygenation, ventilation, and attenuation of markers of lung injury when smoke inhalation injury is treated with nebulized heparin or other anticoagulants in various protocols, but no large prospective studies have been done in burn patients. More recently, in a prospective randomized trial of 214 mechanically ventilated non-burn ICU patients, Bandeshe et al.[69] examined regular saline nebulization against unfractionated sodium heparin (5000 iU/2 mL four times daily) and found no difference in terms of the development of ventilator-associated pneumonia (VAP) or amount of secretions. They concluded that nebulized heparin cannot be recommended for prophylaxis against VAP or to hasten recovery from pneumonia in patients receiving mechanical ventilation.

When chest physiotherapy and pharmacological agents still fail to facilitate expectoration of secretions or ameliorate cast formation, fiberoptic bronchoscopy can be effective for removal of secretions and also to obtain microbiological specimens through bronchoalveolar lavage in suspected cases of pneumonia. Attempts to replace surfactant have also been studied but are not in widespread clinical use. Antibiotics are indicated for suspected or proven pulmonary infection.[64,70]

Mechanical ventilation is indicated when the signs of respiratory failure are either present or imminent. Indications include impaired gas exchange due to pulmonary parenchymal injury, decreased pulmonary compliance, or impending collapse of effort due to fatigue. Burns involving the head and neck may make intubation technically difficult. In these circumstances avoidance of muscle relaxants and the use of an intubation technique that maintains spontaneous ventilation is safest. The flexible fiberoptic bronchoscope is well suited to this task. A nasal endotracheal tube may be preferable for patient comfort, oral hygiene, and stability. A nasal endotracheal tube can be secured by a nasal septal bridle, which is much more secure than tape or ligatures over burned skin and prevents irritation of wounds and disruption of grafts.

Currently there is no consensus on the ideal mode of mechanical ventilation for burn patients. The intricacies of mechanical ventilation in burn patients have been reviewed previously.[22,71–73] Recommendations by the American Thoracic Society (ATS) and the American College of Chest Physicians[74] can generally be applied to the population of mechanically ventilated burn patients: minimize the time the patient is on the ventilator; conduct a spontaneous breathing trial with inspiratory pressure augmentation (5–8 cm H_2O) rather than without (using a T-piece or continuous positive airway pressure [CPAP]); and, for acutely hospitalized patients who have been mechanically ventilated for more than 24 hours, protocolized rehabilitation directed toward early mobilization. In the adult burn population, especially those with inhalation injury and at high risk for extubation failure who have been receiving mechanical ventilation for more than 24 hours and who have passed a spontaneous breathing trial, extubation to preventive noninvasive ventilation is recommended.

The aim is to provide adequate ventilation to maintain airway and alveolar patency without exacerbating the pulmonary injury by overdistension or barotrauma. Ventilation with low tidal volumes (≤ 7 mL/kg) is now generally accepted as a routine practice in patients with acute lung injury, and most burn centers have adopted this approach to reduce ventilator-induced injury. In patients with inhalation injury the small airways may be narrowed by edema and bronchospasm, which increases airway resistance and hence airway pressures during mechanical ventilation. Under these circumstances it is often difficult to provide adequate ventilation of patients with inhalation injury with tidal volumes of less than 7 mL/kg. How this strategy applies to patients with inhalation injury has not been established.[75] Permissive hypercapnia has been found to be a safe technique to assist in limiting airway pressures in burn patients.[76,77] This allows lower airway pressures and smaller tidal volumes to be used when ventilating the patient and is well tolerated when gradual in onset and the pH is kept higher than 7.2–7.25.

A common ventilation strategy is to determine the level of positive end-expiratory pressure (PEEP) by using a pressure–volume curve. This helps maintain alveolar patency and reduces trauma caused by the shear forces imparted as alveoli collapse and are re-expanded with each breath. The lower inflection point of the pressure–volume curve of a mechanical breath is where the slope of the lower curve begins to increase and is the airway pressure below which the alveoli collapse. The PEEP value can be set just above this pressure. Fio_2 should be weaned down as tolerated to reduce oxygen-related complications. The Pao_2 can be maintained between 80 and 100 mm Hg, although values of 65–70 mm Hg can support adequate tissue oxygenation.

Conventional mechanical ventilation is either volume- or pressure-controlled. Volume-controlled ventilation delivers a consistent tidal volume and minute ventilation to the lungs, but this can result in increased airway pressures depending on the compliance of the lungs. Pressure-controlled ventilation limits the inflating pressure used, but the tidal volume then varies depending on compliance and inspiratory time.[77] High-frequency percussive ventilation (HFPV) is a ventilatory mode that delivers subtidal breaths at a high frequency along with tidal, low-frequency breaths.[78] HFPV has become a preferred mode of ventilation in some burn centers.[22] Proponents suggest that HFPV allows gas exchange at lower peak and mean pressures and may also dislodge and facilitate the removal of secretions and debris in the airways. It appears to be associated with decreased work of breathing, improved oxygenation (higher Pao_2/Fio_2 ratios), and lower peak pressures.[79,80] Pediatric patients at our hospital (SBH-Galveston) managed with HFPV also had a significant reduction in the incidence of pneumonia compared to a conventionally ventilated control group.[80]

High-frequency oscillatory ventilation (HFOV) uses a reciprocating diaphragm to deliver respiratory rates in the

range of 3 to 15 Hz (up to 900 breaths/min) through a standard endotracheal tube. This rate is so fast that the airway pressure merely oscillates around a constant mean airway pressure. A retrospective review of HFOV in severely burned pediatric patients showed significant, early, and sustained improvement in oxygenation.[81]

Airway pressure release ventilation (APRV) is a pressure-controlled time-cycled mode of ventilation that also allows spontaneous breathing during the ventilatory cycle without changing the preset pressure settings.[82] Recruitment of alveoli and oxygenation occur at a high-pressure setting, and ventilation occurs by controlled releases to the lower pressure. The mechanical inspiratory phase can be prolonged to achieve higher mean airway pressures without high peak airway pressures. It has so far shown promising results in trauma patients and pediatric patients with mild to moderate lung disease. Comparable or superior oxygenation values were achieved while using lower peak airway pressures.[83] This mode may be useful in the burn population as a means to ventilate while reducing barotrauma.

Although it has become standard practice to use tidal volumes of 7 mL/kg or less when ventilating patients with acute lung injury or ARDS in order to avoid further damage to the lung, it is occasionally difficult to maintain adequate gas exchange with these small tidal volumes. The hypermetabolic state associated with major burns produces larger amounts of CO_2 that require higher minute ventilation to excrete. A certain amount of permissive hypercapnia can be tolerated safely,[76] which facilitates the use of lower tidal volumes to an extent, but an additional feature of the pathophysiology of inhalation injury is the small airway narrowing by edema, bronchospasm, inflammatory infiltrate, fibrinous exudate, and sloughed epithelium. These small airway changes can require higher pressures to support ventilation. Sousse and colleagues did a retrospective comparison of clinical outcomes of patients with inhalation who were ventilated with high tidal volumes (15 mL/kg) with patients after a change in practice to lower tidal volumes (9 mL/kg). In this retrospective study with historical controls, high tidal volumes were associated with decreased ventilator days, atelectasis, and ARDS. The incidence of pneumothorax was increased with high tidal volumes.[84] Further experience is needed before the use of higher tidal volumes becomes a generally accepted practice.

Mechanical ventilation should be weaned as the patient's condition improves and discontinued as soon as it is no longer necessary. During the weaning process, the Fio_2, PEEP, and rate should be reduced as tolerated until the patient is capable of supporting respiratory requirements without assistance. Criteria for a trial of extubation include ability to protect the airway (awake and relatively alert), cough and deep breath (negative inspiratory pressure >25 cm H_2O), adequate minute ventilation (tidal volume 6 mL/kg and respiratory rate adequate without hypercarbia or tachypnea), adequate oxygenation (Pao_2 >60 mm Hg on Fio_2 ≤0.4), and hemodynamic stability (no vasoactive infusions other than lower dose of dobutamine). The presence of acidemia is a relative contraindication to a trial of extubation, and the decision should take into consideration the patient's physiological reserve and the etiology of the metabolic disturbance. The decision to extubate must also take into consider the metabolic state and burn-related decrease in strength of the patient. Increased generation of CO_2 must be matched by increased minute ventilation and respiratory effort. Work of breathing is often also increased by poor pulmonary compliance and diaphragmatic elevation due to hepatomegaly.[85] At the same time skeletal muscle wasting and decreased strength are also products of the hypermetabolic and catabolic state.[86] If the patient's physiological reserve is marginal it may be best to carefully weigh the risks and benefits of extubation to decide if it is best to continue mechanical ventilation. Once the patient is extubated, supplemental, humidified oxygen should be provided, and the patient should be carefully observed for any signs of respiratory compromise that might necessitate re-intubation.

Extracorporeal membrane oxygenation (ECMO) is a technique that can be used in patients with severe respiratory failure, in which the patient's blood is circulated through an extracorporeal cardiopulmonary bypass circuit that facilitates gas exchange through a semipermeable membrane.[87] While this is taking place, much lower ventilatory pressures and a low Fio_2 can be used to allow the lung to heal without the additional complications of mechanical ventilation. Anticoagulation is necessary during treatment, which makes surgical care of burn wounds difficult. Asmussen et al. have published a meta-analysis of experimental and clinical evidence available for the use of ECMO for treatment of hypoxemic respiratory failure associated with burn and smoke inhalation injury.[88] Interpretation of these data and evaluation of the effectiveness of ECMO in burn patients are limited by the small number of studies and patients. In addition, Asmussen and colleagues point out that those available studies with designs suitable for comparison were performed over a long time period during which ECMO techniques and equipment have varied greatly. This, along with absence of control groups, further complicates comparisons of outcomes. As a result, the available literature is insufficient to provide guidelines. Further experience and research with these improved techniques and equipment is necessary.

Opinions on the use of tracheostomy in burn patients are divided and have fluctuated over the years. The most common indication is a need for prolonged mechanical ventilation. This allows removal of the translaryngeal endotracheal tube, which reduces the chance of laryngeal injury and provides a more secure airway. When multiple surgical treatments are predicted, a tracheostomy tube obviates the need for repeated intubation for each procedure. When prolonged mechanical ventilation is needed, patient comfort can also be enhanced with a tracheostomy, and pulmonary toilet is facilitated. Owing to high rates of pulmonary contamination with burn wound bacterial flora and mortality, tracheostomy was discouraged in the past.[89] More recently, with advances in burn care, several studies have found that the risk of pneumonia is not increased by tracheostomy in burn patients.[90,91] As a result, many burn centers routinely perform tracheostomy not only in patients who require prolonged ventilation but in those with extensive burns who will require multiple anesthetics for surgical procedures. In studies involving small groups of patients, tracheostomy has been used without complications.[91] Tracheostomy is an invasive procedure, however, and in larger

patient populations there is a risk of significant morbidity. Saffle et al. found that burn patients treated with conventional ventilation were extubated sooner than those randomized to early tracheostomy.[92] Because clinical outcomes were otherwise not different between groups, it appears that there was no significant benefit of the more invasive tracheostomy. In the absence of clear evidence of benefit, the use of tracheostomy in burn patients remains a matter of clinical judgment, but, in each case, the risk of potential complications should be considered in the decision.

Potential Future Therapeutic Strategies

The pathophysiological processes described offer the possibility for future development of numerous pharmacological interventions. One of the most obvious areas for treatment would be the use of antioxidants. Burned patients are immensely depleted of antioxidants, especially vitamin E.[93,94] In this clinical scenario ROS and RNS play major roles in organ damage in addition to mediation of the pathophysiology.[47] Nebulization of γ-tocopherol, a form of vitamin E that scavenges both ROS and RNS, has been shown to be beneficial.[95,96] On the other hand, inhibitors of NOS1,[54,97] NOS2,[98] and PARP,[99] as well as compounds that catalyze the breakdown of peroxynitrite, have also been shown to be effective in reversing the acute changes in pathophysiology.[42,45,98,99]

Recently there have been reports that hydrogen sulfide may have therapeutic benefits in lung injury.[100] We have tested hydrogen sulfide in both murine and ovine models of burn injury and found therapeutic benefit.[101,102] As we have learned more about the pathophysiology and treatment of inhalation injury, there have been more survivors. Examination of these individuals several years after injury showed that many had evidence of excessive deposition of collagen in their lungs.[103] Perhaps initial treatment of patients might have an important effect on long-term pathophysiology. This is certainly an area for future investigation. NOS, the enzyme that plays a major role in the acute aspects of injury, has the amino acid arginine as its substrate, as does arginase, the enzyme that is the basis of collagen deposition.[104] Thus inhibition of NOS could make more arginine available for the arginase, and hence increase collagen deposition. In a consensus conference, the faculty from the Shriners Hospitals met to discuss potential therapies for inhalation injury.[105–108] Clinical trials will be necessary before the effectiveness of these novel interventions is established.

Long-Term Changes in Pulmonary Function

Although the pathophysiology associated with the acute phase of inhalation injury has been studied extensively both clinically and through experimental models, the same cannot be said for the long-term alterations in pulmonary function that occur in the months and years following a burn and inhalation injury. Palmieri has discussed some of the theoretical reasons why it is difficult to evaluate the long-term clinical effects of inhalation injuries related to burns.[109] Any study of long-term changes in pulmonary function after inhalation injury must distinguish between changes due to the effects of inhaled irritants at the time of injury and those that result from ventilator-induced lung injury or acute lung injury due to the systemic inflammatory response syndrome (SIRS) or sepsis. In addition, outcomes may change over time due to alterations in clinical management. Massive burn injury also impairs muscle mass and strength along with chest wall compliance, which can affect respiratory effort even in the absence of inhalation injury. As Palmieri has pointed out, none of the previous reports of long-term pulmonary changes after inhalation injury relates the degree of acute pulmonary insult to the long-term changes.[109] Pre-existing lung disease was also not considered in previous studies. Most studies involved relatively small groups of patients studied at different times and by different means, which makes it difficult to compare results between studies. In a more recent Canadian review of ARDS incidence in 162 mechanically ventilated burn patients, Cartotto et al.[110] found a significant correlation of development of ARDS with the size of burn injury, size of full-thickness injury, and the duration of intubation, but not with the incidence of inhalation injury. The authors concluded that ARDS develops early after burn and that the extent of full-thickness burn predicted development of moderate to severe ARDS. Increasing severity of ARDS based upon the Berlin definition was associated with a significantly greater duration of mechanical ventilation and a trend toward higher mortality.

One way post-injury pulmonary function has been shown to be manifest is by a hyperactive or bronchospastic condition of the airways. This was shown to persist for at least 6 months in one study, along with inflammatory changes in the bronchial mucosa and elevated inflammatory cytokine tumor necrosis-α (TNF-α), interferon (IFN-γ), and interleukin (IL)-2 levels in serum and bronchioalveolar lavage fluid. The majority of subjects, however, had normal pulmonary function tests.[111]

Longer-term studies have in some cases shown the development of obstructive and restrictive patterns on pulmonary function testing, indicating that normal lung function may not always be regained following recovery from inhalation injury.[103,112,113] In a pediatric burn cohort, no difference in exercise tolerance was noted between children who had sustained an inhalation injury and those who had not. However, those children who had had an inhalation injury achieved their goal with a significantly higher respiratory rate and had a higher incidence of abnormal lung function.[113] Conversely an adult study found no evidence of altered respiratory function after inhalation injury or any significant exercise intolerance in those tested.[114]

Damage to the larynx by inhaled toxins and thermal injury, and also by intubation as a treatment for inhalation injury or upper airway edema, is common and can result in persistent hoarseness, dysphonia, or even exercise intolerance due to dyspnea on exertion. Injury to the laryngeal mucosa can cause scarring that can affect the flexibility and vibratory capacity of the vocal cords and also their ability to open and close properly. Laryngeal morbidity can be severe, as seen in Fig. 17.4. As a result, voice production may be affected, and this may not resolve without

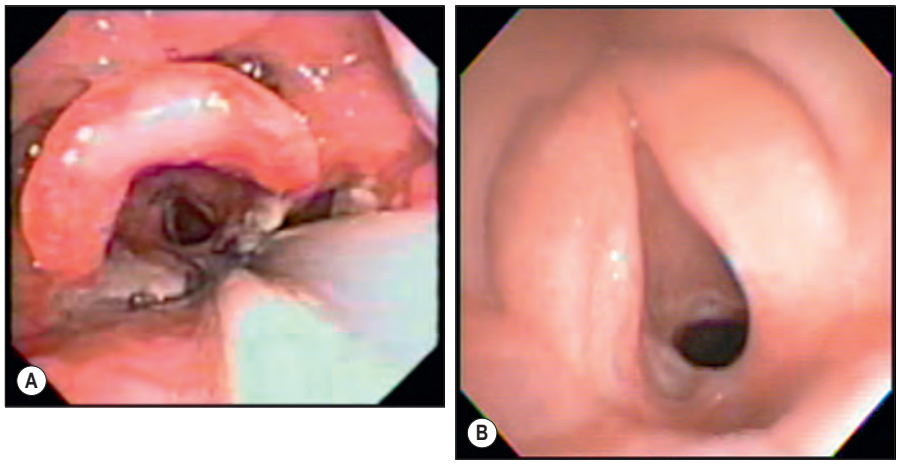

Fig. 17.4 (A) Thermal necrosis of laryngeal structures as seen in this photograph is an indication for tracheostomy to minimize laryngeal injury. A tracheostomy was performed on this patient soon after admission, and, after recovery from his burns and decannulation of his trachea, his voice was normal. **(B)** Thermal and mechanical injury to the larynx can result in posterior glottic scars and webs, as in this endoscopic image. Early diagnosis of injury can facilitate care to minimize long-term effects.

treatment. Some of the phonation problems can be helped by voice therapy, and some of the laryngeal scarring may be amenable to surgical or laser excision.[115] It is important to recognize laryngeal injuries as early as possible. When recognized, tracheostomy can help minimize exacerbation of the injury from a translaryngeal airway. Consultation with a laryngologist may make such interventions more timely.

Introduction

The multitude of respiratory complications caused by smoke inhalation, flame burns, and their treatment epitomize the clinical challenges that confront health care workers. Smoke inhalation injury and its sequelae impose demands on the practitioners who play a central role in its clinical management. These demands may range from intubation and resuscitation of victims in the emergency room to assistance with diagnostic bronchoscopies, performance of pulmonary function studies, monitoring of arterial blood gases, airway maintenance, chest physiotherapy, and mechanical ventilator management.[1] Additional demands are placed on the practitioners in the rehabilitation phase in determining disability or limitations diagnosed by pulmonary function studies or cardiopulmonary stress testing. It is imperative that a well-organized, protocol-driven approach to respiratory care of the burn patient be utilized so that improvements can be made and the morbidity and mortality associated with inhalation injury can be reduced (Box 18.1). This chapter provides an overview of the common hands-on approaches to the treatment of inhalation injury, with emphasis on mucociliary clearance techniques, pharmacologic adjuncts, mechanical ventilation, infection control, and the late complications associated with inhalation injury.

Bronchial Hygiene Therapy

Airway clearance techniques are an essential component of respiratory management of patients with smoke inhalation. *Bronchial hygiene therapy* is a term used to describe several of the modalities intended to accomplish this goal. Therapeutic coughing, chest physiotherapy, bronchial drainage and positioning, percussion and vibration, early ambulation, airway suctioning, and therapeutic bronchoscopy have been effective in the removal of retained secretions.

THERAPEUTIC COUGHING

Therapeutic coughing functions to promote airway clearance of excess mucus and fibrin casts in the tracheal bronchial tree. Impairing the cough mechanism may result in retained secretions, bronchial obstruction, atelectasis, and/or pneumonia. A cough can either be a reflex or a voluntary action. The mechanisms of a cough include:

a. a deep inspiration,
b. the closure of the glottis,
c. contraction of the muscles in the chest wall, abdomen, and pelvic floor,
d. opening of the glottis, and
e. a rapid expulsive exhalation phase.

During a cough, alveolar, pleural, and subglottic pressures may rise as much as 200 cm H_2O. A failure of the cough mechanism may be due to an impairment of any step in the sequence described. When this occurs, it is necessary to perform techniques which are used to improve the cough.

Series of Three Coughs

The patient is asked to start a small breath and small cough, followed by a bigger breath and harder cough, and finally a very deep breath and hard cough. This technique is particularly effective for postoperative patients who tend to splint from pain.[2]

Tracheal Tickle

The respiratory therapist places their index and middle finger flat in the patient's sternal notch and gently massages inward in a circular fashion over the trachea. This is most effective with obtunded patients or with patients recovering from anesthesia.[2]

Cough Stimulation

Patients with artificial airways cannot cough normally since a tube is placed either between their vocal cords (endotracheal tube) or below their cords (tracheostomy). Adequate pressure cannot be built up without the cords in close proximity. A cough may be stimulated by inflating the cuff on the tube, giving a large and rapid inspiration with the manual resuscitation bag, holding the breath for 1–2 s, and rapidly allowing the bag to release and exhalation to ensue. This technique is normally performed by two persons, and it is made more effective with one therapist performing vibration and chest compressions from the time of the inspiratory hold all during exhalation.[2] Cough and deep breathing exercises are encouraged every 2 h to aid in removing retained secretions.

CHEST PHYSIOTHERAPY

The definition of chest physiotherapy has progressed to gravity-assisted bronchial drainage with chest percussion and vibrations. Studies have shown that the combination of techniques are effective in secretion removal.[3–6]

Bronchial Drainage/Positioning

Bronchial drainage/positioning is a therapeutic modality that uses gravity-assisted positioning designed to improve pulmonary hygiene in patients with inhalation injury or retained secretions. Studies have shown that a patient's

Box 18.1 Inhalation Injury Treatment Protocol

- Titrate humidified oxygen to maintain SaO_2s >90%
- Cough, deep breath exercises every 2 h
- Turn patient side to side every 2 h
- Chest physiotherapy every 4 h
- Aerosolize 3 cc of 20% N-acetylcysteine every 4 h with a bronchodilator
- Alternate aerosolizing 5000 units of heparin with 3 cc of normal saline every 4 h
- Nasotracheal suctioning as needed
- Early ambulation on postoperative day 5
- Sputum cultures for intubated patients every M-W-F
- Pulmonary function studies prior to discharge and at outpatient visits
- Patient/family education regarding inhalation injury
- The protocol is continued for 7 days.

Fig. 18.2 Chest physiotherapy techniques.

Fig. 18.1 Patient positioning for secretion mobilization.

Fig. 18.3 Gentle mechanical chest vibrations.

arterial oxygenation may fall during bronchial drainage/positioning.[7] Therefore, it is common practice in intensive care units to turn patients side to side every 2 h to aid in mobilizing secretions (Fig. 18.1).

Percussion

Percussion aids in the removal of secretions from the tracheal bronchial tree. It is performed by cupping the hand to allow a cushion of air to enter between the therapist's hand and the patient. If this is done properly, a popping sound will be heard when the patient is percussed. There should be a towel between the patient and the therapist's hand in order to prevent irritation of the skin.[8] Percussion is applied over the surface landmarks of the bronchial segments that are being drained. The hands rhythmically and alternately strike the chest wall. Incisions, skin grafts, and bony prominences should be avoided during percussion (Fig. 18.2).

Vibration/Shaking

Vibration/shaking is a movement used to move loose secretions to larger airways so that they can be coughed up or removed by suctioning. Vibration involves the rapid shaking of the chest wall during exhalation. The percussor vibrates the thoracic cage by placing both hands over the percussed areas and vibrating into the patient, isometrically contracting or tensing the muscles of their arms and shoulders. Mechanical vibrations have been reported to be clinically effective. Gentle mechanical vibration may be indicated for patients who cannot tolerate manual percussion (Fig. 18.3). Chest physiotherapy techniques should be used every 2–4 h for patients with retained secretions.

EARLY AMBULATION

Early ambulation is another effective means of preventing respiratory complications. Patients routinely should be helped out of bed on postoperative days 3–5, and they should be encouraged to ambulate and sit in a chair. With the appropriate use of analgesics, even patients on continuous mechanical ventilation can be helped out of bed and into a chair (Fig. 18.4). The rocking chair (Fig. 18.5) has several beneficial effects:

- the patient can breathe with regions of the lungs that are normally hyperventilated,
- muscular strength and tone are preserved, and
- contractions are prevented and exercise tolerance is maintained.[9]

Fig. 18.4 Early ambulation.

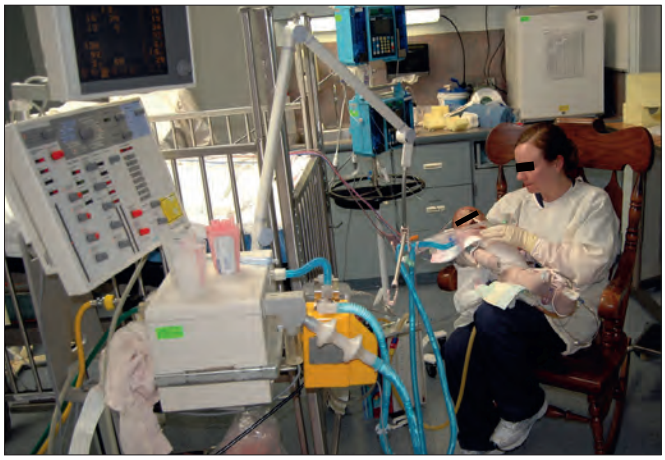

Fig. 18.5 Patient up out of bed, secretions being mobilized by rocking, and chest physiotherapy techniques.

AIRWAY SUCTIONING

Airway suctioning is another method of clearing an airway. Normal bronchial hygiene is usually accomplished by the mucociliary escalator process. When these processes are not effective in maintaining a clear airway, tracheobronchial suctioning is recommended.[10–13] Nasotracheal suctioning is intended to remove accumulated secretions and other foreign material from the trachea that cannot be removed by the patient's spontaneous cough or by less invasive procedures. Nasotracheal suctioning refers to the insertion of a suction catheter through the nasal passages and pharynx into the trachea in order to aspirate secretions or foreign material.

The first step in this process is to hyperoxygenate the patient with 100% oxygen. The patient should be positioned in the Fowler's position, and the catheter slowly advanced through the nares to a point just above the larynx. The operator then listens for air sounds at the proximal end of the catheter. When airflow is felt to be strongest and respiratory sounds are loudest, the tip of the catheter is immediately above the epiglottis. On inspiration, the catheter is advanced into the trachea. After the vocal cords have been passed, a few deep breaths are allowed and the patient is reoxygenated. Suction begins while the catheter is slowly withdrawn from the trachea. The patient should not be suctioned for more than 15 s without being reoxygenated.

Suctioning is not without potential hazards.[14,15] Complications include irritation of the nasotracheal mucosa with bleeding, abrupt drops in P_{O_2}, vagal stimulation, and bradycardia. Preoxygenating and limiting suction time have been shown to decrease or eliminate the fall in the P_{O_2}.[12–14] Sputum cultures should be performed for microbiological identification when they are clinically indicated.

THERAPEUTIC BRONCHOSCOPY

When all other techniques fail to remove secretions, the use of the fiberoptic bronchoscope may be beneficial. In addition to its diagnostic functions, bronchoscopy retains important therapeutic applications. The fiberoptic bronchoscope is small in diameter, flexible, and has a steerable tip that can be maneuvered into the fourth- or fifth-order bronchi for examination or specimen removal. Copious secretions encountered in patients with inhalation injury may require repeated bronchoscopic procedures when more conservative methods are unsuccessful.

PHARMACOLOGIC ADJUNCTS

Bronchodilators can be helpful in select cases. Inhalation injury to the lower airways results in a chemical tracheobronchitis, which can produce wheezing and bronchospasms. Most drugs used in the management of bronchospasms are believed to control bronchial muscle tone. Aerosolized sympathomimetic are effective in two ways: they cause bronchial muscle relaxation, and they stimulate mucociliary clearance. A newer compound of note is metaproterenol, which is available as a cartridge inhaler, as an aerosolized liquid, as a tabular oral medication, or as a syrup. The recommended oral dose is 10–20 mg every 6–8 h, or 1–2 puffs every 3–4 h as an inhaled bronchodilator with a duration of action of 1–5 h.[16]

Albuterol can also be aerosolized or be administered orally or parenterally. Albuterol is available in a metered cartridge inhaler, and its standard dose is 1–2 puffs three to four times daily. Aerosolized albuterol has a duration of action of approximately 4–6 h.[17]

Racemic epinephrine is used as an aerosolized topical vasoconstrictor, bronchodilator, and secretion bond breaker. The vasoconstrictive action of racemic epinephrine is useful in reducing mucosal and submucosal edema within the walls of the pulmonary airways. A secondary bronchodilator action serves to reduce potential spasms of the smooth muscles of the terminal bronchioles. Water, employed as a diluent for racemic epinephrine, serves to lower both adhesive and cohesive forces of the retained endobronchial secretions, thus serving as a bond-breaking vehicle. Racemic epinephrine has also been used for the treatment of

postextubation stridor.[18] Its mode of action is thought to be related to the vasoconstrictive activity, with the resultant decrease in mucosal edema. Aerosolized treatments may be given every 2 h as long as the heart rate is not increased.

Hypertonic saline offers a theoretically more effective form of mucokinetic therapy. The deposition of hypertonic droplets on the respiratory mucosa causes the osmotic attraction of fluids from the mucosal blood vessels and tissues into the airway. Thus, a "bronchorrhea" is induced. The watery solution helps dilute the respiratory tract secretions and increase their bulk, thereby augmenting expectoration. Furthermore, there is evidence that hypertonic saline has a direct effect on the mucoprotein DNA complexes, and, by reducing the cohesive intramolecular forces, the salt helps reduce the viscous properties of the mucoid fluid.[19] Excessive use of hypertonic saline is not recommended because burn patients cannot tolerate the sodium load and may develop edema.

Oxandrolone is a synthetic testosterone analog that has been shown to significantly reduced hypermetabolism and significantly increased height percentile, bone mineral content, lean body mass, and strength in pediatric burn patients.[20] Recently, it has been shown that pediatric patients treated with oxandrolone for 1 year had significantly higher maximum voluntary ventilation compared to untreated patients. [21] Also, during maximal exercise, the subjects treated with oxandrolone had a significantly higher maximal ventilation (V_{EMax}).[21] The administration of oxandrolone may be used as an agent in the future to improve lung function in burned patients.

Aerosolized acetylcysteine is a powerful mucolytic agent in use in respiratory care. Acetylcysteine contains a thiol group; the free sulfhydryl radical of this group is a strong reducing agent which ruptures the disulfide bonds that give stability to the mucoprotein network. Agents that break down these disulfide bonds produce the most effective mucolysis.[22] Of note, acetylcysteine is an irritant to the respiratory tract. It can cause mucosal changes, and it may induce bronchospasms. For this reason, patients are evaluated for signs of bronchospasms, and a bronchodilator may be added if necessary. Acetylcysteine has proved to be effective in combination with aerosolized heparin for the treatment of inhalation injury in animal studies.[23]

Last, heparin and acetylcysteine combinations have been used as scavengers for the free oxygen radicals produced when alveolar macrophages are activated either directly by chemicals in smoke or by one or more of the compounds in the arachidonic oxidative cascade.[24] Animal studies have shown an increased P/F ratio, decreased peak inspiratory pressures, and a decreased amount of fibrin cast formation with the heparin and acetylcysteine combination therapy.[25] In a retrospective review, Desai et al. have shown that the use of heparin and N-acetylcysteine is effective in pediatric patients with inhalation injury.[26] Results indicated a significant decrease in the reintubation rates, the incidence of atelectasis, and improved mortality for patients treated with the combined therapy. Therefore, a standard treatment for patients with inhalation injury may include 5000–10,000 units of heparin and 3 mL normal saline nebulized every 4 h, alternating with 3–5 mL of 20% acetylcysteine for 7 days. This ensures that the patient receives an aerosolized treatment every 2 h. Baseline and daily clotting analyses are recommended for the entire length of the aerosolized treatments.

Mechanical Ventilation

Over the past 30 years, and particularly over the past decade, there has been an increase in new ventilation techniques that present alternatives for the treatment of patients with smoke inhalation. Unfortunately, although the number of options available to the clinician has appeared to increase, randomized and placebo-controlled clinical trials defining the specific role for each mode of ventilation and comparing them to other modes of ventilation have not been forthcoming. The recommendations from the American College of Chest Physicians Consensus Conference on Mechanical Ventilation serve as general guidelines.[27] The consensus concludes:

- The clinician should choose a ventilator mode that has been shown to be capable of supporting oxygenation and ventilation and that the clinician has experience in using.
- An acceptable oxygen saturation should be targeted.
- Based primarily on animal data, a plateau pressure of greater than 35 cm H_2O is cause for concern. However, with clinical conditions that are associated with a decreased chest wall compliance, plateau pressures greater than 35 cm H_2O may be acceptable.
- To accomplish the goal of limiting plateau pressures, P_{CO_2} values should be permitted to rise (permissive hypercapnia) unless other contraindications exist that demand a more normal P_{CO_2} or pH.
- Positive end-expiratory pressure (PEEP) is useful in supporting oxygenation. An appropriate level of PEEP may be helpful in preventing lung damage. The level of PEEP required should be established by empirical trials and reevaluated on a regular basis.
- Large tidal volumes (10–12 mL/kg) with PEEP may be needed to improve oxygenation if the use of protective ventilation strategies becomes ineffective. Peak flow rates should be adjusted as needed to satisfy patient inspiratory needs.[57] Care must be taken to avoid the consequences of utilizing high ventilator pressures if large tidal volumes are required.

Animal studies showed a reduction in ventilator-induced injury with a reduction in plateau pressures to 35 cm H_2O by increasing PEEP and decreasing tidal volume.[28] A number of clinical trials have been conducted to support this treatment strategy.[29–31] A meta-analysis of these trials was conducted by the Cochrane Anesthesia Review Group in 2007.[32] It showed a reduction in mortality and duration of mechanical ventilation with the use of plateau pressure at less than 30 cm H_2O and tidal volume at less than 7 mL/kg body weight. In light of this evidence, the tidal volumes used when initiating mechanical ventilation should be 6–8 mL/kg of predicted body weight. If the patient becomes obstructed with fibrin cast and presents with an acute increase in P_{CO_2} and decrease in Pa_{O_2}, the clinician should first provide aggressive pulmonary toilet, then consider changing over to volume ventilation with higher tidal volumes. If ventilation continues to worsen, tidal volumes

of 10–12 mL/kg may be needed to provide adequate mechanical ventilation.[57]

MODES OF VENTILATION

Control Mode

In the control mode of ventilation, the ventilator automatically cycles at a rate selected by the operator. The ventilator will cycle regardless of the patient's needs or desire for a breath, but it guarantees a minimum level of minute ventilation in the sedated or paralyzed patient. This mode of ventilation is often utilized in patients with acute respiratory distress syndrome (ARDS) because of the high peak pressures needed to achieve adequate chest expansion. The major disadvantage with this mode is that the patient cannot cycle the ventilator; thus, the minute ventilation must be set appropriately.

Assist-Control Mode

In the assist-control mode of ventilation, every breath is supported by the ventilator and a back-up control rate is set. The tidal volume, inspiratory flow rate, flow waveform, sensitivity, and control rate are set.[33–35] The advantages include that assist-control ventilation combines the security of controlled ventilation with the possibility of synchronizing the breathing pattern of the patient and ventilator, and it ensures ventilation support during each breath. Disadvantages are as follows:

- Excessive patient work occurs in case of inadequate peak flow or sensitivity settings, especially if the ventilator drive of the patient is increased,[33–35]
- It is often poorly tolerated in awake, nonsedated subjects, and it can require sedation to insure synchrony of patient and ventilator,
- It can cause respiratory alkalosis, and
- It may worsen air trapping with patients with chronic obstructed lung disease (COPD).[26]

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) combines a preset number of ventilator-delivered mandatory breaths of the present tidal volume with the facility for intermittent patient-generated spontaneous breaths.[36,37] The advantages are as follows:

- The patient is able to perform a variable amount of respiratory work, and the security of a preset mandatory level of ventilation is maintained,
- SIMV allows for variation in the level of partial ventilation support from near total ventilation support to spontaneous breathing, and
- It can be used as a weaning tool.

Disadvantages include:

- Hyperventilation with respiratory alkalosis,
- Excessive work of breathing due to the presence of a poorly responsive demand valve, suboptimal ventilation circuits, or inappropriate flow delivery could occur, and
- In each case, extra work is imposed on the patient during spontaneous breaths.

Pressure Control Mode

In pressure-controlled ventilation all breaths are time- or patient-triggered, pressure-limited, and time-cycled. The length of inspiration, pressure level, and back-up rate are set by the operator. The tidal volume is based on the compliance and resistance of the patient's lungs, the ventilator system, and the preset pressure.

Pressure Support Ventilation

Pressure support ventilation (PSV) is a pressure-targeted, flow-cycled mode of ventilation in which each breath must be patient-triggered. It is used both as a mode of ventilation during stable ventilation support periods and as a weaning method.[37–41] It is primarily designed to assist spontaneous breathing; thus, the patient must have an intact respiratory drive.

Advantages include:

- It is generally considered a comfortable mode of ventilation for most patients,
- Pressure support reduces the work of breathing,
- It can be used to overcome airway resistance caused by the endotracheal tube, and
- Pressure support may be useful in patients who are difficult to wean.

Disadvantages include:

- The tidal volume is not controlled and it is dependent on respiratory mechanics, cycling frequency, and synchrony between the patient and ventilator, and
- Pressure support may be poorly tolerated in some patients with high airway resistances because of the preset high initial flow rates.

ALTERNATE MODES OF VENTILATION

During the past decade, a new concept of ventilation has emerged in the treatment of ARDS patients. In severe cases of ARDS, only a small part of the lung parenchyma remains accessible to gas delivered by mechanical ventilation.[42,43] As a consequence, tidal volumes of greater than 10 mL/kg may overexpand and injure the remaining normally aerated lung parenchyma. High airway pressures may result in overdistension and local hyperventilation of more compliant parts of the lung. Overdistension of lungs in animals has been shown to produce diffuse alveolar damage.[44–46] This is the primary reason that alternative modes of ventilation, which are all based on a reduction of end-inspiratory airway pressures and/or tidal volumes delivered to the patient, have been developed and are used by many clinicians caring for patients with severe forms of acute or chronic respiratory failure. The following four alternative modes of ventilation will be discussed: high-frequency ventilation, high-frequency percussive ventilation, airway pressure release ventilation, and volumetric diffusive ventilation.

High-Frequency Ventilation

High-frequency ventilation (HFV) is the administration of small tidal volumes of 1–3 mL/kg at high frequencies of

100–3000 cpm.[47] This mode of ventilation is based on a marked reduction in tidal volumes and airway pressures, and it has the greatest potential for reducing pulmonary barotraumas. There are a number of different types of high-frequency ventilation techniques. The two most common are high-frequency jet ventilation (HFJV) and high-frequency percussive ventilation (HFPV).

HFJV is the only high-frequency mode routinely used to ventilate patients with ARDS, and it is primarily used in Europe.[27] This type of ventilation uses a brief jet of gas at a high frequency. Comparative data concerning the advantages of HFJV over conventional ventilation are limited. There is no agreement, however, that HFJV is better than conventional mechanical ventilation in ARDS.[48]

HFPV has shown some promise in the ventilation of patients with inhalation injury.[49–51] HFPV refers to ventilation utilizing the Volume Diffusive Respiration (VDR) ventilator, and it oscillates between the inspiratory and expiratory airway pressures. Clinical studies indicate that this mode of ventilation may aid in reducing pulmonary barotrauma.[49,50] In a retrospective study, Cortiella et al. have shown a decreased incidence of pneumonia, peak inspiratory pressure, and an improved P/F ratio in children ventilated with the use of HFPV compared to controls.[52] In the first prospective randomized study of HFPV, Mlcak et al. have shown a significant decrease in the peak inspiratory pressures needed to ventilate pediatric patients with inhalation injury.[53] No significant differences were found for incidence of pneumonia, P/F ratios, or mortality.

Based on clinical experience, the following guidelines are suggested for initial set-up of the HFPV in children (Table 18.1). The pulsatile flow (PIP) rate should be set at 20 cm H_2O, the pulse frequency (high rate) should be set between 500 and 600, and the low respiratory rate should be set between 15 and 20. Oscillatory PEEP levels should be initially set at approximately 3 cm H_2O, and demand PEEP should be set at 2 cm H_2O. Ventilator settings are adjusted based on the patient's clinical condition and blood gas values. To improve oxygenation, the ventilator can be switched to a more diffusive mode (increased pulse frequency); to eliminate carbon dioxide, the ventilator can be switched to a more convective mode (decreased pulse frequency). With HFPV, subtidal volumes are delivered in a progressive stepwise fashion until a preset oscillatory equilibrium is reached, and exhalation is passive.

Clinicians must be familiar with each technique used and its possible limitations. There must be adequate humidification of the respiratory gases or severe necrotizing tracheobronchitis can occur. Special delivery devices for providing adequate humidification during HFV are required. It is not clear when and how it should be used following inhalation injury.[54] As the methodology for HFPV evolves, it is anticipated that HFPV will play a larger role in the care of select mechanical ventilation-dependent populations.[55]

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a pressure-regulated mode of ventilation support that allows for time-cycled decreases in pressure to facilitate CO_2 elimination. This mode allows spontaneous breathing while limiting airway pressures; therefore, it may limit the amount of sedatives or neuromuscular blocking agents needed. APRV is a protective ventilator strategy that uses inverse ratio ventilation at two levels of PEEP. Several limited studies have suggested that APRV may be beneficial for the treatment of burn patients who develop ARDS. Evidence-based recommendations to use this mode of ventilation await outcome studies.

VOLUMETRIC DIFFUSIVE VENTILATION

The volumetric diffusive ventilator (VDR) is a pneumatically powered, pressure-limited ventilator that stacks oscillatory breaths to a selected peak airway pressure by means of a sliding venturi called a *phasitron*. After inspiration, exhalation is passive and ends at a selected level of oscillatory CPAP.[56] Studies comparing VDR to high-volume strategies have shown VDR improves gas exchange, decreases peak pressures, and lowers mortality. However, there is a need to compare VDR to the low tidal volume ventilation practiced more recently. Usage of the VDR requires special training; the other disadvantages are the inability to monitor tidal and minute volumes and the requirement of humidified air and nebulized saline to prevent airway desiccation.

VENTILATOR SETTINGS

A large multicentered study by the Acute Respiratory Distress Syndrome Network evaluated the use of volume ventilation with low versus high tidal volume on ARDS. This study documented a decreased incidence of mortality in patients with ARDS who were ventilated with small tidal volumes.[29] Based on this study in 2000, it has become clinically accepted practice to use low tidal volumes when initially setting up mechanical ventilation (Table 18.2).

Table 18.1 High-Frequency Percussive Ventilation Set-Up Guidelines

Variable	Settings
Pulsatile Flow Rate (PIP)	20 cm H_2O
Pulse Frequency (high rate)	500–600
Low Respiratory Rate	15–20
I:E Ratio	1:1 or 2:1
Oscillatory PEEP	3 cm H_2O
Demand PEEP	2 cm H_2O

Table 18.2 Targeted Mechanical Ventilation Guidelines in Children

Variable	Settings
Tidal Volumes	6–8 mL/kg
Respiratory Rate	12–45 breaths/min
Plateau Pressures	<30 cm H_2O
I:E Ratio	1:1–1:3
Flow Rate	40–100 L/min
PEEP	7.5 cm H_2O

Tidal Volumes

In volume-cycled ventilation, a machine-delivered tidal volume is set to be consistent with adequate gas exchange and patient comfort. The tidal volume selected for burned patients normally varies between 6 and 8 mL/kg of predicted body weight. Numerous factors, such as lung/thorax compliance, system resistance, compressible volume loss, oxygenation, ventilation, and barotrauma, are considered when volumes are selected.[53] Sousse et al. have recently shown that the use of higher tidal volumes in pediatric burn patients with inhalation injury may decrease the incidence of ARDS and atelectasis as well as the number of days on a ventilator when compared to lower tidal volumes.[57] Of critical importance is the avoidance of overdistension. This can generally be accomplished by ensuring that peak airway and alveolar pressures do not exceed a maximum target. Many would agree that a peak alveolar pressure greater than 35 cm H_2O in adults raises concern regarding the development of barotrauma, and ventilator-induced lung injury increases.[58,59] Expired tidal volumes should be measured for accuracy at the connection between the patient's wye and the artificial airway.

The range of tidal volumes will vary depending on the disease process, with some diseases requiring maximum tidal volumes and others needing less. Severe interstitial diseases such as pneumonia and ARDS may require a tidal volume of greater than 8 mL/kg to adequately inflate the lungs and improve gas exchange if protective ventilation strategies become inadequate.

Respiratory Rate

Setting of the mandatory respiratory rate is dependent on mode of ventilation selected, delivered tidal volume, dead space-to-tidal volume ratio, metabolic rate, targeted P_{CO_2} levels, and level of spontaneous ventilation. With adults, the set mandatory rate normally varies between 4 and 20 breaths/min, with most clinically stable patients requiring mandatory rates in the 8–12 range.[60] It is important to have targeted arterial blood gas values set to aid the clinical team in proper management (Table 18.3). Along with the P_{CO_2}, pH, and patient comfort, the primary variable controlling the selection of the respiratory rate is the development of air trapping and auto PEEP.[61]

The respiratory rates of children and infants all need to be set substantially higher than those of adults. For pediatrics, the respiratory rate can be set from 12 to 45, depending on the disease state and the level of targeted P_{CO_2} one wishes to achieve. Slower respiratory rates are useful in the patient with obstructed airways because slower rates allow more time for exhalation and emptying of hyperinflated areas. Arterial blood gases should be checked after the patient has been on the ventilator for approximately 20 min and the respiratory rate adjusted accordingly.

Table 18.3 Arterial Blood Gas Goals

Variable	Goal
pH	7.25–7.45
PO_2	55–80 mm Hg or SaO_2 of 88–95%
PCO_2	35–55 mm Hg (permissive hypercapnia can be used as long as pH >7.25)

Flow Rates

The selection of peak inspiratory flow rate during volume ventilation is primarily determined by the level of spontaneous inspiratory effort. In patients triggering volume breaths, patient effort, work of breathing, and patient ventilator synchrony depend on the selection of peak inspiratory flow.[34] Peak inspiratory flows should ideally match patient peak inspiratory demands. This normally requires peak flows to be set at 40–100 L/min, depending on expired volume and the inspiratory demand.[27]

Inspiratory/Expiratory (I:E) Ratio

The time allowed for the inspiratory and expiratory phases of mechanical ventilation is commonly referred to as the inspiratory/expiratory (I:E) ratio. The inspiratory part of the ratio includes the time to deliver the tidal volume before the exhalation valve opens and exhalation begins. The expiratory part of the ratio includes the time necessary for the tidal volume to exit through the exhalation valve before the next inspiration begins. The inspiratory time should be long enough to deliver the tidal volume at flow rates that will not result in turbulence and high peak airway pressures. Typically, the I:E ratio is 1:1 to 1:3.[62]

In severe lung disease, it is acceptable to prolong the inspiratory time to allow for better distribution of gas and to enhance oxygen diffusion. When a longer inspiratory time is required, careful attention should be given to sufficient expiration to avoid stacking of breaths and impeding venous return. Prolonged inspiratory time creates a more laminar flow, which helps to keep the peak pressures lower. Fast inspiratory times are tolerated in patients with severe airway obstruction. The fast inspiratory time allows for a longer expiratory phase, which may help to decrease the amount of overinflation.

Inspired Oxygen Concentration

As a starting point, a patient placed on a ventilator should receive an oxygen concentration of 100%. The concentration should be systematically lowered based on values from arterial blood gases. Generally, as a result of the concerns regarding the effects of high oxygen concentration on lung injury, the lowest acceptable oxygen level should be selected as soon as possible. In patients who are difficult to oxygenate, oxygen concentrations can be minimized by optimizing PEEP and mean airway pressures and selecting minimally acceptable oxygen saturation.[63]

Positive End-Expiratory Pressure

PEEP is applied to recruit lung volumes, elevate mean airway pressure, and improve oxygenation.[64] The level of PEEP used varies with the disease process. PEEP levels should start at 8–10 cm H_2O and should be increased in 2.5-cm increments. Increasing levels of PEEP, in conjunction with a prolonged inspiratory time, aids in oxygenation and allows for the safe percentage of oxygen to be used. The use of pressure–volume curves to determine the best PEEP level has been recommended to aid in overstretching the alveoli. The process of using the curves is difficult to

perform in the clinical setting. However the use of PEEP trials can determine the best PEEP without decreasing cardiac output.

Optimal PEEP is the level of end-expiratory pressure that results in the lowering of intrapulmonary shunting, significant improvement in arterial oxygenation, and only a small change in cardiac output, arteriovenous oxygen content differences, or mixed venous oxygen tension. To determine the optimal PEEP for patients with ARDS, the ARDS Network performed a multicenter, randomized, prospective clinical trial.[64] ARDS patients were treated with 6 mL/kg predicted body weight tidal volumes and randomized to either low (5 cm H_2O up to 24) or high (12 cm H_2O up to 24) PEEP. The trial showed no effect of higher levels of PEEP on duration of mechanical ventilation, duration of nonpulmonary organ failure, and in-hospital mortality.

EXTUBATION CRITERIA

Standard extubation criteria include a wide variety of physiologic indices that have been proposed to guide the process of discontinuing ventilation support. Traditional indices include:

- $Pa_{O_2}/F_{I_{O_2}}$ ratio of greater than 250,
- Maximum inspiratory pressure of greater than 60 cm H_2O,
- Vital capacity of at least 15–20 mL/kg,
- Spontaneous tidal volume of at least 5–7 mL/kg,
- Maximum voluntary ventilation of at least twice the minute volume,[66–69] and
- Audible leak around the endotracheal tube must be present.

In general, these indices evaluate a patient's ability to sustain spontaneous ventilation. They do not assess a patient's ability to protect the upper airway. For this reason, traditional indices often fail to reflect the true clinical picture of a patient with an inhalation injury. For a complete evaluation prior to extubation, bronchoscopic examination will aid in determining if the airway edema has decreased enough to attempt extubation. Prior to a scheduled extubation, it is recommended that reintubation equipment be set up and that the person doing the extubation be experienced in emergency intubations. If the patient demonstrates signs of inspiratory stridor, the use of racemic epinephrine by aerosol has been shown to be effective in reducing mucosal edema and may prevent the patient from being reintubated.[18]

Infection Control of Respiratory Equipment

Pneumonia has become one of the most frequent, life-threatening infections, and its incidence has become an important determinant of mortality in burned patients.[68] The majority of pneumonias are nosocomial, occur in burned patients after 72 h of hospitalization, and are often associated with either an inhalation injury or endotracheal intubation with exposure to respiratory care equipment, or both.[70–75] One of the most important risk factors predisposing to pneumonia in burned patients is endotracheal intubation.[76,77] The incidence of pneumonia developing is estimated to be five times higher for intubated than non-intubated patients, and tracheostomy increases this risk even higher.[78] Exposure to respiratory care equipment adds an increased risk of pneumonia above and beyond the risk associated with endotracheal intubation.[79,80] After the use of nebulization equipment in respiratory care became popular, several epidemics of nosocomial pneumonia were reported.[81] The risk of pneumonia from mechanical ventilators was significant, but it decreased with better understanding of the necessity to decontaminate respiratory equipment.[82,83] Respiratory care equipment, if not properly cared for, may provide a source of extraneous organisms that can contaminate the patient's respiratory tract.

The potential role of respiratory care equipment in providing reservoirs for organisms that are capable of infecting the lungs is well established. This problem, particularly pertaining to reservoir devices and medications, has been recognized for a number of years, and effective control strategies have been developed. Most hospitals maintain a bacteriological monitoring system, and significant contamination by this route is not likely.[84] Nebulization equipment delivers a fine-particle aerosol, and, if contaminated, the aerosol droplets may contain bacteria.

Bag-mask units have been shown to allow the persistence of infectious organisms and the subsequent infection of other patients on whom the equipment has been later used.[85] Also, ventilator circuits are inevitably contaminated by the patient's own respiratory tract flora during exhalation and coughing, and the fluid that collects in this tubing is thereby contaminated. However, the American Association for Respiratory Care evidence-based clinical practice guidelines suggest that ventilator circuits should not be changed routinely for infection control purposes.[86]

HANDWASHING

Handwashing is generally considered the single most important procedure for preventing nosocomial infections. The recommended handwashing procedures depend on the purpose of washing. In most situations, a vigorous brief washing with soap and water is adequate to remove transient flora. Antimicrobial handwashing procedures are indicated before all invasive procedures, during the care of patients in strict respiratory or enteric isolation, and before entering intensive care units. The most commonly used agents are 70% isopropyl alcohol, iodophors, and chlorhexidine. Scrub regimens such as povidone-iodine surgical scrub are appropriate as well.[87]

CHEMICAL AGENTS FOR STERILIZATION/ DISINFECTION

Disinfectants act to kill microorganisms by several methods:

- oxidating microbial cells,
- hydrolyzing,
- combining with microbial proteins to form salts,
- coagulating the proteins of microbial cells,
- denaturing enzymes, and/or
- modifying cell wall permeability.[88]

Aldehydes

Aldehydes contain some of the most commonly used antimicrobials in respiratory care practice. These agents achieve their antimicrobial action through the alkylation of enzymes.

The cidal action of glutaraldehyde is accomplished by disruption of the lipoproteins in the cell membrane and cytoplasm of vegetative bacterial forms. This reaction between the chemical glutaraldehyde and cell proteins depends on both time and contact. Items to be disinfected must be free of material that would inhibit contact, and adequate contact time is needed for the chemical reaction to be complete. Alkaline glutaraldehyde, buffered by a 0.3% bicarbonate agent, is used as a 2% solution. This solution is bactericidal, virucidal, and tuberculocidal within 10 min and produces sterilization when applied for 10–20 h. Equipment disinfected or sterilized with glutaraldehyde should be thoroughly rinsed and dried prior to use because any residue would be irritating to mucous membranes.

Glutaraldehyde solutions are commonly used for cold disinfection or sterilization of respiratory care equipment, and they have a large degree of safety. These solutions can be used to disinfect bronchoscopes as well as many of the current respiratory supplies.

Alcohols

Alcohols, especially ethylene and isopropyl alcohol, are perhaps the most commonly used disinfectants. Alcohols as a chemical family have many desirable characteristics needed in disinfectants. They are generally bactericidal and accomplish their bactericidal activity by damaging the cell wall membrane. They also have the ability to denature proteins, particularly enzymes called dehydrogenases. For alcohol to coagulate microbial proteins, water must be present. For this reason, 70% has been considered the critical dilution for alcohol, with a rapid loss of bactericidal activity with dilutions less than 50%. Both ethyl and isopropyl alcohols are rapidly effective against vegetative bacteria and tubercle bacilli but are not sporicidal.

To be sure that the current infection control practice is effective in each institution, random microbiological cultures should be done whenever a problem is suspected or to test the reliability of the disinfection or sterilization techniques.

Late Complications of Inhalation Injury

TRACHEAL STENOSIS

Tracheal complications are commonly seen and consist of tracheitis, tracheal ulcerations, and granuloma formation. The location of the stenosis is almost invariably subglottic and occurs at the site of the cuff of the endotracheal or tracheostomy tube.[89] Several problems arising after extubation represent sequelae of laryngeal or tracheal injury incurred during the period of incubation. While tracheal stenosis or tracheomalacia is usually mild and asymptomatic, each can present as severe fixed or dynamic upper airway obstructions in some patients. These conditions can require surgical correction. In the management of intubated patients, such complications should be mostly preventable by meticulous attention to the tracheostomy or endotracheal tube cuff. Inflation of the cuff should be to the minimal pressure level consistent with preventing a leak in the ventilator at end inspiration.

OBSTRUCTIVE/RESTRICTIVE DISEASE

Chronic airway disease is a relatively rare reported sequel of inhalation injury and its supportive treatment. Spirometry is a useful screening tool for airway obstruction. Reports in the literature for adults indicate that lung function returns to normal after inhalation injury.[90,91] However, Mlcak et al. reported pulmonary function changes following inhalation injury for up to 10 years post-injury in a group of severely burned children.[92] In the great majority of cases, eventual resolution of both symptoms and physiologic abnormalities will occur. During the resolution phase, serial measurement of airflow obstruction should be obtained.[93] Desai et al. demonstrated that physiologic insults that occur as a result of thermal injury may limit exercise endurance in children.[94] Data from exercise stress testing showed evidence of a respiratory limitation to exercise. This was confirmed by a decrease in the maximal heart rate, decrease in the maximal oxygen consumption, and increase in respiratory rate. In the cases of persistent severe respiratory symptoms, the severity of the impairment should be documented and the patient evaluated for a pulmonary rehabilitation program.

Summary

Inhalation injury and associated major burns provide a challenge for healthcare workers who provide direct hands-on care. The technical and physiologic problems that complicate the respiratory management of these patients require a practical knowledge of the possible sources of nosocomial infections. Patients with inhalation injury frequently require the use of respiratory care equipment that, if not properly cared for, can aid in the spread of infections. Important priorities for reducing the risk of infections include an aggressive bronchial hygiene therapy program, adherence to established infection control practices, the use of universal precautions during procedures, and meticulous cleaning of respiratory care equipment, as well as routine epidemiologic surveillance of the established infection control practices within each institution. It is imperative that a well-organized, protocol-driven approach to respiratory care of the burn patient be utilized so that further improvements can be made and the morbidity and mortality associated with inhalation injury be reduced.

19 The Systemic Inflammatory Response Syndrome

TRACY TOLIVER-KINSKY, MAKIKO KOBAYASHI, FUJIO SUZUKI, and EDWARD R. SHERWOOD

Introduction

Burn patients, with or without inhalation injuries, commonly exhibit a clinical picture that is largely produced by systemic inflammation. The term *systemic inflammatory response syndrome* (SIRS) was introduced to designate the signs and symptoms of this condition. SIRS has a continuum of severity ranging from physiologic alterations such as tachycardia, tachypnea, fever, and leukocytosis to refractory hypotension and, in its most severe form, shock and multiple organ system dysfunction. In thermally injured patients, the most common cause of SIRS is tissue damage caused by the burn itself. Sepsis, characterized by SIRS in the presence of infection, is also common in burn patients and is a significant cause of morbidity and mortality. Starting from a local infection at the burn wound, an infected catheter tip, or pulmonary infection, the spread of microbes and their toxins can further potentiate systemic inflammation. Pathological alterations of metabolic, cardiovascular, pulmonary, renal, gastrointestinal, and coagulation systems occur as a result of the hyperactive immune system. This chapter will review current understanding of SIRS and the associated immunological, cardiovascular, and pulmonary dysfunction that occurs following trauma and thermal injury.

Definition of SIRS

The term *systemic inflammatory response syndrome* (SIRS) was recommended by the American College of Chest Physicians/Society for Critical Care Medicine (ACCP/SCCM) consensus conference in 1992 to describe a systemic inflammatory process, independent of its cause.[1] The proposal was based on clinical and experimental results indicating that a variety of conditions, both infectious and noninfectious (i.e., burns, ischemia–reperfusion injury, multiple trauma, pancreatitis), induce a similar host response. Two or more of the following conditions must be present for the diagnosis of SIRS to be made:

- Body temperature of greater than 38°C or less than 36°C;
- Heart rate of greater than 90 beats/min;
- Respiratory rate of greater than 20/min or a $Paco_2$ of less than 32 mm Hg;
- Leukocyte count of greater than 12,000/μL, less than 4000/μL, or more than 10% immature (band) forms.

All of these pathophysiologic changes must occur as an acute alteration from baseline in the absence of other known causes. This definition is very sensitive and nonspecific, and most of the SIRS criteria are also addressed in other scoring systems of injury-induced physiologic derangement, such as the Acute Physiology and Chronic Health Evaluation (APACHE), Mortality Probability Model (MPM), and Simplified Acute Physiology Severity (SAPS) systems. Several investigators have criticized the definition of SIRS as being too sensitive and encompassing the majority of ICU patients and certainly the vast majority of patients suffering extensive thermal injury.[2,3] The initial definition of SIRS also did not address the continuum of disease severity defined for sepsis. Criteria for the diagnosis of severe sepsis included the additional derangements of organ dysfunction, hypotension, and hypoperfusion. Evidence of hypoperfusion included, but was not limited to, the presence of lactic acidosis, oliguria, and altered mental status. Septic shock was characterized by hypotension and hypoperfusion in patients who were adequately volume resuscitated or required treatment with catecholamines or other vasoactive drugs to support cardiovascular function. Muckart and Bhagwangee,[2] in an effort to define a continuum of severity for SIRS, later proposed the categories of severe SIRS and SIRS-associated shock. These conditions were defined by the same criteria as severe sepsis and septic shock in the absence of demonstrable infection. In its most severe form, SIRS can induce organ injury and subsequent multiple organ dysfunction syndrome (MODS).

Despite the limitations in the definitions of SIRS and sepsis, most clinicians and investigators generally adopted the SIRS concept. However the initial definition and criteria were not felt to be optimized. To address these issues, a second consensus conference was assembled in 2001.[4] The goal of this conference was to revisit the previously defined criteria for SIRS and sepsis as well as to determine whether revision of these criteria was indicated. The consensus was that the concepts of sepsis and SIRS are useful, but the diagnostic criteria are overly sensitive and nonspecific. The participants added additional criteria that defined metabolic, biochemical, and functional alterations associated with SIRS and sepsis. Among these were hyperglycemia, edema, elevated plasma C-reactive protein (CRP) concentration, coagulation abnormalities, thrombocytopenia, ileus, and hyperbilirubinemia. The group further proposed a staging system for sepsis and SIRS that could be used to stratify patients for prediction of outcome. This staging system, termed PIRO, defined several criteria, including the predisposition of patients to a poor outcome as determined by premorbid conditions and possible genetic factors. Other factors include the severity and type of insult, the host

response to injury, and the presence of organ dysfunction. The participants proposed that this model could be used to generate more specific criteria for defining the SIRS phenomenon. Although the validity of this approach remains to be established, Rubulotta recently reported that the PIRO criteria have predictive value regarding mortality in septic patients.[5] More recent studies have also validated the PIRO model. Macdonald and colleagues reported that the PIRO model performed better than SOFA or MEDS scores in predicting mortality in patients presenting to the emergency room with severe sepsis or septic shock.[6] Some practitioners advocate for the validity and value of the PIRO system, but the system is not widely used in clinical practice.[7]

Although inflammation is certainly present in patients with burn injuries, sepsis, and other severe injuries, the contribution of SIRS to the pathogenesis of those conditions is under question. The most recent consensus conference assembled to define clinical criteria for sepsis dropped SIRS from the defining criteria.[8] The conference participants defined sepsis as "life threatening organ dysfunction due to a dysregulated host response to infection" and noted that SIRS criteria have poor predictive validity among patients who are infected.

Another pitfall in the designation of SIRS is the difficulty of applying the initial criteria to children. Some of the criteria, particularly those for heart and respiratory rates, fall within the normal physiologic range for young children. In 2002, a consensus conference was assembled to define criteria for sepsis and SIRS in children.[9] The participants defined six age groups based on clinical and physiological characteristics (Table 19.1). SIRS was defined as the presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

- temperature of greater than 38.5°C or less than 36°C;
- tachycardia, defined as a mean heart rate of greater than 2 SD above normal for age *or* for children younger than 1 year;
- bradycardia, defined as a heart rate of less than 10% of normal for age;
- mean respiratory rate of greater than 2 SD above normal for age or requirement for mechanical ventilation;
- leukocyte count elevated or depressed for age.

Severe sepsis was defined as sepsis plus one of the following: cardiovascular dysfunction, acute respiratory distress syndrome, or two or more organ dysfunctions (respiratory, renal, neurologic, hematologic, or hepatic).

The definition of septic shock is problematic in children because children can maintain blood pressure until they become severely ill. Therefore hypotension is not a useful criterion for diagnosing shock in children. This group proposed criteria for septic shock that included the presence of tachycardia in conjunction with signs of decreased peripheral perfusion, such as decreased capillary refill, decreased peripheral pulses, decreased urine output, altered mental status, and cold/mottled extremities.[9]

Table 19.1 Pediatric Age Groups for SIRS Criteria

Newborn 0 day to 1 week
Neonate 1 week to 1 month
Infant 1 month to 1 year
Toddler or preschool 2 to 5 years
School age 6 to 12 years
Adolescent 13 to 18 years

Several studies have been conducted with the goal of determining the prognostic value of the SIRS designation. In the acute setting, SIRS has been demonstrated in the majority of critically injured patients, and the intensity of the response correlates directly with the severity of injury.[3,10] The presence of SIRS within the first 24 hours after severe injury has not served as a reliable predictor of mortality in trauma or burn patients.[3,10] However, the presence of shock is an important predictor of poor outcome, particularly when associated with MODS.[2] In addition, the presence of more than two of the SIRS criteria in the setting of acute injury has correlated with increased morbidity and mortality.[11,12] A study by Rangel-Frausto et al.[12] showed that trauma patients who did not meet SIRS criteria had a mortality rate of 3%, compared to 6% in those with two SIRS markers. Patients with three or four SIRS criteria had mortality rates of 10% and 17%, respectively, whereas those with culture-negative shock had a 46% death rate. Haga et al.[13] have shown that the persistence of SIRS for more than 3 days in surgical patients is a harbinger of complications and is associated with increased morbidity. Talmor et al.[10] reported that persistence of SIRS to the second postoperative day in high-risk surgical patients correlated with an increased incidence of MODS. Additional studies have shown that persistence of SIRS criteria for more than 3 days in trauma and burn patients is associated with worse outcome.[13–16] Therefore, three important factors appear to determine the effect of SIRS on the host. The first is the severity of the initial inflammatory response. This response is proportional to the severity of injury, and the presence of shock or MODS within the first 24 hours after injury carries a poor prognosis. The second determinant is the persistence of SIRS beyond the first few days of injury. Specifically prolongation of SIRS beyond the second day after severe trauma or thermal injury is associated with an increased complication rate. Factors that appear to be important in reducing the incidence of a prolonged inflammatory state include adequate fluid resuscitation within the first 24 hours after injury, aggressive excision of necrotic tissue, and enteral feeding.[14–16] A third factor is the adaptive capacity of the host. Results of several studies have shown that extremes of age and the presence of coexisting disease will diminish the adaptive capacity of the host and predict a worse prognosis for any given severity of injury.[17,18] As noted earlier in this chapter, the actual contribution of SIRS to the pathogenesis of sepsis and other forms of systemic injury are in question.[8]

The Initiating Event

The crucial pathophysiologic event that precipitates systemic inflammation is tissue damage. This can occur both as a result of direct injury to tissues from mechanical or thermal trauma and as a result of cellular injury induced by ischemia and reperfusion. Injury results in the acute release of pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin (IL)-1, and IL-6. If injury

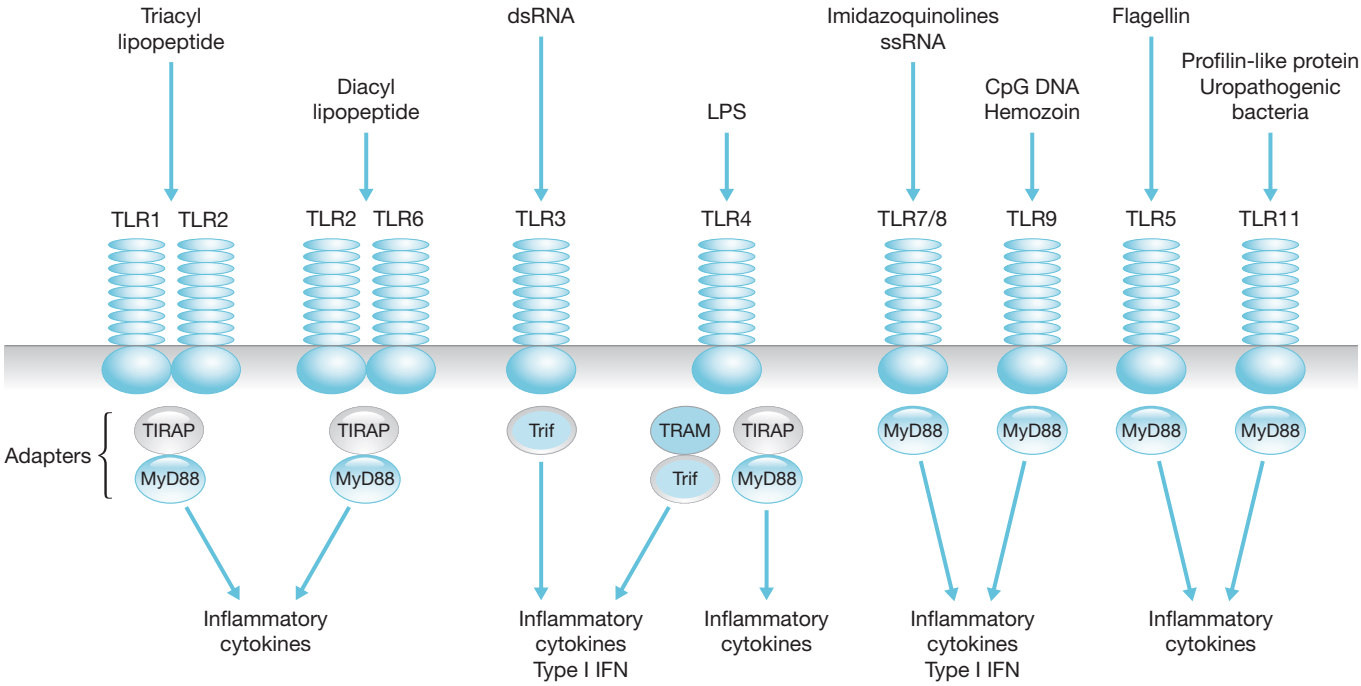

Fig. 19.1 Toll-like receptor signaling. Toll-like receptors (TLR) are membrane-associated receptors that recognize microbial products and endogenous products released during tissue injury, allowing the host to recognize the presence of microbes or tissue injury. TLR activation initiates intracellular signaling pathways that facilitate transcription of pro-inflammatory gene products. (From Kawai T, Akira S. TLR Signaling. Cell Death Differ. 2006; 13:816–825.)

is severe, as in extensive thermal injury, a profound release of cytokines and noncytokine mediators of inflammation occurs, resulting in the induction of a systemic inflammatory reaction. The ability of the host to adapt to this systemic inflammatory response depends on the magnitude and duration of the response as well as the adaptive capacity of the host. If the insult and the host's response to it are beyond the adaptive capacity of the host, or if adequate resuscitation is not promptly initiated, organ injury may ensue during the early post-injury period. Factors that have been implicated in the worsening or prolongation of SIRS include inadequate resuscitation during the acute phase following thermal injury, persistent or intermittent infection, ongoing tissue necrosis, and translocation of bacteria or endotoxin across the bowel.[18,19]

The actual mechanisms that initiate trauma-induced inflammation at the cellular and molecular levels are becoming increasingly understood. Two primary sensing systems have been identified. Toll-like receptors (TLR) respond to endogenous cellular factors that are produced or released following tissue trauma. TLR are expressed by leukocytes and some parenchymal cells. They allow the host to sense the presence of microbes via pathogen-associated molecular patterns (PAMPs) and initiate an innate immune response (Fig. 19.1). TLR also have the ability to respond to endogenous ligands that are leaked from cells upon their destruction by burn injury. These molecules are referred to as damage-associated molecular patterns (DAMPs) and are typically intracellular molecules with normal cellular functions (Fig. 19.2). As cells are damaged by thermal injury, these molecules are released into the extracellular matrix. Due to their normal intracellular localization, these molecules are recognized as danger signals and can bind to the same TLRs that are activated by microbial products. Among the proposed endogenous TLR ligands are heat shock proteins (recognized by TLR4 and TLR2), high-mobility group box 1 (HMGB1; recognized by TLRs 4 and 2), histones (recognized by TLR4), and mitochondrial DNA (recognized by TLR9).[20–22] Activation of TLR signaling pathways results in the transcription of genes associated with inflammatory responses. A second sensing system is comprised of cytoplasmic NOD-like receptors (NLRs) that sense endogenous and exogenous ligands during loss of cellular compartmentalization or membrane integrity and cause activation of inflammasomes (Fig. 19.3).[23] DAMPs that activate NLRs, either directly or via adapter molecules, include uric acid, endogenous DNA, and adenosine triphosphate (ATP).[22] Inflammasome assembly ultimately results in activation of inflammatory caspases such as caspase-1. Activated caspase-1, also known as IL-1-converting enzyme, causes cleavage of pro-IL-1 and pro-IL-18 into active mature proteins. The IL-1 and IL-18 produced by this interaction are released from cells and facilitate the pro-inflammatory response.

SIRS and Immunological Perturbations

Inflammatory responses are important for the early initiation of tissue repair and activation of innate immune cells in response to local infection. Cytokines such as IL-6, TNF-α, and IL-1 recruit and activate macrophages and neutrophils at sites of infection. To prevent tissue damage caused by prolonged or excessive inflammation, local anti-inflammatory responses are initiated to resolve the early

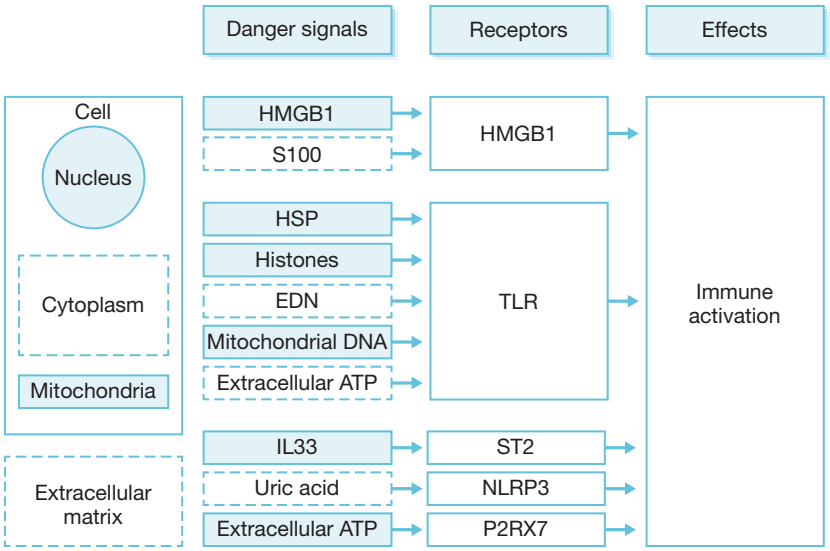

Fig. 19.2 Damage-associated molecular patterns (DAMPs). DAMPS are typically intracellular molecules with normal cellular functions that serve as danger signals when released into the extracellular matrix from damaged cells. DAMPs bind to various Toll-like receptors (TLRs) and other pathogen-associated molecular pattern receptors on leukocytes to activate inflammatory cascades. *HMGB1*, high mobility group box-1 protein; *HSP*, heat shock protein; *EDN*, eosinophil-derived neurotoxin; *IL-33*, interleukin-33; *TLR*, Toll-like receptor; *RAGE*, receptor for advanced glycation end-products; *NLRP3*, NOD-like receptor family, pyrin domain containing 3 (From Fontaine M, Lepape A, Piriou V, Venet F, Friggeri A. Innate danger signals in acute injury: From bench to bedside. *Anaesth Crit Care Pain Med.* 2016;35:283–292.)

inflammatory response. In the case of large burn injuries, the inflammatory response is massive and becomes systemic. A compensatory anti-inflammatory response referred to as the counter anti-inflammatory response syndrome (CARS) may be mounted in an attempt to restore homeostasis and control SIRS. Increased production of anti-inflammatory cytokines such as IL-10 and transforming growth factor-β (TGFβ) and leukocyte apoptosis are part of this response.[24,25] A prolonged or excessive anti-inflammatory response predisposes the patient to infection. The pathogenesis of injury-induced immunosuppression is discussed in detail elsewhere in this book. Nevertheless there is likely great heterogeneity in the host response to injury and infection. A recent report by Davenport and colleagues showed that there is great interindividuality in the peripheral blood transcriptomic response during sepsis but that patients exhibiting a signature reflective of immunosuppression, endotoxin tolerance, and T-cell exhaustion had a worse prognosis.[26] They further noted that the immunosuppressed phenotype can develop early during sepsis and may render the septic host unable to adequately mount an adequate response to clear the primary infection.

Our understanding of these syndromes has evolved to better describe this response that is shared by burn and severe non-burn trauma patients. For decades, the host response to injury-induced systemic inflammation has been described by the SIRS/CARS paradigm. It was initially believed that SIRS was resolved during CARS due to mutual regulatory effects of the mediators associated with the respective syndromes. However, examination of the transcriptome of leukocytes from trauma patients has revealed that SIRS and CARS exist simultaneously. Specifically, genes associated with both inflammatory and anti-inflammatory pathways were simultaneously up-regulated after injury, and this was described as a "genomic storm."[27] Genes associated with adaptive immune responses were down-regulated at the same time, suggesting impaired effector functions. The magnitude and duration of these responses correlated with complications after injury. This is supported by earlier studies examining levels of pro-inflammatory IL-6 and anti-inflammatory IL-10 in the circulation of burn patients.[28] Burn patients who eventually developed sepsis during their acute care had substantially higher levels of circulating IL-6 and IL-10 as early as 1 day post-burn. Later development of lethal sepsis was associated with persistently high levels of these cytokines. More recently, a new model has been proposed to characterize the responses and outcomes of patients following severe traumatic injury (Fig. 19.4). This model proposes that patients who rapidly resolve their SIRS and CARS responses return to immune homeostasis and recover from injury without major complications. However, if SIRS and CARS are not resolved, the patient develops persistent inflammation, immunosuppression, and catabolism syndrome (PICS), in which persistent inflammation and immunosuppression are accompanied by severe muscle protein catabolism (described in other chapters).[29] Secondary nosocomial infections are a risk and can exacerbate the existing inflammation, leading to multiorgan failure and death.

The Two-Hit Hypothesis

Some investigators have described a phenomenon in which the injured host manifests an exaggerated inflammatory response if confronted with a secondary inflammatory stimulus during the post-injury period. This phenomenon has been termed the "two-hit hypothesis." Although the pathobiology of the two-hit hypothesis is not completely understood, monocytes and macrophages appear to play a

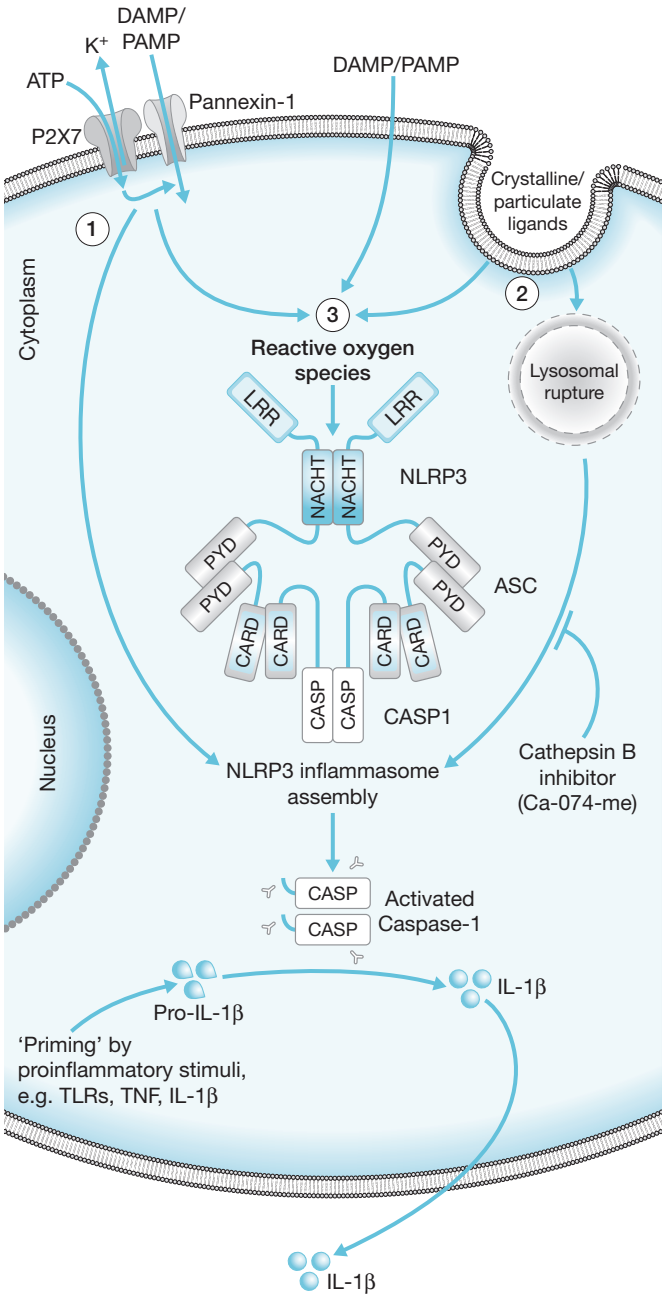

Fig. 19.3 The inflammasome is an intracellular signaling complex that is activated by a variety of endogenous and microbial products and causes activation of inflammatory caspases such as caspase-1. Activation of this system results in release of interleukin-1 (IL-1) and IL-18 during periods of inflammation. (From Schroder K, Tschopp J. The inflammasomes. *Cell* 2010;140:821–832.)

central role in mediating the process. For example, the lymphokine α-interferon (IFN-α), produced during the initial injury, might act as the first signal and prime macrophages for a heightened inflammatory response if a second stimulus is encountered. Several changes in macrophage function, including an increase in the transcription rate of mRNA for TNF-α, can be induced by exposure to IFN-α. However, TNF-α protein is not produced in large amounts in response to the first inflammatory insult. If a second stimulus, such as endotoxin exposure, is provided in even a small dose, macrophages are triggered to become fully activated and to secrete large amounts of TNF-α. Studies by Paterson et al.[30] showed that macrophages have increased responsiveness to ligands for TLR2 and TLR4 following burn injury. TLR2 and TLR4 play an integral role as components of receptor complexes for DAMPs and various microbial products such as peptidoglycans, lipoproteins, and lipopolysaccharide. Enhancement of TLR2 and TLR4 responses during the post-injury period may be one mechanism contributing to the two-hit phenomenon.

The exaggerated response to a secondary stimulus seen in severely injured patients appears to have functional consequences. Several studies that focused on organ injury caused by systemic inflammatory processes indicate that a phenomenon comparable to the cellular events just described can occur in severely injured patients.[31] Dehring et al. found more persistent pulmonary hypertension and an exaggerated hyperdynamic response to bacteremia in sheep when a week-old thermal injury preceded systemic bacterial challenge.[32] In a rat model of intestinal ischemia–reperfusion injury and endotoxemia, lung albumin leak and mortality rate increased only if both injuries occurred sequentially.[33] Combined administration of low doses of endotoxin and TNF-α to rats caused hypotension and metabolic effects that are commonly seen after giving a highly lethal dose of either compound alone.[34] These findings are in keeping with the fact that multiple organ damage usually develops over a prolonged period during which several insults might occur. It also emphasizes why it is so important to minimize inflammatory insults such as tissue ischemia or infection, particularly in patients in whom systemic inflammation is already present.

Cytokine and Noncytokine Mediators of SIRS

Several pro-inflammatory cytokines, chemokines, and noncytokine inflammatory mediators play a role in the pathogenesis of SIRS. Cytokines comprise a broad group of polypeptides with varied functions within the immune response (Table 19.2). The classic mediator of systemic inflammation is TNF-α. TNF-α is released primarily by macrophages within minutes of local or systemic injury and modulates a variety of immunologic and metabolic events.[35] At sites of local infection or inflammation, TNF-α initiates an immune response that activates antimicrobial defense mechanisms and, once the infection is eradicated, tissue repair. It is a potent activator of neutrophils and mononuclear phagocytes and also serves as a growth factor for fibroblasts and as an angiogenesis factor. However, systemic release of TNF-α can precipitate a destructive cascade of events that can result in tissue injury, organ dysfunction, and, potentially, death. Among the systemic effects of TNF-α are the induction of fever, stimulation of acute-phase protein secretion by the liver, activation of the coagulation cascade, myocardial suppression, induction of systemic vasodilators with resultant hypotension, catabolism, and hypoglycemia.[35,36] Numerous studies have shown that administration of TNF-α to experimental animals will mimic the systemic inflammatory response observed in sepsis and after severe injury. Another important effect

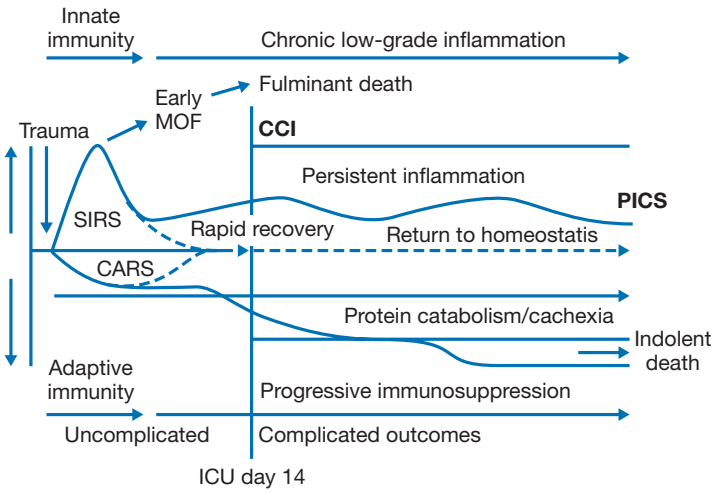

Fig. 19.4 The SIRS–CARS–PICS model of the systemic response to severe injury. Tissue injury induces the production of pro-inflammatory mediators resulting in the systemic inflammatory response syndrome (SIRS). A compensatory anti-inflammatory response may be simultaneously mounted in an attempt to control inflammation, resulting in the counter anti-inflammatory response syndrome (CARS). Patients able to resolve these syndromes recover whereas persistent perturbations in inflammatory balance may lead to persistent inflammation, immunosuppression, and catabolism syndrome (PICS). In this state, patients are susceptible to infection and are at risk for lethal systemic inflammatory responses and severe protein catabolism that leads to cachexia and, if unresolved, death. (From Vanzant EL, Lopez CM, Ozrazgat-Baslanti T, et al. Persistent inflammation, immunosuppression, and catabolism syndrome after severe blunt trauma. *J Trauma Acute Care Surg.* 2014;76:21–30.)

Table 19.2 Cytokine and Chemokine Mediators of Systemic Inflammation

Cytokine	Polypeptide Size	Cell Source	Cell Target	Primary Effects
Tumor necrosis factor- α (TNFα)	17 kDa	Monocytes, macrophages, T lymphocytes	Neutrophil Endothelial cells Hypothalamus Liver Muscle, fat Heart Macrophages T lymphocytes Various tissues	Activation (inflammation) Activation (inflammation/coagulation) Release of vasodilators (NO) Fever Acute-phase response Catabolism Myocardial suppression Release of cytokines, inflammation Inflammation Apoptosis?
Interleukin-1 (IL-1)	17 kDa	Monocytes, macrophages	T cells Endothelial cells Liver Hypothalamus Muscle, fat	Activation (inflammation) Activation (inflammation/coagulation) Release of vasodilators (NO) Acute-phase response Fever Catabolism
Interleukin-6 (IL-6)	26 kDa	Monocytes, macrophages, T cells, endothelial cells	Liver B cells	Acute-phase response Activation
Interleukin-8 (IL-8)	10 kDa	Monocytes, macrophages, endothelial cells	Neutrophils	Chemotaxis, activation
Interferon-γ (IFN-γ)	21–24 kDa	T cells, NK cells	Macrophages	Activation (inflammation)
Interleukin-12 (IL-12)	70 kDa	Macrophages	T cells, B cells, NK cells	Activation, differentiation
Interleukin-18		Macrophages	T cells, NK cells	Activation, differentiation
IL-10		Monocytes/Th2 lymphocytes, mast cells, regulatory T cells	Macrophages Th1 lymphocytes, NK cells	Inhibition, activation regulation

of TNF-α is its ability to induce apoptosis of a variety of cell types.[37] TNF-induced apoptosis may be one mechanism by which it induces tissue injury at high systemic concentrations.

TNF-α is also a potent stimulus for the release of other pro-inflammatory mediators, particularly IL-1 and IL-6. IL-1 is released primarily by mononuclear phagocytes, and its physiologic effects are essentially identical to those of TNF-α.[38] However, important differences exist between the functions of IL-1 and TNF-α. Most notably, IL-1 does not induce tissue injury or apoptotic cell death by itself, but can potentiate the injurious effects of TNF-α. The IL-1 family of

proteins, including IL-18, is the only group of cytokines for which known natural antagonists have been identified. The IL-1 receptor antagonists (IL-1ra) bind to the IL-1 receptor but do not induce receptor activation.[38] These proteins appear to function as competitive inhibitors of IL-1 action. As noted earlier, the systemic release of IL-1 is dependent on the activation of inflammasomes and caspase-1.[23]

IL-6 is another protein that is commonly increased in the circulation of patients with SIRS.[38] Macrophages, endothelial cells, and fibroblasts secrete this protein. IL-6 itself does not induce tissue injury, but its presence in the circulation has been associated with poor outcome in trauma patients, probably because it is a marker of ongoing inflammation. The primary effect of IL-6 is to induce secretion of acute-phase proteins from the liver as well as to serve as a growth and differentiation factor for B lymphocytes.

Interferon-γ (IFN-γ) is a cytokine that facilitates the amplification of the acute inflammatory response, particularly the stimulation of cytokine secretion, phagocytosis, and respiratory burst activity by macrophages. IFN-γ is secreted primarily by T lymphocytes and natural killer (NK) cells in response to antigen presentation, as well as by macrophage-derived cytokines such as IL-12 and IL-18. The primary effect of IFN-γ is to amplify the inflammatory response of macrophages. In response to IFN-γ, the phagocytic and respiratory burst activities of macrophages are increased, secretion of inflammatory mediators such as TNF-α and IL-1 is enhanced, and antigen presentation is potentiated by upregulation of class II major histocompatibility complex. Blockade of IFN-γ production or function has been shown to markedly reduce the deleterious inflammatory effects induced by bacterial endotoxin.[39] Therefore IFN-γ is believed to be an important factor in the amplification of SIRS.

Chemokines are a family of proteins that function primarily as chemotactic factors for leukocytes and, when produced inappropriately or in excess, can contribute to damaging systemic or local inflammation (Table 19.3). IL-8 is the most widely studied chemokine in the setting of sepsis and SIRS; it is a potent chemoattractant for neutrophils and is a major factor in recruiting neutrophils to inflammatory foci. Several studies have shown that IL-8 plays a role in mediating tissue injury in the setting of trauma and burn injury, particularly in the lung.[40,41]

Production of most soluble mediators of inflammation is regulated at the transcriptional level. Some of the key transcription factors that control pro-inflammatory gene expression include nuclear factor-κB (NF-κB), AP-1, and IRF-3 (Fig. 19.5). NF-κB is composed of a family of proteins including p50 (NF-κB1), p65 (RelA), C-Rel, and p52 (NF-κB2) that combine to form homo- or heterodimers and ultimately function to regulate the transcription of a variety of cytokine, chemokine, adhesion molecule, and enzyme genes involved in SIRS.[42] Increased translocation of NF-κB has been associated with a poor outcome in some studies. Activation of NF-κB in peripheral blood monocytes correlates with increased mortality in septic patients, and alveolar macrophages from patients with adult respiratory distress syndrome (ARDS) exhibited higher nuclear NF-κB levels than critically ill patients without ARDS.[43,44] The AP-1 complex is activated through activation of MAP kinases by stimuli that are similar to those required for NF-κB mobilization. IRF-3 is mobilized through activation of the Trif-associated signaling pathway and results primarily in transcription of type I interferon (IFN-α) genes. The STAT1 pathway is induced by activation of type I (IFN-α) and type II (IFN-γ) receptors. Together these transcription factors mediate the transcription of numerous factors involved in inflammation and tissue repair (Fig. 19.6).

Table 19.3 Classification of Chemokines

Chemokine Type	Target Cell
CXC CHEMOKINES	
CXCL8 (IL-8, mouse MIP-2)	Neutrophils
CXCL1 (GROα, mouse KC)	Neutrophils
CXCL2 (GROβ, mouse KC)	Neutrophils
CXCL3 (GROγ, mouse KC)	Neutrophils
CXCL5 (ENA-78)	Neutrophils
CXCL6 (GCP-2)	Neutrophils
CXCL4 (PF4)	Fibroblasts, stem cells
CXCL9 (Mig)	T and NK cells
CXCL10 (IP-10)	T and NK cells
CXCL11 (I-TAC)	T and NK cells
CXCL12 (SDF-1α/β)	T lymphocytes
CC CHEMOKINES	
CCL3 (MIP-1α)	Monocyte/macrophages, T and B cells, NK cells, basophils
CCL4 (MIP-1β)	Same as above
CCL22 (MDC)	Monocyte, T lymphocytes
CCL25 (TECK)	Macrophages, T lymphocytes
CCL17 (TARC)	T lymphocytes
CCL5 (RANTES)	Monocyte/macrophages, T/NK cells
BASOPHILS	
CCL14 (HCC-1)	Monocytes
CCL16 (HCC-4)	Monocytes, lymphocytes
CCL18 (DC-CK-1)	T lymphocytes
CCL20 (MIP-3α)	T lymphocytes
CCL19 (MIP-3β)	T lymphocytes
CCL2 (MCP-1)	T lymphocytes, monocytes,
CCL8 (MCP-2)	Same as above
CCL7 (MCP-3)	Same as above
CCL13 (MCP-4)	Same as above
CCL11 (Eotaxin)	Eosinophils
OTHER CHEMOKINES	
XCL1 (Lymphotactin)	T lymphocytes, NK cells
CX3CL1 (Fractalkine)	T lymphocytes, monocytes

The current conventional names of chemokines are presented and original names are provided in parentheses for reference.

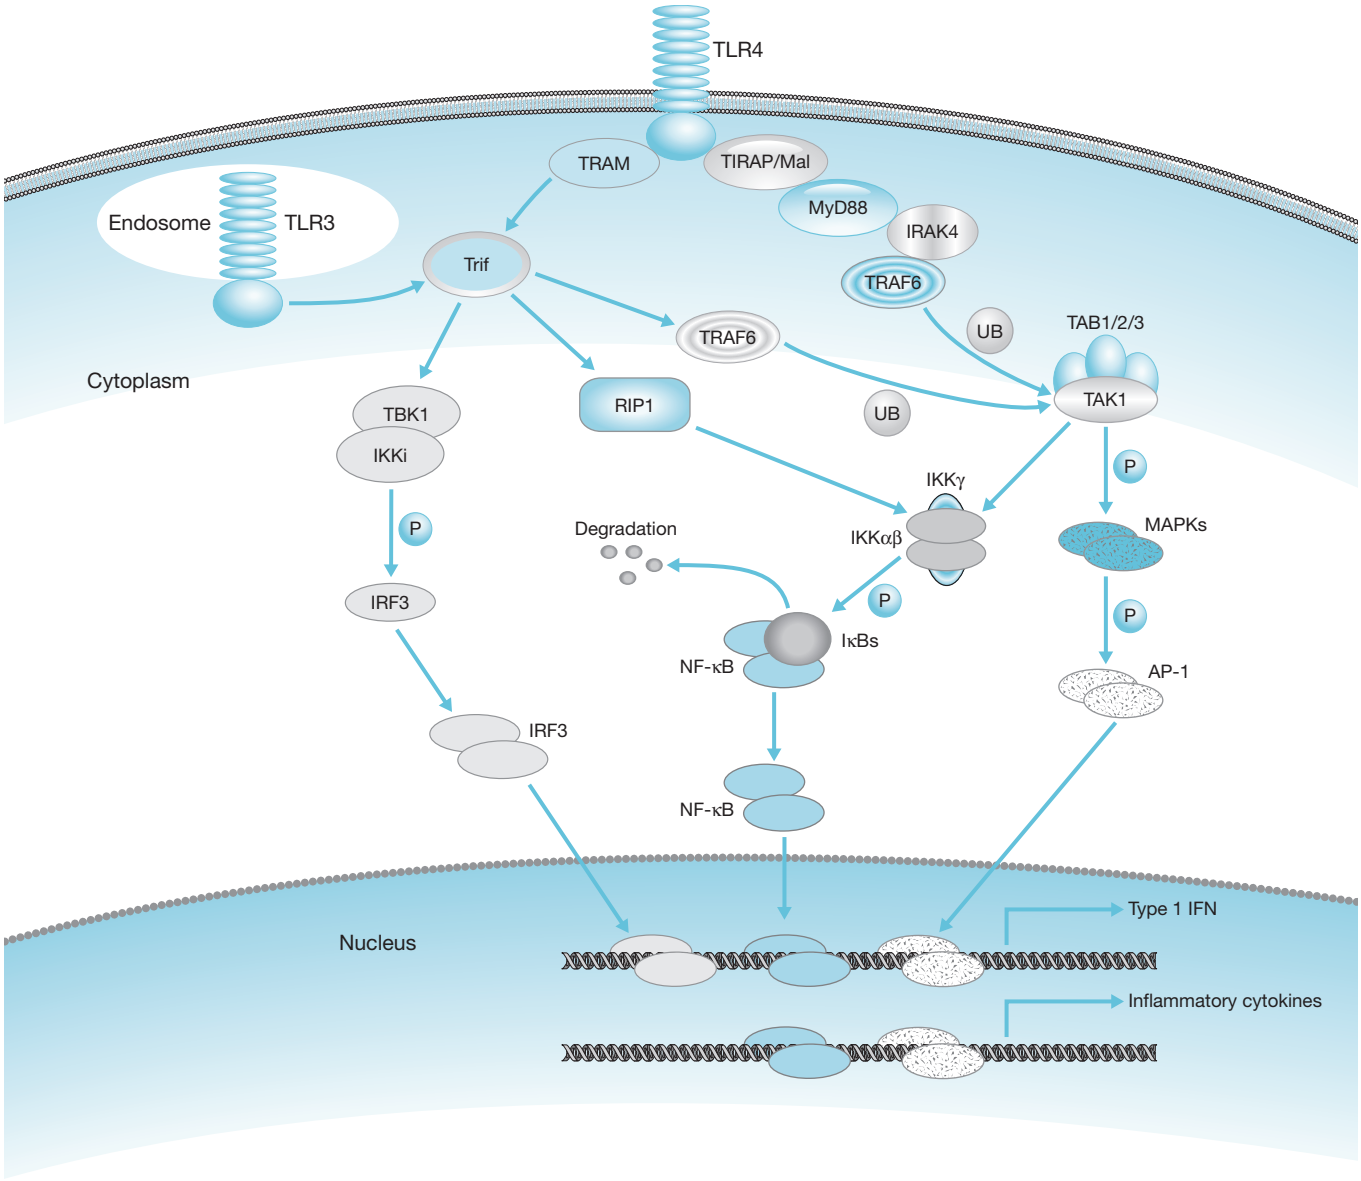

Fig. 19.5 Major inflammation-associated transcription factors include nuclear factor-κB (NF- κB), AP-1, and IRF-3. Activation of these pathways is mediated through MyD88- and Trif-dependent signaling after Toll-like receptor ligation. (From Kawai T, Akira S. TLR Signaling. Cell Death Differ. 2006;13:816–825.)

Several noncytokine factors have been implicated in the pathogenesis of SIRS. Platelet-activating factor (PAF) is a phospholipid autocoid released by endothelial cells that regulates the release of cytokines and amplifies the proinflammatory response. It appears to be an important factor in the adhesion of neutrophils to endothelial cells. The prolonged presence of PAF in the serum of patients with SIRS has correlated with poor outcome.[45] Eicosanoids are arachidonic acid metabolites that regulate many aspects of the immune response. Leukotrienes (LTC4–LTE4) induce contraction of endothelial cells and encourage capillary leakage.[46] Thromboxane A2, a macrophage- and platelet-derived factor, promotes platelet aggregation, vasoconstriction and, potentially, tissue thrombosis.[47]

The complement cascade is composed of more than 30 proteins that interact in a complex fashion to mediate inflammation and direct lysis of microbes and other cells (Fig. 19.7). However, in SIRS, excessive complement activation appears to cause significant cellular injury in the host. Products of the complement cascade, most notably C3a and C5a, are potent activators of inflammation and leukocyte chemotaxis.[48] C3a and C5a also directly activate neutrophils and promote release of reactive oxygen intermediates and proteases. Excessive release of these factors can result in significant tissue injury. The membrane attack complex (MAC) is the terminal component of the complement cascade. MAC results from the aggregation of the complement components C5–C9 on biological membranes. The accumulation of MAC on cell surfaces can result in significant tissue and cellular injury and may be a major factor in the pathogenesis of MODS. Suber and colleagues[49] have reported that complement-mediated responses to self-antigens exacerbate tissue injury after burn injury.

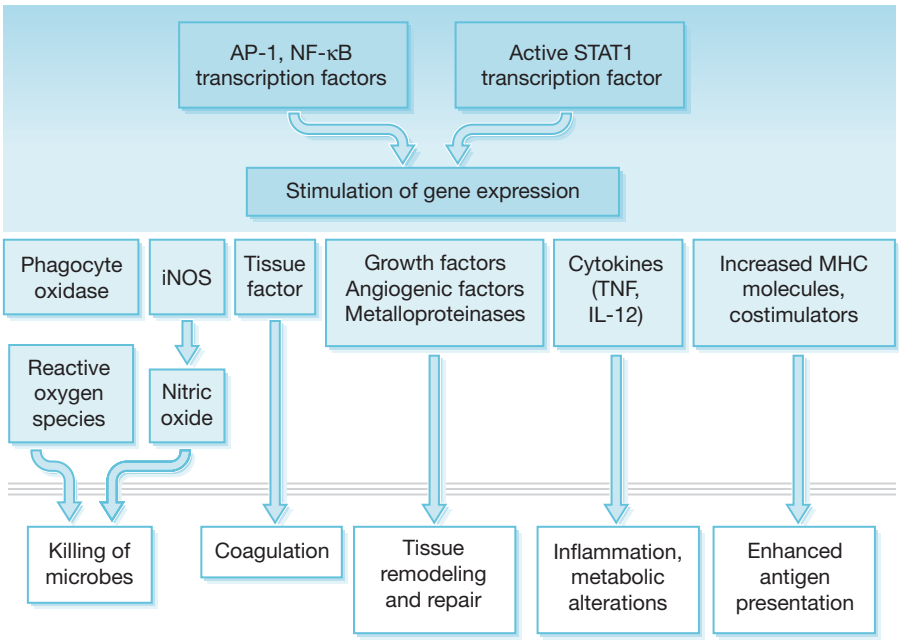

Fig. 19.6 Regulation of pro-inflammatory gene expression. Inflammatory stimuli induce activation of transcriptional pathways mediated by nuclear factor-κB (NF-κB), AP-1, and STAT1 that result in production of pro-inflammatory mediators. (From Cotran R, Kumar V, Collins T, eds., *Robbins pathologic basis of disease*, 6th edn. Philadelphia: WB Saunders; 1999:75.)

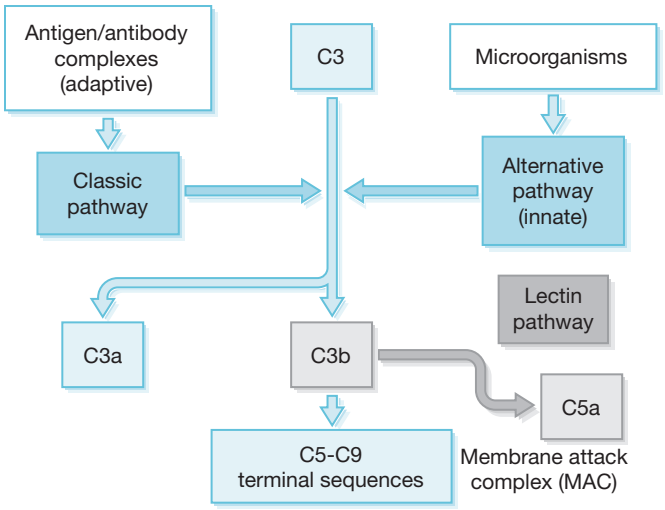

C3a and C5a (anaphylactotoxins): increase vascular permeability, chemotactic factors, opsonins

Fig. 19.7 The complement system can be activated by three primary mechanisms and facilitates the amplification of innate and acquired immune responses as well as directly mediating microbial lysis. The primary functions of complement are opsonization, leukocyte chemotaxis, and direct killing of microbes. (From Abbas AK and Lichtman AH, *Cellular and molecular immunology*, 5th edn., Saunders).

Circulating Cytokines as Markers of SIRS and Predictors of Outcome

Numerous studies have been undertaken with the goal of using plasma cytokine levels as diagnostic and prognostic markers in patients with SIRS or sepsis. This approach seems logical based on the observation that circulating cytokines have been observed in several clinical studies of trauma, sepsis, and thermal injury. Given its central role in the activation and regulation of the pro-inflammatory response, TNF-α has been studied extensively as a plasma marker of SIRS. The results have been inconsistent. Martin et al.[50] showed that TNF-α levels were markedly elevated in patients with septic shock and correlated with fatal outcome. However, their results also showed that trauma patients did not exhibit the same marked elevations in circulating TNF-α, nor did circulating TNF-α concentrations correlate with increased mortality in trauma patients. In some published studies, measurement of circulating TNF-α levels in burn patients has not provided a useful marker of outcome.[51,52] Overall, plasma TNF-α levels have been variable and inconsistent and have not correlated with mortality or the development of MODS. However a study by Zhang et al.[53] in 25 patients with greater than 30% total body surface area (TBSA) burns demonstrated marked increases in plasma TNF-α levels and a significant correlation between TNF-α concentration and shock, MODS, and death. These findings support the results of Marano et al.,[54] who showed a significant correlation between circulating TNF-α concentration and mortality in burned patients. Therefore, taken together, these results show that TNF-α could serve as a useful marker of ongoing inflammation as well as an indicator of morbidity and mortality in the setting of burn injury, but controversy remains.

TNF-α interacts with two known cell surface receptors designated tumor necrosis factor receptor (TNFR)-I and TNFR-II. TNFR-I, also known as TNF-R55 or p55, is expressed on a variety of cells and its activation mediates most of the activities of TNF-α, including induction of apoptosis. Activation of TNFR-II (TNF-R75 or p75) results

in cellular proliferation and activation. During inflammatory states, TNFR are released from cells and may serve as antagonists of TNF-α. Several investigators have characterized surface-bound and soluble TNFR (sTNFR) in sepsis and trauma.[53,55,56] Hubl et al.[55] showed that surface TNFR-I was up-regulated, whereas TNFR-II was down-regulated in patients with SIRS. Increased TNFR-I correlated with increased body temperature but not with survival. SIRS patients with decreased surface TNFR-II had a trend toward increased mortality. A study by Zhang et al.[53] showed a higher incidence of shock, MODS, and mortality in burn patients with increased plasma sTNFR-I and sTNFR-II levels. Presterl et al.[56] showed a correlation between sTNFR and APACHE III scores, as well as the incidence of shock and mortality in septic patients. Sikora and colleagues[57] have reported increased concentrations of sTNFR-I and sTNFR-II in the plasma of burned children. sTNFR concentrations correlated with burn surface area and decreased with adequate treatment. Children with hypovolemic shock had higher plasma concentrations of sTNFR. Overall, in the studies published to date, the presence of high levels of circulating sTNFR correlates with ongoing inflammation and may serve as an indicator of poor prognosis.

Another family of proteins that has been extensively analyzed as markers of SIRS is IL-1 and IL-1ra. In burn patients, low IL-1ra levels correlated with mortality in two independent studies.[58,59] Plasma IL-1ra levels have been shown to correlate with body surface area burned, extent of third-degree burn, and the presence of inhalational injury, both in adults and children.[52,57,58]

Recently, IL-8 has been reported as a predictor of poor outcome in burn patients.[60] In burn patients with lower levels of IL-8 (<234 pg/mL), IL-8 levels were predictive for multiorgan failure and correlated with the size of the burn injury. In burn patients with high levels (>234 pg/mL), IL-8 was predictive for the development of sepsis and mortality.

Of the cytokine markers studied to date, elevated levels of IL-6 appear to be one of the more consistent markers of poor outcome in burn, trauma, and septic patients. One of the known functions of IL-6 is induction of acute-phase proteins such as CRP by the liver. In some studies, CRP has been shown to parallel IL-6 as a marker of increased mortality.[59] Although IL-6 itself does not appear to have any known direct injurious effects, it apparently serves as a consistent marker of ongoing inflammation. Elevated plasma IL-6 levels have correlated with increased mortality in experimental and clinical studies of thermal injury, sepsis, trauma, and hemorrhagic shock.[51,61] A study by Taniguchi et al.[61] showed that an increased ratio of IL-6 to the anti-inflammatory cytokine IL-10 was a predictor of poor outcome in patients with SIRS.

In trauma and burn patients it is often difficult to differentiate whether SIRS is a result of the injury itself or due to superimposed infection. Most of the clinical signs of systemic infection, such as fever and leukocytosis, are by definition present in SIRS. Therefore considerable attention has been placed on identifying indirect markers of systemic infection that could serve to differentiate SIRS caused by infection from that caused by trauma. It is important clinically to identify patients with systemic infection in order to initiate antibiotic therapy in a timely fashion. Additionally positive blood cultures are the gold standard for diagnosis of systemic infections. Although blood cultures provide important information regarding the presence of infection and the identity of the infecting organism, it can often take several days to obtain reliable results, and the presence of negative cultures does not assure the absence of infection. Therefore efforts have been made to identify other markers of systemic infection. The two markers that have been most consistently elevated in patients with infection are procalcitonin and CRP. Studies have shown that increased plasma levels of procalcitonin or CRP are sensitive markers of systemic infection.[62] Both of these markers have been shown to be more reliable than clinical signs in the diagnosis of infection in high-risk surgical and trauma patients. Recent studies show that procalcitonin and CRP can be used to distinguish patients with systemic infection from those with noninfectious systemic inflammatory processes.[63–65]

Overall several markers of inflammation and infection have been identified in burn and trauma patients. Some of these have been shown to be consistent indicators of injury severity. However, cytokine and noncytokine markers of inflammation are not used routinely in the laboratory evaluation of burned patients. With further research and demonstration of the reliability of these markers, they may become an accepted part of clinical practice. In addition, technology is evolving to measure these markers in a rapid and cost-effective manner, which may allow blood cytokine markers to become a component of patient management in the future.

Anti-Inflammatory Therapy for SIRS

Despite our increased understanding of the role of inflammatory mediators in the pathogenesis of SIRS and sepsis, most anti-inflammatory drug regimens have had little success in the treatment of this problem. Neutralizing approaches to several inflammatory mediators have been studied. All of these studies have demonstrated, at best, marginal improvement in septic morbidity and mortality. None of the direct anti-inflammatory strategies has been successfully employed to minimize burn-associated inflammation. One of the most widely studied approaches for the treatment of SIRS is the use of monoclonal antibodies to TNF-α. Several multicenter, prospective clinical trials were undertaken in septic patients using several different antibodies to TNF-α.[66,67] Those studies did not demonstrate improved outcome in patients receiving anti-TNF-α compared to placebo. One study evaluated the efficacy of a chimeric antibody to TNF in patients with severe sepsis.[67] Circulating levels of TNF-α as well as a variety of other inflammatory mediators were assessed. Although circulating levels of TNF-α were transiently decreased, anti-TNF-α therapy did not result in reduction of circulating levels of other inflammatory mediators such as IL-1β, IL-1ra, sTNFR, or IL-6. In addition, evidence of systemic inflammation was not reduced and overall mortality was not improved in anti-TNF-α-treated patients. Similarly, the use of sTNFR as a strategy to neutralize the systemic effects of TNF-α and reduce sepsis-associated morbidity and mortality was unsuccessful.[68] Other anti-inflammatory approaches that have been studied and found to be largely ineffective include

the use of IL-1ra,[69,70] anti-bradykinin,[71] PAFra,[72,73] and ibuprofen.[74,75]

Because of the relative ineffectiveness of anti-inflammatory therapy aimed at neutralizing single mediators, more broad-based strategies were developed with the goal of simultaneously neutralizing, removing, or inhibiting the production of numerous inflammatory mediators. Hemofiltration was one approach that received considerable attention. Several studies have shown that hemofiltration will increase the clearance of inflammatory mediators, particularly IL-6, from blood in patients with sepsis.[76,77] However none of these studies has demonstrated a significant reduction in IL-6 plasma levels. A study by Kellum et al.[77] showed that continuous venovenous hemofiltration (CVVH) reduced plasma TNF-α concentrations by 13%, and the use of continuous venovenous hemodialysis (CVVHD) resulted in a 32% increase in circulating TNF-α levels. Overall the use of hemofiltration has been largely ineffective in removing significant amounts of inflammatory mediators from the blood of patients with sepsis, and there is currently no evidence that this approach will reduce morbidity and mortality.

The use of glucocorticoids in the treatment of sepsis has been proposed for more than 30 years. A meta-analysis[78] of studies using high-dose glucocorticoids in the treatment of sepsis was published in 1995 and later summarized by Zeni and colleagues.[79] Overall the use of high-dose glucocorticoids to treat sepsis and septic shock has not been beneficial. In many studies, the use of glucocorticoids in septic patients was associated with increased mortality. In burned patients there is no evidence that administration of glucocorticoids provides effective treatment for systemic inflammation. More recent studies show that replacement dose steroids will improve survival in septic patients who have adrenal insufficiency.[80] Recent guidelines from the Surviving Sepsis Campaign advocate the use of replacement dose glucocorticoids in septic patients refractory to conventional management.[81]

The failure of anti-inflammatory approaches to improve outcome in patients with severe sepsis or septic shock is likely to be multifactorial. First, the inflammatory response to injury and sepsis is induced by a complex array of mediators that are largely interrelated and have significant redundancy. Therefore, blocking or neutralizing a single mediator is not likely to have a marked effect on the overall response. Second, the same mediators that are important in inducing tissue injury also play an important role in antimicrobial immunity, and blockade of these mediators may leave the host more susceptible to subsequent infection. Third, many of the mediators, particularly TNF-α and IL-1β, are released within minutes of injury and mobilize the inflammatory cascade shortly thereafter. Therefore, by the time that signs of SIRS or sepsis are apparent, many of the injurious effects of the inflammatory response have already been set in motion, making therapy ineffective. A recent emphasis has been placed on the identification of late mediators of inflammatory injury. This search has been prompted by the observation that SIRS- and sepsis-associated death occur days after the peak effect of inflammatory cytokines. One potential late mediator that has recently been identified is HMGB-1.[82] HMGB-1 is released by macrophages up to 8 h after lipopolysaccharide (LPS) challenge and persists in the circulation for days. Administration of anti-HMGB-1 to septic mice has been shown to improve survival. Conversely systemic administration of HMGB-1 to mice is lethal. Whether HMGB-1 plays an important role in inflammatory injury in humans remains to be determined. However the concept of late mediators of inflammatory tissue injury may improve our understanding of the pathophysiology of SIRS.

As discussed earlier, factors that appear to be important in limiting the extent of SIRS and, in many cases, reducing the incidence of shock and MODS are appropriate fluid resuscitation, hemodynamic support, treatment of infection with antibiotics, excision of necrotic tissue, and adequate nutritional support.[83] There is controversy regarding the ideal fluid for volume resuscitation in trauma and burn patients. However, recent studies show that hypertonic saline has beneficial effects in modulating the SIRS-associated immunological cascade as well as in restoring hemodynamic parameters and microcirculatory flow. The effect of hypertonic saline on immune function has largely centered on attenuation of post-injury immunosuppression. Recent studies have shown that resuscitation with hypertonic saline will improve macrophage and T-cell function as well as increase resistance to infection in experimental models of trauma and hemorrhage.[84,85] However, the use of hypertonic fluids has not gained widespread support in burn resuscitation because of the risk of hypernatremia and associated complications. Proper nutritional support is also an important factor in the treatment of severely injured patients. Enteral feeding formulas supplemented with glutamine, arginine, omega-3 fatty acids, and nucleotides have been shown to improve outcome in trauma patients.[86] Overall, trauma patients receiving immune-enhancing diets have been shown to have fewer infectious complications. In general, enteral feeding has been shown to maintain gut integrity and improve outcome in burn patients.

Tracey and colleagues have described a cholinergic anti-inflammatory pathway that may be important in the regulation of inflammation and could be exploited for therapeutic benefit.[87,88] As described, local inflammation activates afferent fibers of the vagus nerve that signal the brain to elicit an anti-inflammatory response through efferent vagal fibers (Fig. 19.8). Acetylcholine released by the vagus interacts with α7 nicotinic acetylcholine receptors (α7 nAChR) on macrophages and suppresses the production of pro-inflammatory mediators. Those investigators have shown that electrical stimulation of the vagus nerve will attenuate the pro-inflammatory response induced by cecal ligation and puncture or endotoxin challenge. Acetylcholine has also been shown to inhibit the release of pro-inflammatory cytokines by cultured macrophages following endotoxin challenge.[87,88] More specific α7 nAChR agonists are under investigation for the treatment of hyperinflammatory states, and the possibility of exploiting the cholinergic anti-inflammatory pathway for therapeutic benefit remains to be established.

ACTIVATION OF THE COAGULATION CASCADE DURING INFLAMMATION

Inflammation and coagulation are intimately intertwined. The coagulation cascade is activated during both tissue

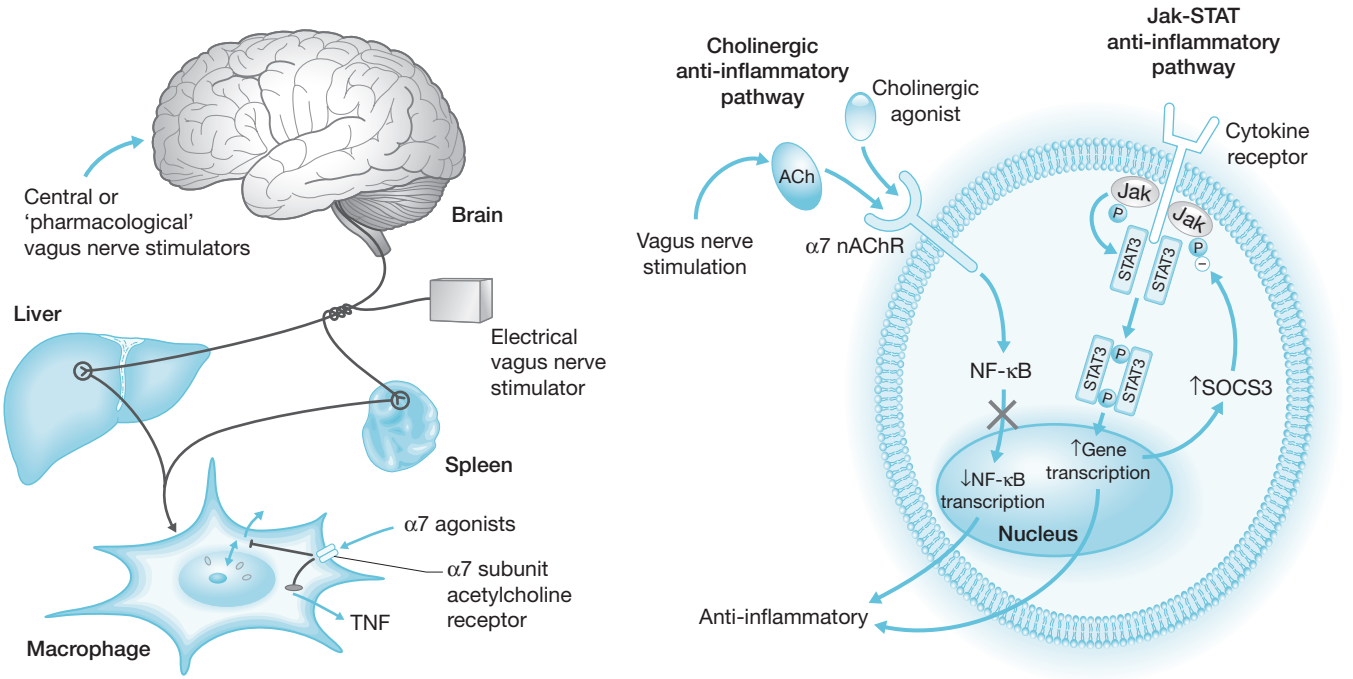

Fig. 19.8 The cholinergic anti-inflammatory pathway. Tissue inflammation sends afferent signals to the central nervous system, resulting in activation of the cholinergic anti-inflammatory pathway. Release of acetylcholine by the vagus nerve induces anti-inflammatory effects by binding to nicotinic receptors on the surface of leukocytes. (Adapted from Czura CJ and Tracey KJ. Automatic neural regulation of immunity. *J Int Med.* 2005;257:156–166; Metz CN, Tracey KJ. It takes nerve to dampen inflammation. *Nat Immunol.* 2005;6(8):756–757; Pavlov et al. *Crit Care Med.* 2007;35:1139.)

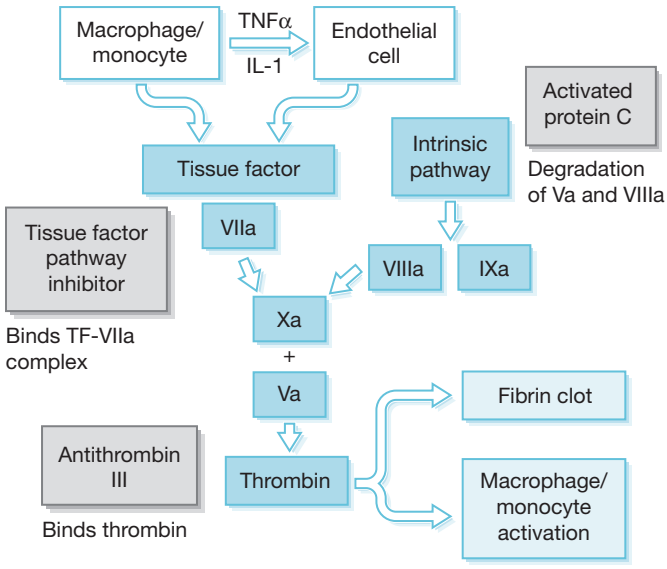

Fig. 19.9 Regulation of the coagulation cascade during inflammation. Inflammation primarily causes activation of the extrinsic coagulation pathway.

injury and infection. It is divided into two pathways that converge and ultimately cause the activation of thrombin, with subsequent cleavage of fibrinogen into fibrin (Fig. 19.9). The intrinsic pathway is a series of plasma proteins that are activated by Hageman factor (factor XII), a protein synthesized in the liver that is activated by binding to collagen, basement membrane, or activated platelets. Activated Hageman factor triggers a cascade of proteins to become activated, resulting in the formation of thrombin. The intrinsic pathway is most commonly activated by direct tissue trauma. In contrast, the extrinsic pathway is initiated by the production of tissue factor. Recent studies indicate that the extrinsic pathway is the primary coagulation pathway activated during infection and systemic inflammation, particularly during sepsis and SIRS.[89] Tissue factor is expressed on tissue surfaces that are not normally exposed to the vascular compartment, such as subcutaneous tissues and the adventitial layer of blood vessels. In addition, endothelial cells and activated monocytes produce tissue factor during periods of inflammation in response to TNF-α, IL-1, IL-6, and CRP.[90] The presence of tissue factor causes activation of factor VII, which then forms a complex with tissue factor and ultimately causes the formation of thrombin by the activation of a series of coagulation factors (Fig. 19.9). Activation of the coagulation cascade is not only important in the formation of fibrin clots but also has important effects on the pro-inflammatory response. Factor Xa, thrombin, and the tissue factor-VIIa complex have been shown to elicit pro-inflammatory activity. Specifically, thrombin and the tissue factor-VIIa complex can induce production of pro-inflammatory cytokines such as TNF-α by mononuclear and endothelial cells.[89] That effect appears to be mediated by the binding of these factors to protease-activated receptors on the surface of target cells. Therefore acute inflammation causes activation of the coagulation cascade, which can then further potentiate the inflammatory response.

Activation of the clotting cascade during inflammation is limited by several factors. This is important because it prevents uncontrolled induction of procoagulant mechanisms.

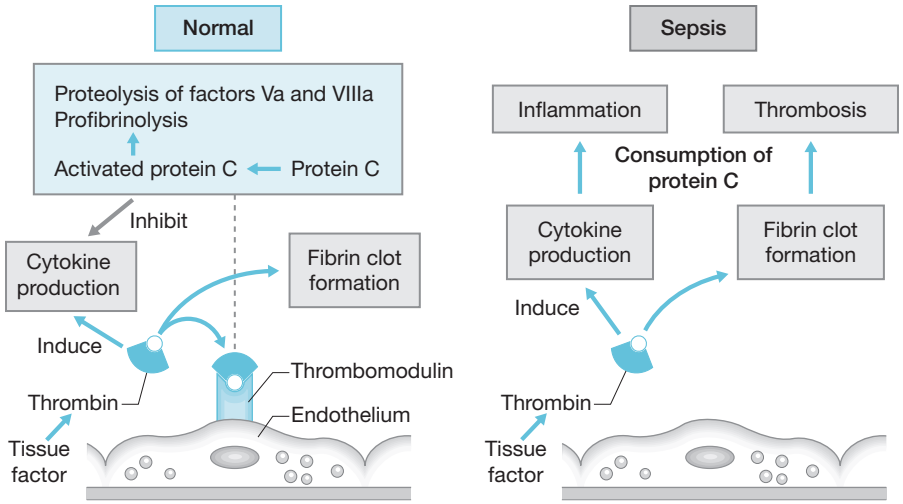

Fig. 19.10 Protein C is a circulating protein that is activated by the thrombin–thrombomodulin complex on the surface of endothelial cells. Activation of protein C decelerates the clotting cascade by inactivating factors Va and VIIIa. Activated protein C also inhibits thrombin-induced production of tumor necrosis factor-α (TNFα) by monocytes by inhibiting the activation of transcription factors nuclear factor-κB (NF-κB) and AP-1.

The best-defined factors are antithrombin, the protein C system, and the tissue factor pathway inhibitor. Antithrombin is produced in the liver and directly binds to and inactivates thrombin.[91] The binding of antithrombin to thrombin is greatly potentiated by heparin and by glycosaminoglycans present on the endothelial cell surface. In rodents interaction of antithrombin with the endothelial cell surface promotes the release of PGI_2, which inhibits TNF-α production by monocytes through the inhibition of transcription factor NF-κB activation.[92] Thus antithrombin may have anti-inflammatory properties in addition to its function in regulating coagulation.

Protein C is a circulating protein that is activated by the thrombin–thrombomodulin complex on the surface of endothelial cells (Fig. 19.10). Activation of protein C decelerates the clotting cascade by inactivating factors Va and VIIIa. Activated protein C (APC) also inhibits thrombin-induced production of TNF-α by monocytes by inhibiting the activation of transcription factors NF-κB and AP-1.[93] Therefore APC has both anticoagulant and anti-inflammatory properties. During sepsis, APC levels can become depleted due to consumption and inflammation-induced down-regulation of thrombomodulin. This results in unchecked formation of thrombin, causing accelerated coagulation and increased pro-inflammatory activity. The importance of protein C in regulating thrombin formation during sepsis is demonstrated by increased mortality in septic patients with low APC levels.[94] Those findings led to the investigation of APC as an intervention in patients with sepsis. Early trials showed that APC therapy was effective in improving survival in patients with severe sepsis.[95] However, further investigation did not demonstrate significant benefit.[96,97]

A third important factor in the regulation of thrombin formation is the tissue factor pathway inhibitor (TFPI). TFPI is present on the surface of endothelial cells and bound to lipoproteins in plasma. TFPI inactivates tissue factor by forming a quaternary complex with tissue factor and factor VIIa. Factor Xa is the fourth component of the complex.[98] Inhibition of tissue factor function inhibits activation of the extrinsic clotting pathway during inflammation. Infusion of TFPI has also been shown to reduce pro-inflammatory cytokine production during endotoxin infusion in baboons but not in humans.

THE HEMODYNAMIC RESPONSE

The full clinical picture of systemic inflammation after thermal injury is characterized by two primary phases. After the initial injury, inflammation leads to increased vascular permeability and the exudation of protein-rich fluid from the vascular compartment to the interstitium. This early fluid leak results in intravascular hypovolemia and interstitial edema formation. If the patient is adequately resuscitated, a hyperdynamic phase will ensue that is characterized by a low systemic vascular resistance and high cardiac output. Patients who are not well resuscitated or whose cardiac function is compromised may not be able to increase their cardiac output to the extent needed to maintain arterial blood pressure during states of extensive vasodilatation and so might exhibit tissue hypoperfusion and shock. A reduced vascular responsiveness to vasoconstrictors may inhibit successful pharmacologic intervention, and patients could develop irreversible shock. An intravenous bolus injection of 4 ng/kg endotoxin into healthy volunteers mimics some aspects of the hemodynamic response seen in septic patients and adequately resuscitated burn victims.[99,100] The low systemic vascular resistance and the elevated cardiac output can also be induced in animal models by continuous infusion of low-dose endotoxin[101] or bacteria.[102,103]

Changes in Endothelial Permeability

Burn injury, trauma, and sepsis increase microvascular permeability in both the systemic[104] and the pulmonary

circulations.[105] Increased vascular permeability and cutaneous edema are hallmarks of burn shock. The increase in systemic vascular permeability results in the exudation of protein-rich fluid from the vascular compartment into the interstitium. This results in intravascular volume loss and the concomitant development of interstitial edema. If resuscitation is not prompt and adequate, this loss in intravascular volume will lead to intravascular hypovolemia, hypotension, and inadequate tissue perfusion. Severe interstitial edema formation can lead to the development of compartment syndrome, with compromise of neurovascular integrity. The lungs may also be affected. Edema formation due to an increase in microvascular permeability is a hallmark of the acute lung injury. The factors that determine the transvascular fluid flux are summarized in the Starling-Landis equation:[106,107]

$$J_v = K_f[(P_{mv} - P_i) - \alpha(\pi_{mv} - \pi_i)]$$

where J_v is the transvascular fluid flux, K_f is the filtration coefficient (measure of the endothelial permeability to small solutes and water as well as of the permeability surface area), P_{mv} is the microvascular hydrostatic pressure, P_i is the interstitial hydrostatic pressure, α is the osmotic reflection coefficient to protein, π_{mv} is the microvascular oncotic pressure, and π_i is the interstitial oncotic pressure.

Several investigators have studied lymph flow and lymph protein flux after administration of bacteria or short-time infusion of 1–2 μg/kg of endotoxin in sheep. Two phases of permeability change could be distinguished in these models.[108] During phase 1 there was a high microvascular hydrostatic pressure, as defined by the Gaar equation.[109] This was associated with an increase in lung lymph flow, but the lymph protein concentration was low. It was concluded that the high microvascular hydrostatic pressure was responsible for the early increase in transvascular fluid flux. Thromboxane A2 (TXA2) has been found to be responsible for the vasoconstriction that causes local increases in hydrostatic pressure. Therefore it is not surprising that administration of the thromboxane synthetase inhibitor OKY046 prevented the rise in lymph flow during phase 1.[110] That effect was also noted after blockage of cyclooxygenase by ibuprofen.[111] Early edema formation at the site of burn injury might be due to a different mechanism. Data suggest that a marked fall in interstitial hydrostatic pressure might occur in the injured tissue, which could explain the immediate onset of edema formation after thermal injury.[112,113] These changes might be the result of an inhibition of the fibroblast β1-integrin attachment to collagen.

During phase 2, lymph flow continues to be high. However, the lymph protein concentration rises considerably and the pulmonary artery pressure is only mildly elevated.[108] The oncotic pressure gradient between microvasculature and interstitial space is reduced during that period.[114] Together these data suggest that the permeability of the pulmonary endothelium to protein increases in phase 2. In fact, the reflection coefficient for total protein fell from 0.73 to 0.58, with respective changes in the reflection coefficients for albumin (0.66 to 0.5), IgG (0.76 to 0.64), and IgM (0.91 to 0.83) after 4 hours of *Escherichia coli* sepsis in sheep.[115] Confirmation of this hypothesis is still pending in models of endotoxemia, but it has been generally accepted that the changes in pulmonary transvascular fluid flux in phase 2 represent changes in microvascular permeability. The mechanisms of the increased microvascular permeability are still under discussion.

Endothelial cells play an important role in the regulation of vascular permeability. It has been hypothesized that endothelial cells can contract upon stimulation.[116] As a result, the intercellular gaps might increase in number and/or size, establishing the so-called capillary leak syndrome. The development of the protein-rich high-permeability edema can be ameliorated if substances are administered that raise the endothelial cell content of cyclic adenosine or guanosine monophosphate.[117,118] However, endothelial cells do not merely serve as targets during systemic inflammation: they actively contribute to the ongoing inflammatory process. The endothelial cell can be stimulated by endotoxin, TNF-α, or IL-1 to express E-selectin, an adhesion molecule.[119] E-selectin on the surface of endothelial cells interacts with the corresponding L-selectin complex on polymorphonuclear neutrophils (PMNs) to facilitate rolling of these cells along the endothelium.[120] Moreover endothelial cells secrete the pro-inflammatory cytokines TNF-α and IL-1, which activate PMNs. Conflicting data exist regarding the role of PMNs in SIRS. PMNs are usually found at the site of tissue injury, to which they migrate following a concentration gradient of chemotactic stimuli. Upon stimulation, PMNs roll along endothelial cells, and, in a further step mediated by PMN CD18/CD11b interactions with endothelial ICAM-1, emigrate from the vessel into the interstitial space. Antibodies against the common CD18β chain showed beneficial effects in an animal model of sepsis-induced lung injury, suggesting that integrin-mediated PMN emigration is a functionally important process in the development of acute lung injury.[121] On the other hand, patients who are deficient in CD18 have abundant PMNs in their alveolar spaces, and the monoclonal antibody 60.3 was ineffective in completely blocking the migration of PMNs into the lung in a number of conditions.[122] We have found that in chronic endotoxemia there are few PMNs in the lung but numerous macrophages. Activated PMNs and macrophages release oxygen free radicals and proteases at sites of inflammation. Those processes appear to be functionally important in the development of vascular permeability because administration of oxygen free radical scavengers and antiproteases proved to be useful in diminishing edema accumulation after endotoxin challenge.[123] However, proteases and oxygen radicals are also released by macrophages, which are already present in the tissue, and by monocytes that migrate to sites of inflammation. Depletion of granulocytes by anti-PMN antiserum or by treatment with nitrogen mustard did not prevent the changes in microvascular permeability following the administration of endotoxin.[124,125] Moreover patients deficient in PMNs still develop acute respiratory distress syndrome (ARDS) associated with sepsis.[126,127] On the other hand, treatment of sheep or goats with hydroxyurea, which is another compound used to deplete granulocytes, was effective and diminished fluid accumulation in the lung after endotoxin challenge.[128] However, urea scavenges free radicals, which might explain its efficacy.[129] As the inflammatory response becomes chronic, many

mediators have been released and more than one mechanism may be responsible for capillary leak.

The role of arachidonic acid metabolites in facilitating increased vascular permeability has been extensively investigated. Administration of the thromboxane synthetase inhibitor OKY046 not only reduced transvascular fluid flux in phase 1, but was also effective in phase 2 after endotoxin challenge.[110] This finding suggests that thromboxanes participate in permeability alterations during systemic inflammation. Oxygen free radicals can also increase microvascular permeability, both by activation of endothelial cell contraction and by damaging the endothelial cell membrane. OKY046 has been shown to reverse oxygen free radical-induced lung injury.[130,131] On the other hand, inhibition of cyclooxygenase did not affect transvascular fluid flux during phase 2, even though thromboxane A2 is a cyclooxygenase metabolite.[111] This discrepancy is still unexplained; however, prostacyclin is elevated after endotoxin administration, and this material has many actions that counter the actions of thromboxane. Administration of a cyclooxygenase inhibitor will prevent the release of this salutary eicosanoid.

TNF-α is one of the early mediators in systemic inflammation. It has been reported to be elevated during sepsis and endotoxemia after hemorrhagic shock or thermal injury. It is considered to be one of the most important mediators in the cascade because it has the potential to stimulate or enhance most of the steps in the inflammatory response. Moreover administration of human recombinant TNF-α in the chronic sheep model reproduced most of the effects of endotoxemia, including alterations in pulmonary microvascular permeability.[132,133] TNF-α also induces the secretion of PAF, which is a further early mediator of systemic inflammation. PAF causes an increase in lung lymph flow and permeability to protein when it is infused into conscious sheep.[134] Administration of a PAF antagonist abolished the cardiopulmonary response that occurs during phase 1 and attenuated it during phase 2. However, PAF had no direct effect on endothelial cells. This suggests that it probably increases microvascular permeability through other mechanisms, such as its priming effect on PMNs.[135,136]

If burn patients are adequately resuscitated, they most commonly enter into a phase characterized by hyperdynamic cardiovascular function. The hyperdynamic cardiovascular response is associated with profound changes in pulmonary transvascular fluid flux in the ovine model of continuous endotoxemia.[104,137] The lymph protein concentration gradually decreased after phase 2, and after 24 hours of endotoxemia, the reflection coefficient to protein was at baseline level, whereas the lymph flow was still high. Microvascular hydrostatic pressure, evaluated by Holloway's technique, was not significantly different from baseline.[138] The elevated transvascular fluid flux was attributed to a high filtration coefficient. An increase in both perfused surface area and pore numbers might have contributed to the change in filtration. Repeated injections of endotoxin also reduced subsequent lung lymph production in response to endotoxin.[132] These changes in lung lymph flow were associated with elevations in endothelin and atrial natriuretic peptide.[138,139] However, further studies must determine whether these factors affect pulmonary microvascular changes during the late phases of sepsis and multiple organ failure.

INCREASED EPITHELIAL PERMEABILITY

Permeability changes during systemic inflammation are not restricted to the endothelium. Loss of epithelial barrier function has been noted both in the lung and in the intestine. Administration of 2–4 ng/kg endotoxin to healthy human volunteers increased their alveolar epithelial permeability to the inhaled 492 Da molecule [^{99m}Tc] diethylenetriamine pentaacetate (DTPA) 3 hours after endotoxin had been given.[100] Human volunteers demonstrated a higher intestinal epithelial permeability to mannitol/lactulose.[140] Bacterial translocation occurred during endotoxemia,[141] thermal injury,[142] and multiple trauma with hemorrhagic shock.[143] This might well be interpreted as a loss of intestinal barrier function. Nevertheless one must bear in mind that epithelial permeability to molecules such as lactulose/mannitol and bacterial translocation do not necessarily relate to each other. The epithelium could also be injured by ischemia–reperfusion.[144] In addition to changes in vascular permeability, burn injury also causes marked alterations in vascular tone and myocardial function that are characterized by a variety of temporal alterations.

The Hyperdynamic State

Continuous infusion of endotoxin into sheep and pigs results in a hyperdynamic circulation.[145,146] In addition to a low systemic vascular resistance and a high cardiac output with a slightly decreased mean arterial pressure, the hyperdynamic response is further characterized by hyporesponsiveness of isolated vessels to vasoconstrictors and an increased pulmonary shunt fraction in the presence of a reduced pulmonary hypoxic vasoconstriction.[145,147–149] The high cardiac output is due to low systemic vascular resistance and increased heart rate.[150,151] Paradoxically myocardial function is depressed during sepsis and in severely burned patients.[152,153] The underlying cause of impaired myocardial function is not fully understood. However, reports indicate that pro-inflammatory mediators such as TNF-α, IL-1, IL-6, and nitric oxide (NO) contribute to this alteration.[153,154] The treatment of myocardial function during sepsis and after burn trauma is an important consideration in overall hemodynamic management. The combination of myocardial dysfunction and increased pulmonary vascular resistance is a likely cause of right heart failure in pediatric burn patients. Treatment options include dobutamine and phosphodiesterase inhibitors such as milrinone. The Surviving Sepsis Campaign recommends dobutamine as a first-line agent for treatment of hypotension and hypoperfusion in pediatric patients with sepsis, especially when myocardial dysfunction is present.[81]

NO has been implicated as a mediator of systemic vasodilation and myocardial depression during sepsis and after major burn injury. NO can be synthesized from its precursor L-arginine by three different enzymes (Fig. 19.11). The calcium-dependent constitutive nitric oxide synthases (NOS) such as endothelial NOS (eNOS) and neuronal NOS (nNOS) are responsible for the basal release of NO, which seems to play an important role in the regulation of vascular tone under physiologic conditions. In vitro data suggest that these enzymes might become inactivated early after

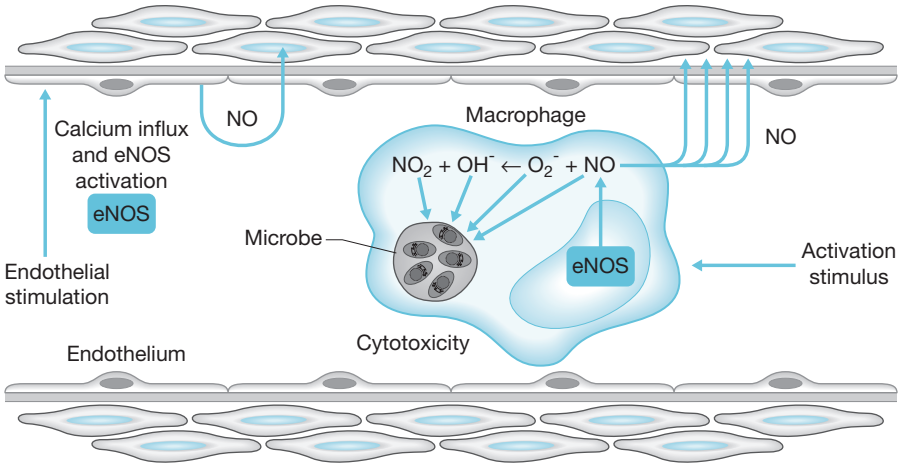

Fig. 19.11 Nitric oxide is an important mediator of inflammation-induced vasodilation, myocardial depression, and organ injury. The synthesis of nitric oxide is mediated by three major nitric oxide synthase (NOS) isoforms.

administration of endotoxin, thereby accounting for some of the vasoconstrictive phenomena seen in phases 1 and 2.[155] Inducible NOS (iNOS) is the major NOS isoform induced during acute inflammation. Depending on the species, cells producing the inducible NOS upon stimulation by endotoxin, TNF-α, IL-1, or IFN-α include macrophages, vascular smooth muscle cells, and vascular endothelium.[156] NO is a lipophilic gas that can easily enter vascular smooth muscle cells where it stimulates the soluble guanylate cyclase to synthesize cyclic guanosine monophosphate (cGMP).[157,158] High levels of cGMP stimulate cells to lower their intracellular Ca^{2+} concentration. This leads to vascular dilatation and hyporesponsiveness to vasoconstrictors. Administration of an NOS inhibitor to septic humans and to endotoxemic sheep increases their vascular resistance and restores their responsiveness to vasoconstrictors.[159–161] Overall it appears that NO is an important mediator of SIRS-induced vascular alterations. However, administration of NOS inhibitors in humans has not improved overall outcome during sepsis or SIRS. Therefore, the mechanisms by which NO alters vascular function during SIRS in humans require further investigation.

Peroxynitrite is an additional NO-associated factor that appears to contribute to SIRS-induced pathology. Peroxynitrite is a free radical that is generated through interactions of NO and oxygen free radicals during periods of severe inflammation and is known to cause cellular injury and organ dysfunction in experimental burn models.[162,163] Treatment of burned sheep with a peroxynitrite degradation catalyst has been shown to reduce lung injury in an ovine model of burn and smoke inhalation injuries.[164] Therefore peroxynitrite appears to be an important mediator of organ injury during periods of systemic inflammation. However, further research is needed to determine the efficacy of treatment approaches aimed at promoting peroxynitrite degradation and neutralization in the clinical setting.

Conclusion

Burn injuries, associated ischemia–reperfusion injury, the presence of necrotic tissue, and sepsis are all events that contribute to SIRS after severe burn injury. Widespread increases in microvascular permeability lead to intravascular hypovolemia and interstitial edema, thereby impairing oxygen diffusion to the tissue. Blood flow may become maldistributed owing to a loss of vasoregulatory function and as a result of widespread microthrombosis. Oxygen utilization also appears to be impaired. The resultant hypoxic cell damage further promotes organ dysfunction. Oxygen free radicals, peroxynitrite, and cytokines also appear to contribute to tissue damage and organ dysfunction. Despite improved understanding of the cellular and molecular mechanisms underlying SIRS, targeting the inflammatory response is not currently an effective treatment option for patients with burn-induced SIRS. Treatment is supportive and includes adequate fluid resuscitation, appropriate use of vasoactive drugs, support of failing organ systems, excision of necrotic tissue, and treatment of infection with antibiotics.

20 Host Defense Antibacterial Effector Cells Influenced by Massive Burns

MAKIKO KOBAYASHI, TRACY TOLIVER-KINSKY, and FUJIO SUZUKI

Introduction

Infectious complications are one of the leading causes of death in patients with severe burn injuries.[1–5] Increases in the total body surface area and depth of burn injuries correlate with the excessive risk of infectious complications.[6] Burn patients are commonly treated with many components such as fluid resuscitation, wound excision, grafting and coverage, infection control, and nutritional support. Progress in each treatment has contributed significantly to reduce mortality in severely burned patients. However mortality rates associated with infectious complications still remain high, and bacterial infections are a major cause of morbidity in burned patients.[7–9]

Infections in severely burned patients frequently occur as opportunistic infections. In these patients, a majority of the causative infectious pathogens come from their own microbiota distributed in and on the skin, respiratory tract, and intestines.[5] For example, staphylococci are found in 40% of wound isolates, and 14%–17% of burned patients become infected once they are colonized.[10–12] Although antibiotics are useful to control infections, excessive antibiotic usage is directly related to the development of methicillin-resistant *Staphylococcus aureus* (MRSA).[13] Vancomycin is utilized clinically to treat MRSA; however, the management of invasive MRSA infection will become a serious problem if VISA/GISA strains spread widely.[14–16] Currently, newer antibiotics such as linezolid (oxazolidinones) and quinupristin/dalfopristin (macrolides) are available to treat MRSA infection.[17] In general, however, these agents are of limited usefulness because of their propensity to create antibiotic-resistant bacteria.[13] These facts strongly indicate that a new strategy, apart from antibiotic therapy, is required to treat infections.[18,19]

Sepsis stemming from wound infections is usually found in patients with severe thermal injuries. Topical antibacterials (silver sulfadiazine, silver nitrate, mafenide acetate, etc.) are very useful for controlling the colonization and multiplication of microorganisms on the surface of burn wounds. However, due to the burn-induced defects of the host's antibacterial defenses, very small amounts of *Pseudomonas aeruginosa* that escape from this treatment are enough to spread throughout the whole body.[20] In fact, only 50 colony-forming units (CFU) of *P. aeruginosa* applied to burn wounds are sufficient to kill severely burned mice, whereas more than 1×10^8 CFU applied intradermally are required to kill noninjured mice. Similarly, burn-associated defects in host antibacterial defenses have been demonstrated against enteric bacteria in severely burned mice (Fig. 20.1). In addition, polymicrobial sepsis frequently occurs in severely burned patients. Because such infections do not usually develop in healthy individuals, immune dysfunctions associated with burn injuries are a major reason for the increased susceptibility of severely burned patients to these infections.

The innate immune system is the first line of host defense against microbial invasion.[21] The cells and molecules of innate immunity are rapidly activated by microbes or some signals induced by damaged tissues.[22–25] The innate immune system consists of (1) soluble recognition molecules, (2) physical barriers, and (3) cellular components (myeloid cells and lymphoid cells). Soluble recognition molecules include natural antibodies (IgM and IgA), acute phase proteins, and the complement system. In heathy individuals, natural IgM is constitutively produced. However, reduced levels of antibodies are evident in severely burned patients.[26] Burn-associated hypermetabolic responses stimulate the synthesis of acute phase proteins located in the liver and intestinal mucosa.[27–29] Burn injury to tissues leads to complement activation with subsequent depletion of complement components, mainly C3, C4, and C5.[30–32] As physical barriers, epithelial cells produce antimicrobial peptides (β-defensins and LL-37/hCAP-18), which are small molecular weight proteins with broad-spectrum antimicrobial activity.[33,34] After injury or infection, epithelial cells produce alarmins such as thymic stromal lymphopoietin (TSLP), interleukin (IL)-25 and IL-33. This causes the initiation of type 2 immune responses.[35–37] Although β-defensins are normally produced by epidermal keratinocytes,[33] mRNA expression of these peptides is greatly decreased in the tissue around the burn wound when compared with normal skin in thermally injured patients.[38,39] Decreased local production of antimicrobial peptides around burn wounds allows the local growth of bacteria, putting the patient at risk for wound-derived systemic infections. Studies in animal models of burn injury suggest that decreased antimicrobial peptide production by epidermal keratinocytes around burn wounds is due to the infiltration of suppressive myeloid and lymphoid cells that appear in response to burn injuries.

It is well established that burn injury initiates an early proinflammatory innate immune response followed by an adaptive counter-inflammatory response.[40–42] The innate immune system is activated in response to either pathogen-associated or damage-associated molecular patterns.[22–25] Both patterns are recognized by pattern recognition

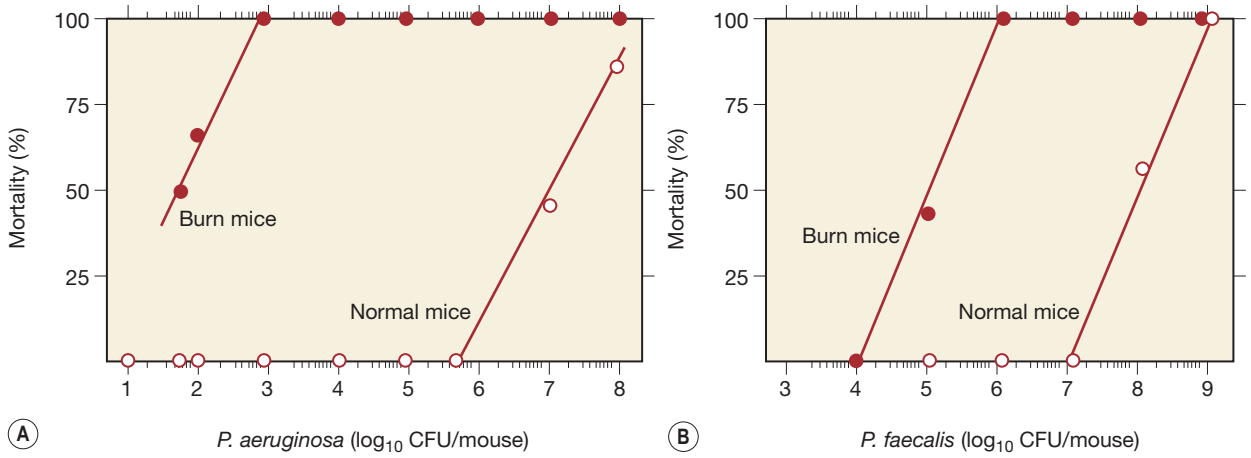

Fig. 20.1 Susceptibility of burn mice to *Pseudomonas aeruginosa* and *Enterococcus faecalis* infections. Severely burned mice are 10^4-times or more susceptible to *P. aeruginosa* (**A**) or *E. faecalis* (**B**) infection when compared to normal mice.

receptors (PRRs) on innate immune cells. Depending on the molecular patterns recognized, pro- or antiinflammatory soluble factors are rapidly released from these cells. Thus the development of burn-associated immunosuppression is initiated early after burn injury. Antiinflammatory responses are helpful for wound healing[43–45] and the resolution of liver and intestinal inflammation[21,46,47] in burn patients. However, dysregulated immunosuppression and persistent inflammation cause immunoparalysis,[48] and patients with immunoparalysis become extremely susceptible to infections.[49] This chapter will discuss cell populations and their functions involved in innate immunity as influenced by severe burn injuries.

Neutrophils

Neutrophils are the most abundant white blood cells in the innate immune system. They are rapidly recruited to the injury or infection site, where they phagocytose and kill invading microorganisms.[50] The maturation of neutrophils is under the control of transcription factors PU.1 and C/EBP.[51] During maturation, the neutrophil goes through several stages, namely myeloblast, promyelocyte, myelocyte, metamyelocyte, band cell, and, finally, polymorphonuclear (segmented) cell.[52] In the absence of infection or inflammation, mature neutrophils die within 15 hours by caspase 3-mediated spontaneous apoptosis.[53,54] Inflammatory signals are capable of prolonging the life span of neutrophils by several days.[53] However, even during inflammation, mature neutrophils die by apoptosis or NETosis (death during formation of neutrophil extracellular traps [NETs] for extracellular killing) while performing their antimicrobial function.[55,56] These dead neutrophils are engulfed by macrophages.[57]

IMPAIRED NEUTROPHIL RECRUITMENT

Mature neutrophils leave the bone marrow and enter to the circulation.[58] Getting neutrophils to the site of infection is of prime importance, and an elaborate series of adhesion events between neutrophils and the endothelium ensures that neutrophils leave the bloodstream only at the inflammatory site.[59] This process includes tethering (capturing), rolling, adhesion, crawling, and transmigration. IL-8 production by activated neutrophils plays a central role in the recruitment of additional neutrophils to the infection site.[60] After severe burn injuries, levels of IL-8 in plasma are approximately 60 times higher than those in plasma of healthy controls.[61] An increase in peripheral blood neutrophils is seen in patients 2–5 days after burn injury. However, the chemotactic function and efficient migration of neutrophils are impaired in severely burned patients due to the decreased expression of CXCR2 (a receptor for IL-8).[62] Migration speed of neutrophils toward the chemoattractant source is also impaired in severely burned patients.[63] Such impairment of neutrophils starts as early as 24 hours after burn injury, reaches a maximum at 3 to 5 days after burn injury, and correlates to the size of the burn injury.

IMPAIRED NEUTROPHIL KILLING

Neutrophils are efficient phagocytes that engulf microbes into phagosomes. The phagosome fuses with granules to produce a phagolysosome, in which microbes are exposed to many destructive enzymes, antimicrobial peptides, and reactive oxygen species.[55] These components synergize and effectively kill microbes. Highly activated neutrophils kill extracellular microbes by releasing NETs, which consist of fibrils formed by active expulsion of DNA, chromatin, antimicrobial protein, and enzymes.[64] The sticky DNA fibers of the NETs bind and immobilize pathogens and thus inhibit their further spread. NETs kill pathogens directly by means of antimicrobial histones and proteases. IL-8 is well-known to enhance NET formations of neutrophils.[56,64] As described earlier, increased levels of IL-8 in the circulation of severely burned patients have been demonstrated.[61] Increased levels of KC and MIP-2 have also been demonstrated in the sera and lungs of mice 2–8 hours after burn injury.[65,66] KC and MIP-2 are functionally homologous to human IL-8. However, phagocytosis, oxidative metabolism, granular enzyme contents, and intracellular killing of neutrophils are greatly reduced in severely burned patients compared with those of neutrophils from healthy individuals.[67] The

attenuating CXCR2 expression on neutrophils is,[62] at least in part, responsible for neutrophil dysfunction following burn injury.

PRO- AND ANTIINFLAMMATORY NEUTROPHILS

Experimental studies in rodents have identified distinctive types of neutrophils that affect resistance to MRSA infections in burned mice (Fig. 20.2).[68] Neutrophils isolated from slightly burned (5% TBSA burn, MRSA-resistant hosts) or severely burned mice (25% TBSA burn, MRSA-susceptible hosts) are biologically and histologically different from the neutrophils isolated from naïve mice. These three neutrophil populations have unique cytokine/chemokine-producing patterns. Also, these three neutrophils express Toll-like receptors (TLRs) and surface CD49d/CD11b integrins differently. Neutrophils isolated from MRSA-resistant mice are proinflammatory IL-12^{+} CCL3^{+}

Properties	PMN-N	PMN 1	PMN 2
CCL2	trace	trace	17.1 ng/ml
CCL3	trace	11.6 ng/ml	trace
IL-12	trace	0.5 ng/ml	trace
IL-10	trace	trace	1.3 ng/ml

C

Fig. 20.2 Properties of PMN-N, PMN 1, and PMN 2. Peripheral blood neutrophils (PMNs), isolated from slightly burned mice (5% TBSA burn, PMN 1) or severely burned mice (25% TBSA burn, PMN 2), were biologically and histologically different from naive mouse neutrophils (PMN-N). (Modified from Tsuda Y, Takahashi H, Kobayashi M, et al. Three different neutrophil subsets exhibited in mice with different susceptibilities to infection by methicillin-resistant *Staphylococcus aureus*. *Immunity*. 2004;21:215–226.)

cells (PMN 1 or N1), whereas neutrophils from MRSA-susceptible mice are an antiinflammatory IL-10$^+$ CCL2$^+$ cells (PMN 2 or N2). Neutrophils isolated from naïve mice are IL-12$^-$ and IL-10$^-$ cells. These neutrophils also differ in their promotion of macrophage differentiation. Quiescent macrophages from the lamina propria of normal mice convert to the M1 phenotype after cultivation with polymorphonuclear leukocyte (PMN) 1 in dual-chamber transwells supplemented with a mixture of TLR3/TLR9 agonists. In contrast, quiescent macrophages convert to the M2 phenotype after cultivation with PMN 2 in the same transwells. Neither M1 nor M2 macrophages appear even when quiescent macrophages are transwell-cultured with naïve PMN. Also, PMN 2 are shown to be inhibitory for macrophage conversion to the M1 phenotype under stimulation with TLR3/TLR9 agonists. Subsequently, IL-10 and CCL2 produced by PMN 2 are identified as inhibitors of TLR3/TLR9-induced macrophage polarization toward the M1 phenotype. Another distinguishing feature is their morphology. Although IL-12$^-$and IL-10$^-$ neutrophils have a round nucleus, PMN 1 has a multilobular nucleus (indicative of mature neutrophils), and the nucleus of PMN 2 is ring-shaped. PMN 2 is predominantly demonstrated in severely burned mice.[68]

Furthermore the role of PMN 1 and PMN 2 on host anti-MRSA resistance has been examined in γ-irradiated NSG mice (lacking the functional immunocompetent cells) reconstituted with normal mouse macrophages (Mϕ-reconstituted γNSG mice).[68] Mϕ-reconstituted γNSG mice become more resistant after inoculation with PMN 1, whereas the same mice become susceptible after inoculation with PMN 2. Additionally, γNSG mice are shown to be resistant against MRSA infection when they are inoculated with normal mouse macrophages previously cultured with PMN 1. Macrophages previously cultured with PMN 2 do not protect Mϕ-reconstituted γNSG mice infected with a lethal dose of MRSA. Similar results are obtained when Mϕ-reconstituted γNSG mice are orally infected with a lethal dose of *Enterococcus faecalis*.[69] These results indicate that MRSA infection and *E. faecalis* translocation are not controlled in hosts predominantly bearing PMN 2. IL-10 and CCL2 released from PMN 2 are characterized as active cytokines that induce M2 macrophages from quiescent macrophages.[68,70,71] Therefore these cytokines are targets for the macrophage polarization influenced by PMN 2. Infectious complications due to MRSA infection and enteric bacterial translocation have been successfully controlled in severely burned mice depleted of CCL2 or IL-10 by their antisense oligodeoxynucleotide (ODN).[72,73] Thus antiinflammatory neutrophils appearing in hosts after severe burn injury suppress effective immune responses and increase susceptibility to infections.

ROLE OF DAMAGE-ASSOCIATED MOLECULAR PATTERNS IN INDUCING ANTIINFLAMMATORY NEUTROPHILS POSTBURN INJURY

In microbial infection, pathogen-associated molecular patterns (PAMPs) present in diverse organisms but, when absent in the host, provide exogenous signals that alert the immune system to the presence of pathogens, thereby promoting immunity.[74] For instance, bacterial lipopolysaccharide (LPS) is a PAMP and is recognized by TLR4 on the immune cell surface. Bacterial DNA that contains unmethylated CpG motifs is also a PAMP and is recognized by TLR9, which is located in the endosomal compartment of neutrophils. Both TLR4 and TLR9 are PRRs. In contrast, a variety of stressed, injured, or dying cells (including epithelial cells following burn injury) release damage-associated molecular patterns (DAMPs) as the endogenous danger signals that alert the innate immune system to unscheduled cell death and microbial invasion and in response to stress (Fig. 20.3).[22–25] HMGB1, hyaluronic acid, formyl peptides, heat-shock protein 70, S100A8, S100A9, and serum amyloid A are well-known DAMPs. These DAMPs are specifically recognized by several receptors (Table 20.1).[75] These ligand-specific interactions are able to induce either pro- or antiinflammatory effects. In severely burned patients, circulating mitochondrial DAMP levels are notably elevated (>10-fold) within 72 hours of burn injury. These mitochondrial DAMPs cause systemic inflammation, which is commonly characterized by fever, leukocytosis, increased

Table 20.1 Receptors of Pathogen-Associated Molecular Patterns (PAMPs) and Damage-Associated Molecular Patterns (DAMPs)

Receptor	PAMPs	DAMPs
TLR1/TLR2	Lipopeptide	Serum amyloid A
TLR4	LPS	Fatty acid
		Hyaluronic acid
		S100A8/A9
NLRP3	Uric acid	Uric acid
		ATP

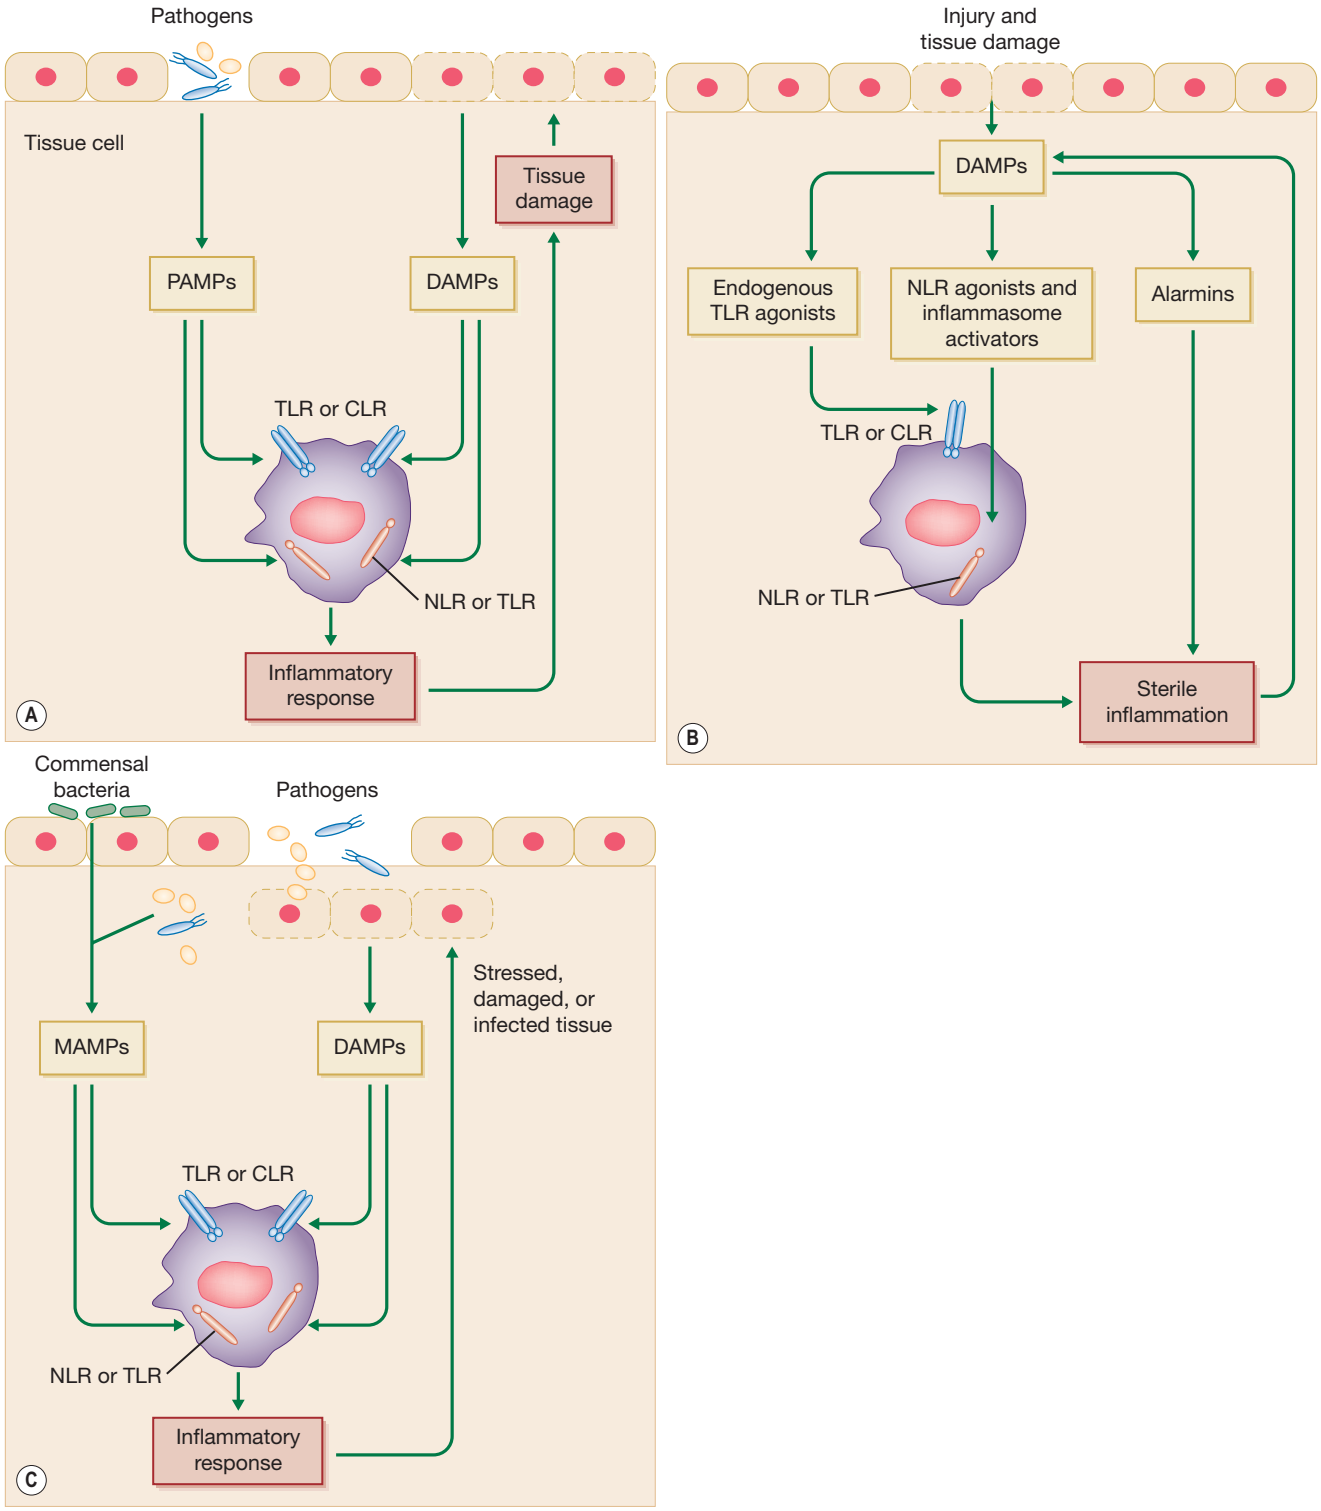

Fig. 20.3 Pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs). (**A**) PAMPs (including TLR, NLR, and CLR ligands) mediate the induction of proinflammatory cytokines in response to infection. (**B**) DAMPs or alarmins released from dead or dying cells mediate the induction of proinflammatory cytokine production from tissues in response to injury or stress. (**C**) In combination with DAMPs released from pathogen-infected or damaged host cells, microorganism-associated molecular patterns (MAMPs) mediate the induction of proinflammatory cytokines in response to pathogens. *ATP,* Adenosine 5′-triphosphate; *CLR,* C-type lectin receptor; *NLR,* NOD-like receptor; *TLR,* Toll-like receptor. (Modified from Mills KH. TLR-dependent T cell activation in autoimmunity. *Nat Rev Immunol.* 2011;11:807–822.)

secretion of adrenocorticotropic hormone and glucocorticoids, and alterations in plasma protein concentrations.[76–78] Simultaneously, these DAMPs cause desensitization of chemokine receptors and formyl-peptide receptors on neutrophils. Neutrophils influenced by DAMPs lose their antimicrobial functions. Also, Clec12a (binding to uric acid crystals) mediates the antiinflammatory response of neutrophils influenced by DAMPs.[79] Antiinflammatory neutrophils secrete high amounts of IL-10 and CCL2,[68,69] potent antiinflammatory cytokines, and have been implicated in impaired host antibacterial immunity in severely burned patients.[80]

SUPPRESSING ADAPTIVE IMMUNITY

Neutrophils have long been recognized as professional killer cells. They also participate in adaptive immunity. PMN 1 stimulates naïve T cells to polarize to T helper (Th1) cells through the production of interferon (IFN)-γ and IL-12, whereas PMN 2 promotes Th2 responses through the production of CCL2 and IL-10.[68] Because PMN 2 (but not PMN 1) appears in severely burned patients[80] and Th2 responses develop in these patients,[81–83] the blockage of PMN 2 is a potential effective strategy to control Th2 responses in severely burned patients.

Macrophages

Macrophages play a pivotal role in recognizing and eliminating various microbes. Macrophages, together with dendritic cells (DCs), function as antigen-presenting cells. Together with natural killer (NK) cells and lymphocytes, macrophages eliminate microbes. Macrophages are characterized by plasticity and flexibility.[84–86] Depending on the environmental stimuli, macrophages have a wide array of functions, especially in the modulation of innate immune responses through the release of several factors. Macrophages have been primarily classified into two major phenotypes: M1 and M2.[87–89]

TISSUE MACROPHAGES AND INFILTRATING MONOCYTE-DERIVED MACROPHAGES

In various tissues, macrophages acquire long-term, respective populations (e.g., peritoneal macrophages in the peritoneal cavity, Kupffer cells in the liver, alveolar macrophages in the lungs, microglia in the brain, etc.). Kupffer cells, microglia, and cardiac tissue macrophages are primarily yolk sac-derived cells.[90] Recent growing evidence clearly shows that yolk sac-derived tissue macrophages are self-maintained throughout adulthood.[91–93] The development and maintenance of tissue macrophages require specific growth factors and are regulated by tissue-selective transcriptional factors.[94] For example, macrophage colony-stimulating factor (M-CSF) is essential for Kupffer cells;[95] transforming growth factor (TGF)-β1 and IL-34 are essential for microglia and Langerhans cells;[96,97] and granulocyte macrophage colony-stimulating factor (GM-CSF) is essential for alveolar macrophages.[98] The transcription factor GATA6 is responsible for the transcriptome profile of resident peritoneal macrophages as well as for their proliferation under homeostatic conditions and in response to inflammation.[99,100] Peripheral blood monocytes are classified into three different populations. In humans, these populations correspond to $CD14^{++}CD16^{-}$ (classical monocytes), $CD14^{+}CD16^{+}$ (intermediate monocytes), and $CD14^{+}CD16^{++}$ (nonclassical monocytes); and in mice the equivalent populations are $Ly6C^{+}CD62L^{+}CD43^{-}CCR2^{+}$ (classical monocytes), $Ly6C^{int}CD62L^{-}CD43^{+}CCR2^{-}$ (intermediate monocytes), and $Ly6C^{-}CD62L^{-}CD43^{+}CCR2^{-}$ (nonclassical monocytes).[101] Classical monocytes can transport antigens to lymph nodes with minimal differentiation changes from their state in blood, although a proportion can convert to nonclassical monocytes. However, in the context of inflammation, recruited monocytes differentiate to macrophages. These monocyte-derived macrophages are distinct from resident macrophages.[102] Severe burn injuries induce inflammation in various organs including liver, intestine, and lung due to burn-induced hypermetabolic responses.[103] In these tissues, yolk sac-derived tissue macrophages coexist with monocyte-derived macrophages. Studies to determine the functional differences of these macrophage subsets in the organs of severely burned hosts are needed to develop therapeutic approaches for proper resolution of inflammation.

M1 MACROPHAGES AS AN ANTIBACTERIAL EFFECTOR CELL

In steady-state conditions, macrophages are immunologically quiescent. In the event of infection, quiescent macrophages are activated through the engagement of TLRs or the binding of IFN receptors.[104] IFN-γ induces downstream phosphorylation of Signal transducer and activator of transcription 1 (STAT1). In particular, LPS activates TLR4, which affects mitogen-activated protein kinases (MAPK), interferon regulatory factors (IRF), and nuclear factor kappa B (NF-κB) pathways. Thus, the activation of transcription factors NF-κB, activator protein 1 (AP-1), CCAAT/enhancer-binding protein α (C/EBPα), Krüppel-like factor 6 (KLF6), IRF5, and STAT1 promote macrophage polarization toward the M1 phenotype.[85,104,105] M1 macrophages exhibit (1) high oxygen consumption, (2) the ability to kill cells infected with intracellular pathogens, (3) the ability to express inducible nitric oxide synthase (iNOS), and (4) the ability to secrete nitric oxide, some proinflammatory cytokines, Th1 response-associated cytokines, and various chemokines.[87–89] Thus the dissemination of bacteria following local infection is prevented by M1 macrophages. M1 macrophages have been demonstrated in bacterial translocation site tissues such as lamina propria (LP) and mesenteric lymph nodes (MLNs)[106,107] and are the major effector cells in host antibacterial resistance against enterococcal translocation.

M2 MACROPHAGES AS INHIBITORS FOR MACROPHAGE POLARIZATION FROM QUIESCENCE TO THE M1 PHENOTYPE

Even though M1 macrophages play a role in host antibacterial responses, sustained inflammation can be very detrimental to the host. For controlling inflammation-associated damage, a large number of M2 macrophages

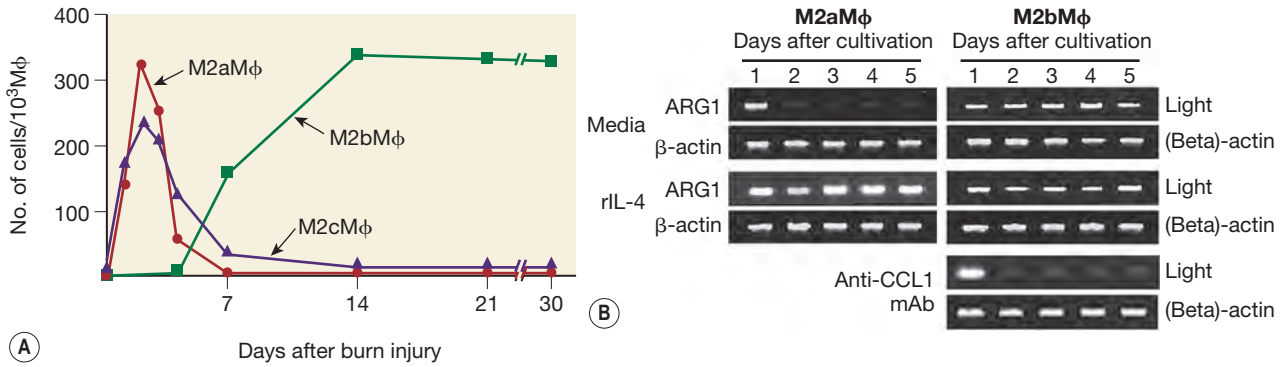

Fig. 20.4 M2a, M2b, and M2c macrophages in severely burned mice. **(A)** M2b macrophages were detected in the mesenteric lymph nodes (MLNs) of mice 1–3 weeks after burn injury. M2a macrophages lost their properties within 2 days of cultivation in IL-4-depleted media, whereas M2b macrophages lived longer once they appeared (**B**).

are generated.[108] M2 macrophages suppress the development of protective type 1 immune responses to pathogens[84] and thereby facilitate uncontrolled or persistent infections. IL-4 and IL-13, produced by a wide variety of cells (e.g., PMN 2, group 2 innate lymphoid cells, NKT cells, Th2 cells, etc.),[68,109] are typical cytokines to induce M2 macrophages. CCL2, produced by PMN 2, also stimulates M2 macrophage generation.[70–72] The macrophage polarization to the M2 phenotype is mediated via the activation of transcription factors, such as STAT3/6, KLF4, IRF4, PPARγ, and C/EBPβ.[85,104] Although the activation of NF-κB, STAT1, and MAPK signaling pathways is required for the macrophage polarization to the M1 phenotype, IL-10 inhibits these transcription factors and promotes STAT3 activation.[110,111] Therefore M1 macrophages are not generated from quiescent macrophages when M2 macrophages are present.

M2 macrophages are composed of three different subtypes: M2a (which expresses CD163, CD206, FIZZ1/Retna, Ym1/Chu3l3, and ARG1 and produces IL-10 and CCL17), M2b (which expresses CD163 and LIGHT, and produces IL-10, CCL1, TNF-α, IL-1, and IL-6), and M2c (which expresses CD163, CD206, ARG1, and FIZZ1, and produces IL-10, TGF-β, and CXCL13).[112] IL-4 and IL-13 are inducers for M2a macrophages. IL-10 and TGF-β in combination with cortisol (which increases 10- to 50-fold in the plasma of severely burned hosts within 24 h of burn injury)[113] are inducers for M2c macrophages. Although M2b macrophages are generally known to be induced by immune complexes and TLR or IL-1 receptor agonists,[112] the mechanism involved in the appearance of M2b macrophages after burn injuries remains unclear. Although all three M2 macrophages appear in severely burned hosts, the kinetics of the appearance of each M2 subtype are different. In LP and MLNs, M2a and M2c macrophages appear 1–4 days after burn injury in mice, and M2b macrophages appear 1–4 weeks after burn injury (Fig. 20.4A).[71,114] In humans, M2b monocytes are predominantly distributed in the circulation of patients 7–10 days after burn injury and persist for 1–2 months. M2a and M2c monocytes are present minimally in the circulation of patients after burn injury.[80] Experimental studies have shown that elimination of M2b macrophages from severely burned mice improves resistance against opportunistic infections.[114–116] Thus M2b macrophages may be an effective therapeutic target for controlling opportunistic infections in severely burned patients.

PLASTICITY OF VARIOUS PHENOTYPES OF MACROPHAGES

Macrophages easily switch from one functional phenotype to another in response to new microenvironmental signals.[84–86] Shortly after severe burn injury, quiescent macrophages switch to the M1 phenotype in response to invading pathogens. Subsequently, certain microRNAs (miRNAs) are produced in M1 macrophages through this stimulation or after efferocytosis of apoptotic phagocytic cells, which skews these macrophages toward the M2 phenotype.[117–119] miRNAs are short noncoding RNAs of approximately 21–23 nucleotides that function in RNA silencing and post-transcriptional regulation of gene expression.[120] Furthermore M2a macrophages can switch to quiescent macrophages depending on the presence of IL-4[121] or be reprogramed to switch to M1 macrophages in response to TLR agonists. Therefore the M2a phenotype is transient and relatively short. In vitro, M2a macrophages lose their properties within 2 days of cultivation in IL-4-depleted media (Fig. 20.4B). In contrast, M2b macrophages live longer once they appear and do not require exogenous growth factors (e.g., IL-4), due to the self-sustaining production of CCL1, which is an essential chemokine for the maintenance of M2b properties.[114] These results indicate that M2b macrophages have poor plasticity and may explain why M2b macrophages are persistent in severely burned hosts.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are a population of lymphocyte-like lineage-negative (Lin^-; i.e., lacking surface markers for T, B, NK, and monocytes/macrophages lineages) cells. These cells are present in a wide variety of epithelial compartments and have important effector functions in the innate immune response.[122,123] ILCs develop from common lymphoid progenitors that express IL-7Rα (CD127). Mature ILCs rapidly respond to alarmins emanating from epithelial cells or from myeloid cells and are potent innate cellular

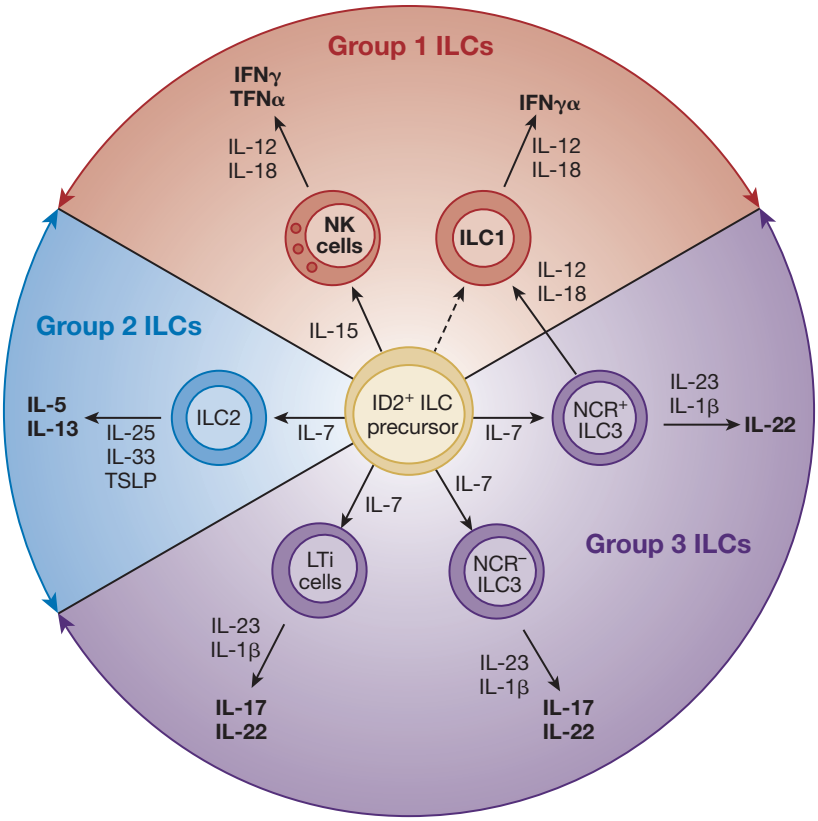

Fig. 20.5 Classification of innate lymphoid cells (ILCs) into three groups. ILCs are immune cells that belong to the lymphoid lineage, but do not express antigen-specific receptors. *LTi,* Lymphoid tissue inducer; *NCR,* natural cytotoxic receptor; *TSLP,* thymic stromal lymphopoietin. (Modified from Spits H, Artis D, Colonna M, et al. Innate lymphoid cells–a proposal for uniform nomenclature. *Nat Rev Immunol.* 2013;13:145–149.)

sources of multiple proinflammatory and immunoregulatory cytokines. ILCs are now classified into three groups, group 1 ILCs (ILC1s), group 2 ILCs (ILC2s), and group 3 ILCs (ILC3s), based on their abilities to produce cytokines and to express transcription factors typically associated with Th1-, Th2-, and Th17-type immune responses, respectively (Fig. 20.5).[124] ILC1s and ILC3s have a crucial role in promoting type 1 immune responses that provide protection against many microorganisms. By contrast, ILC2s have a role in promoting type 2 immune responses.[125] Cell transfer experiments and in vivo fate-mapping approaches have estimated the half-life for ILC subsets to be 2–3 weeks.[126]

IMPAIRED ILC1 GENERATION DUE TO IMPAIRED IL-12 PRODUCTION AFTER BURN INJURY

ILC1s respond to IL-12.[123] These cells are the dominant innate source of IFN-γ (and TNF-α) after infection and have a role in recruiting inflammatory cells that control infection. ILC1s, constitutively expressing T-bet, can be divided into at least three subsets: conventional NK (cNK) cells, $CD103^+$ $CD127^{low}$ intraepithelial ILC1s, and $CD127^+$ ILC1s.[123] cNK cells are $CD56^+$ $NKp44^+$ $CD161^+$ $CD127^-$ cells, and they require eomes and IL-15 for the development from NK-cell progenitors.[127] cNK cells exhibit cytotoxic activity by degranulating granzyme and perforin, both of which induce apoptosis of target cells, such as infected epithelial cells. $CD103^+$ $CD127^{low}$ intraepithelial ILC1s bear resemblance to cNK cells because they are $CD56^+$ $NKp44^+$ $CD161^+$ cells and express perforin/granzyme, whereas $CD127^+$ ILC1s are noncytotoxic cells. Both subsets of ILC1s lack eomes. $CD127^+$ ILC1s express TNF-α and TNF-related apoptosis-inducing ligand (TRAIL), which can induce apoptosis after binding to TRAIL-R1 (DR4) and/or TRAIL-R2 (DR5) on virus-infected cells.[126]

Many studies have demonstrated that the numbers and activities of cNK cells decrease due to severe burn injuries.[128–130] In severely burned patients, the expression of NKG2D (a natural cytotoxicity receptor) by peripheral blood cNK cells is significantly reduced.[131] NKG2D is constitutively expressed on the surface of circulating and tissue-resident cNK cells. Activated NKG2D stimulates cytotoxic effects of cNK cells against infected, transformed, or stressed cells in vitro and in vivo via interactions with NKG2D ligands (such as MICB and ULBP1) expressed on the surface of target cells. However, serum concentration levels of NKG2D ligands (shed from damaged tissues or from other tissues responding to stress) increase 3- to 20-fold within 24 hours after severe burn injury and are maintained for several weeks.[131] As an active immune-evasion mechanism, high concentrations of soluble NKG2D ligands may be involved in suppressed cNK cell activity in severely burned patients. Little is known about the influence of severe burn injuries on the numbers and activities of $CD103^+$ $CD127^{low}$ ILC1s or $CD127^+$ ILC1s. Because impaired IL-12 production by various antigen-presenting cells has been demonstrated

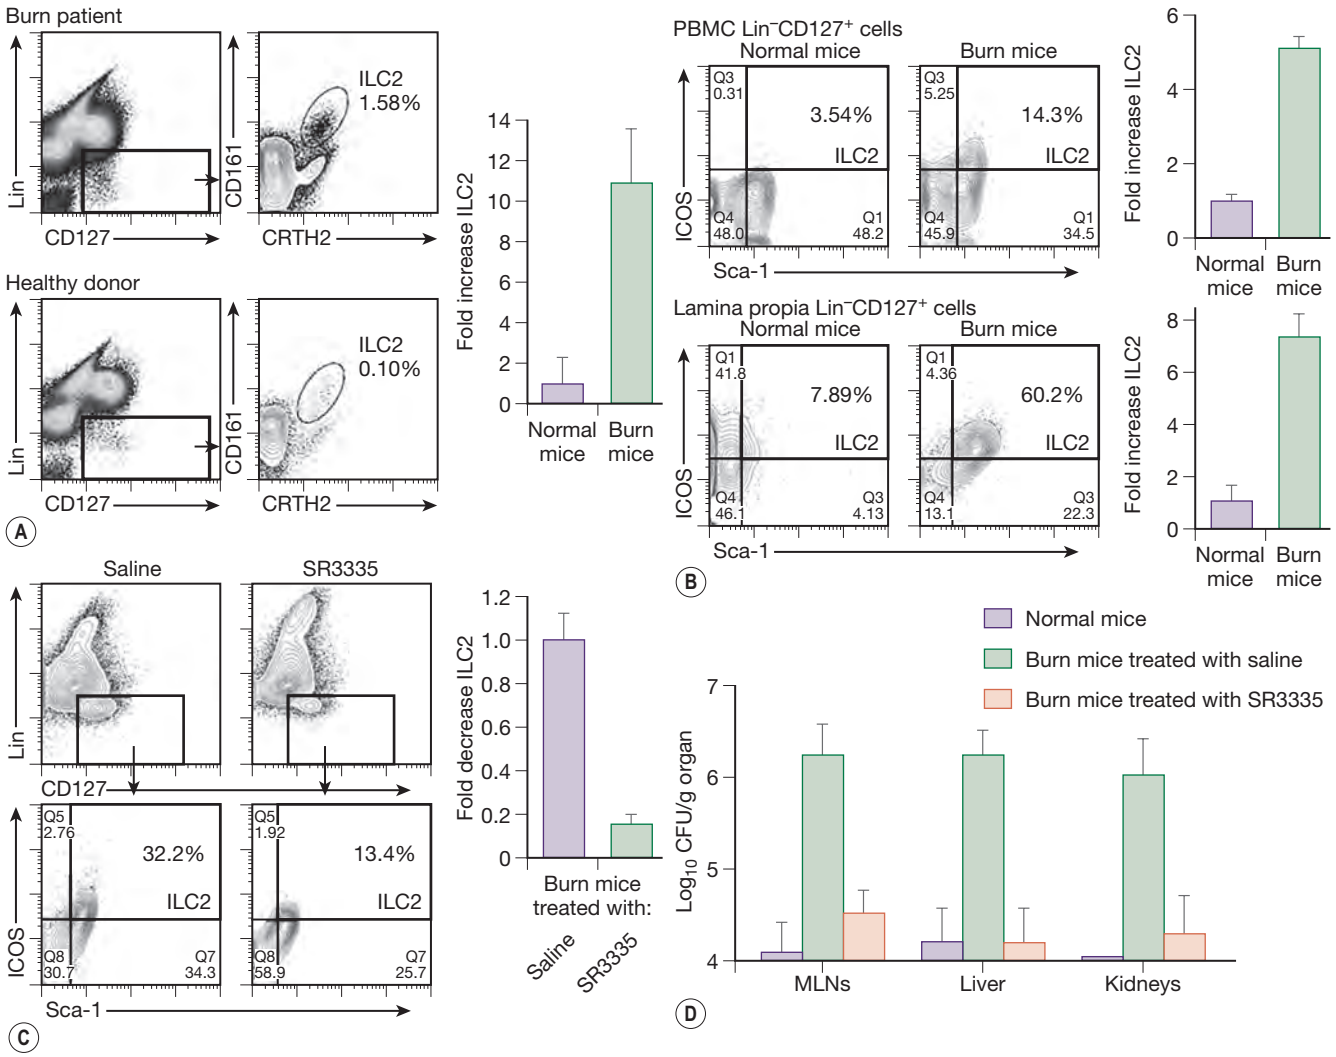

Fig. 20.6 Innate lymphoid cells-2 (ILC2s) appearing in severely burned patients and mice are responsible for the increased susceptibility to gut bacteria-associated sepsis. ILC2 increased in PBMCs of severely burned patients (**A**) and PBMCs and lamina propria (LP) of mice 1 day after burn injury (**B**). ILC2 decreased in LP of burned mice treated with SR3335 (**C**). The resistance of severely burned mice to gut bacteria-associated sepsis was improved by treatment with SR3335 (**D**).

in severely burned patients and mice,[80,81] burn-associated defects in IL-12 production cause insufficient activities of $CD103^+$ $CD127^{low}$ ILC1s or $CD127^+$ ILC1s for the production of IFN-γ.

TYPE 2 IMMUNE RESPONSES INDUCED BY ACTIVATED ILC2S

ILC2s respond rapidly to IL-25, IL-33, and TSLP, which are produced by epithelial cells and macrophages during inflammation and infection.[123] ILC2s have a crucial role in boosting type 2 immune responses by producing IL-4, IL-5, IL-9, and IL-13.[125] Although the type 2 immune responses have important host protective functions to maintain mucosal homeostasis, hyperreactive type 2 immune responses suppress the development of protective type 1 immune responses to pathogens and thereby facilitate uncontrolled or persistent infection. ILC2s constitutively express high levels of GATA3, which is required for their development from ILC progenitors. GATA3 is also required for the maintenance and function of mature ILC2s, and RAR-related orphan receptor (ROR)-α is an essential transcription factor of ILC2 maturation.[123,126] In fact, ILC2s are not detected in any tissues of RORα KO mice.[132] In mice, two distinct ILC2s are isolated: natural ILC2s ($ST2^+$, nILC2s) and inflammatory ILC2s ($ST2^-$, iILC2s).[133] nILC2s are present in steady-state conditions and support the maintenance of IgA secretion from B cells in the intestine, whereas iILC2s are induced in inflammatory circumstances.

Increased numbers of ILC2s have been detected in the peripheral blood of severely burned patients (Fig. 20.6A), as well as in the peripheral blood and lamina propria of severely burned mice (Fig. 20.6B). After depletion of ILC2 by treatment with a specific inhibitor against the RORα-dependent transcription factor (SR3335, a synthetic ligand for RORα[133]) (Fig. 20.6C), sepsis stemming from enteric bacterial infections was controlled in severely burned mice (Fig. 20.6D). Thus ILC2s play an important role in the

impaired host antibacterial defenses influenced by severe burn injuries.

INTESTINAL ILC3S

Similar to ILC1s, ILC3s have a crucial role in promoting type 1 immune responses.[123] ILC3s are predominantly present in gut-associated lymphoid tissues. These ILC3s respond to IL-1β, IL-6, and IL-23, which are produced by DCs or myeloid cells. They are IL-22 (and IL-17) producer cells and constitutively express RORγt. ILC3s are classified into three subsets including lymphoid tissue-inducer (LTi) cells and two RORγt$^+$ subsets distinguished by their expression or lack of expression of NK cell receptors (NCR$^+$ ILC3s and NCR$^-$ ILC3s).[123,126] LTi cells produce lymphotoxin and TNF-α and stimulate the mesenchymal cell production of chemokines and adhesion molecules essential for lymphoid organogenesis. NCR$^+$ ILC3s express NK-specific molecules (NKp46 in mice and NKp44 in human); however, these cells lack cytotoxicity and do not produce IFN-γ. In contrast, NCR$^-$ ILC3s are IFN-γ producers. Through the production of IL-17, NCR$^-$ILC3s stimulate neutrophil migration and the secretion of antimicrobial peptides by epithelial cells.[134] In the intestine, ILC3s have an important role in regulating tissue repair.[123,135] ILC3s rapidly respond to extracellular bacterial or fungal infections and produce IL-22 for the maintenance of the epithelial barrier, production of antimicrobial peptides, and suppression of the reactivity of commensal bacteria-specific T cells by presenting a peptide derived from commensal bacteria. ILC3 crosstalk with macrophages and DCs promotes intestinal homeostasis by enhancing the levels of regulatory T cells.[136] In response to IL-1β, which is produced by macrophages stimulated with extracellular bacteria, LTi cells and NCR$^+$ILC3s produce GM-CSF to promote oral tolerance. ILC3s differentiate into ILC1s on stimulation with IL-2 and IL-12.[137]

In severely burned patients, bacteria-elicited IL-12 production by macrophages and neutrophils is greatly impaired.[80,81] Also, mitogen-stimulated T-cell production of IL-2 is decreased in these patients.[83,138] The deficiency of IL-2 and IL-12 production results in minimal differentiation of ILC3s into ILC1s. The decrease of ILC1s in severely burned patients leads to reduced antibacterial effector cell generation and subsequent impaired adaptive immune responses. Since ILC3s resolve intestinal inflammation and enhance intestinal barrier function through the stimulation of antimicrobial peptide production by epithelial cells,[123] ILC3s play an important role in reducing bacterial translocation following severe burn injuries.

Dendritic Cells

DCs are phagocytic cells that play an important role in initiating both innate and adaptive immune responses to infection. DCs reside in areas of high antigen exposure, such as the skin, airway, and intestine. As phagocytes, DCs detect invading microbes and produce cytokines and antimicrobial peptides that can attract and activate other innate immune cells to limit microbial growth and spread. As antigen-presenting cells, DCs present antigens to T cells to initiate adaptive immune responses. Both of these DC roles are important for controlling and eliminating infections. Circulating DCs are significantly depleted in burn patients. As early as 1 day after injury, burn patients have significantly lower numbers of both conventional and plasmacytoid classes of DCs. In burn patients who do not develop sepsis, circulating DCs are restored within a week. However, in burn patients who develop sepsis during the acute post-burn recovery phase (within 20 days of injury), DCs are not restored to normal levels and remain significantly lower than DC levels in burn patients who do not develop sepsis.[139] This suggests that a burn-associated deficit in DCs decreases the ability of burn patients to fight infection. The inability to replenish DCs after burn injury is associated with a decrease in differentiation from their myeloid precursor cells. Monocytes from burned patients show decreased DC differentiation potential in vitro and are associated with high monocyte expression of MafB, a transcription factor that promotes the differentiation of myeloid progenitor cells into monocytes instead of DCs. In vitro silencing of MafB in burn patient monocytes restored their differentiation potential into DCs.[140] This is also observed in mouse models of burn injury, where the differentiation potential of myeloid precursors favors the production of monocytes and not DCs. Severely burned mice show a significant decrease in DC numbers for up to 2 weeks postinjury, and this is associated with increased expression of MafB, and a decrease in the expression of GATA-1, a DC differentiation transcription factor.[141,142]

In addition to depletion of DCs, burn injury also impairs some DC functions that are critical for effective responses to infection. Locally, skin DCs are not only depleted near the burn wound, but their expression of human leukocyte antigen-D related (HLA-DR; a MHC-II antigen presentation molecule) and TLR4 (important for DC activation) and their ability to stimulate T lymphocytes, are impaired after burn injury.[143,144] Local impairment of DC functions can increase susceptibility to wound infections. Rodent models of burn injury demonstrate similar impairments in DC functions. DC expression of TLR4 and production of Th1-associated cytokines such as IL-12 are decreased, while production of Th2-associated cytokines such as IL-10 is increased after burn injury. T-cell activation by DCs is impaired by burn injury.[145,146] Additionally, the ability of DCs to produce antimicrobial β-defensins is decreased following burn injury, and this is associated with decreased in vitro killing of bacteria.[147] Collectively, the burn-induced depletion and impairment of DCs can reduce both innate and adaptive immune responses to infection.

Experimental studies have investigated pharmacological stimulation of DC production in mice after burn injury as a mechanism to restore DC numbers and functions after burn injury. Treatment of burned mice with the DC growth factor *fms*-like tyrosine kinase-3 ligand (Flt3L) after severe burn injury restores and increases DC numbers, increases DC production of Th1-associated cytokines, and increases DC stimulation of neutrophil and lymphocyte activation.[148,149] This results in improved bacterial clearance, decreased systemic inflammation, and increased survival in response to burn wound infection. This suggests that DC impairment plays a critical role in susceptibility to infections after burn injury and that DC-targeted therapies may help to restore immune function in severely burned patients.

Summary

The immunological perturbations induced by burn injury are heterogeneous and may differ in each burn patient. Therefore, targeting a sole cell type or implementing a single-agent therapy may not be sufficient to significantly decrease the morbidity and mortality of severely burned patients. Defining patient-specific immune deficits and then targeting these defects with a cocktail of immunotherapies without inducing exaggerated inflammatory activities will be the best approach for boosting the immune system and reducing infection-associated mortality of severely burned patients. Therefore identification of predictive biomarkers is necessary for the future development of personalized immunotherapy for severely burned patients.

21 Biomarkers in Burn Patient Care

AMINA EL AYADI, DAVID N. HERNDON, and CELESTE C. FINNERTY

Introduction

Each year, more than 8 million people are burned. Approximately 1 million sustain severe burn injuries covering more than 30% of the total body surface area (TBSA). Burns cause considerable morbidity and mortality; burn injuries are often complicated by inhalation injury, infections, and sepsis, all of which can lead to systemic inflammation, acute respiratory distress syndrome (ARDS), multiple organ dysfunction (MODS), and death.[1] Despite advances in critical care and resuscitation, infections develop and lead to sepsis in 40–60% of burn patients.[2–6] The ability to prospectively identify or monitor organ function, infections, clinical trajectory, or patient outcome in severely burned patients would enable early intervention, reduce morbidity and mortality, and significantly lower the cost of clinical care. In recent years, biomarkers ranging from single proteins (e.g., procalcitonin, interleukin-8 [IL-8]) to the combination of variables (e.g., proteins, urinary markers, clinical parameters) have been used to predict or identify the risk of infection, sepsis, organ failure, or likelihood of survival, in patients with severe burns. The first 72 hours postinjury are critical for the prevention of complications, so the ability to use biomarkers to guide care during this period enhances our ability to improve patient care. We and others have identified candidate biomarkers that can be used to identify infection or sepsis, predict patient survival, reveal injury severity, or monitor organ function or wound healing. Biomarkers can take the form of single molecules, gene or protein families, injury characteristics, or clinical parameters. A good biomarker can be used for either diagnostic or prognostic purposes, be sensitive, specific, easy to measure, and reproducible.[7] When applicable, the expression of the biomarker of interest can be modified by pharmacologic interventions, and this altered expression then monitored to determine impact on patient outcome.

Burn injury also affects long-term health and quality of life. With the many body systems that are impacted and negative sequelae that can result, the ability to predict patient outcomes or to determine whether therapy is efficacious would enable targeted therapies to improve patient outcomes. Here we review candidate biomarkers in burn patients for infections and sepsis, survival, inhalation injury, organ function, and wound healing.

Prediction of Sepsis and Infection

The expression of pro- and antiinflammatory cytokines is significantly altered following burn injury,[8] and the concentration of these cytokines alone or with respect to each other (the expression profile) can be used to predict patient outcome.[9] Characterization of the post-burn cytokine response shows an immediate spike in the expression of mediators such as IL-6 and IL-8, among others, that then slowly returns to levels detected in nonburned patients over the next several weeks to months.[8–10] The cytokine expression profile at the time of admission and during the course of the hospital stay can predict which patients may develop sepsis or multiple organ failure (MOF).[11–13] The expression of the following pro- and antiinflammatory cytokines has been linked to patient outcome: tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), IL-1β, IL-I7, IL-4, IL-6, and IL-8. Increased expression of inflammatory cytokines contributes significantly to the burn-induced hypermetabolic response and to the increased incidence of infection and sepsis. While initial studies focused on the correlation of single cytokines with patient outcomes,[14–18] technologies allowing detection of multiple proteins at a single time enable the correlation of analyte expression profiles back to clinical trajectory or other outcome.[11,13] The standard criteria for diagnosing sepsis in the critically ill are not used in the burn population due to overlap with the pathophysiological response to burn injury. Because the clinical presentation of sepsis in the burn patient is sufficiently unique, a burn-specific definition of sepsis was developed.[19] Given the massive inflammatory, acute-phase, and coagulopathic responses induced by burn injury[10,20,21] and the perturbations of these responses that occur with infection, there are many candidate biomarkers for the identification and/or prediction of sepsis and infection.

TNF-α

TNF-α is mainly secreted by activated macrophages immediately postburn. The host immune response is activated by TNF-α, as is the subsequent release of cytokines following trauma and infection. TNF-α also plays a role in angiogenesis and wound healing.[22] Several studies have identified TNF-α as a predictive marker for the development of septic complications in burn patients.[11,23] In fact, TNF-α expression is increased immediately post-burn, triggering the inflammatory response, and then decreasing again.[8,9,24] A later elevation in TNF-α expression appears to be indicative of the onset of infection or sepsis.[23,25]

IL-8

IL-8 (or CXCL8) is a chemokine that is released early postinjury mainly by macrophages. IL-8 is an important protein related to inflammation, where it plays a key role in the recruitment of neutrophils and other immune cells to the site of infection.[26] In addition to macrophages, IL-8 is also released by epithelial cells, airway smooth muscle cells, and endothelial cells. This chemokine has been shown to be

involved in many cellular processes including cell proliferation, tissue remodeling, and angiogenesis.[27]

IL-8 has been proposed as a survival biomarker following burn injury. Expression of IL-8 has been consistently shown to be greater in burn patients who do not survive than in those who do.[11,13,14,24] Whereas IL-8 expression returns to baseline within 8–10 days of injury in burn survivors, IL-8 concentrations remained significantly elevated in the nonsurvivors until the time of death.[24] When assayed over the course of hospitalization, the temporal increase in IL-8 expression in nonsurvivors occurs approximately 8–10 days post-burn, which may indicate the initiation of infection or sepsis. A more recent study has shown that in 468 pediatric burn patients, concentrations of IL-8 that met or exceeded a cutoff limit of 234 pg/mL were associated with higher incidence of MOF, sepsis, and mortality.[28]

IL-6

IL-6 is released by T cells and activated macrophages during the acute-phase response following injury or trauma and may lead to inflammation or infection. IL-6 has both pro- and antiinflammatory properties.[29] In burns, IL-6 concentrations are significantly increased when compared to IL-6 levels in nonburn volunteers.[24] Although the initial spike in IL-6 elevation reflects the early antiinflammatory response, chronic and excessive increases in serum IL-6 concentrations following burn injury are associated with a higher incidence of infection, sepsis, and death.[11,16,24] Detection of IL-6 in serum is significantly greater in nonsurviving versus surviving burn patients at all time points between the time of admission and time of death or discharge.[11,24]

C-REACTIVE PROTEIN

C-reactive protein (CRP) is a serum amyloid P component belonging to the pentraxin family of calcium-dependent ligand-binding proteins; it serves as a marker of inflammation. Synthesis of CRP occurs in the liver and is triggered by the release of IL-6 in response to tissue damage or infectious stimuli. Elevation of CRP expression occurs several hours after the onset of the increase in IL-6.[30] CRP measurements are inexpensive and readily available. High concentrations of CRP occur with inflammation; however this response is not specific. In burns, elevation of serum CRP is well documented.[31–33] CRP has been proposed as an early predictor of sepsis in burned children.[34] In a study of 918 pediatric burn patients, we found that CRP levels correlate significantly with burn size and mortality, but the changes in CRP expression did not correlate with the incidence of major infections or sepsis in severely burned children.[35] Additional studies showed that although CRP may correlate with burn size or mortality, the relationship to infection or sepsis is not well-supported.[36]

PROCALCITONIN

Procalcitonin (PCT) is a peptide precursor of the hormone calcitonin, synthesized by the parafollicular cells of the thyroid gland, and involved in calcium homeostasis. The major function of calcitonin is to decrease calcium absorption by osteoclastic cells, which increases circulating calcium levels. The half-life of PCT is 25–30 hours. Serum PCT concentrations are significantly increased in response to infectious stimuli, fungal infections, trauma, and surgery. In burn patients, elevation of PCT concentrations begins approximately 4 hours postinjury.[37] Following burn injury, significantly higher concentrations of PCT are reported in septic versus nonseptic patients.[1,37–39] Furthermore it has been suggested that PCT concentrations be incorporated into the burn-specific definition of sepsis.[37] At present, the utility of the PCT assay is somewhat limited due to the lack of availability of rapid, cost-effective tests.

LEPTIN

Leptin is a circulating hormone primarily secreted by adipose tissue and involved in the regulation of feeding and energy homeostasis through central nervous system afferent pathways.[40] Leptin also plays a role in angiogenesis[41] and stimulates T cells and monocytes to induce cytokine release.[42] Recent reports suggest a possible role for leptin as a biomarker in burns; serum leptin levels are significantly increased following burn injury.[25,41] Leptin concentrations are elevated in septic burn patients compared to nonseptic patients and in burn survivors compared to nonsurvivors.[25] The increased expression of leptin by septic patients may be related to leptin's role in regulating the stress response.[27] Elevated expression of leptin may play a crucial role in survival of acute sepsis. The high leptin concentrations in septic burn survivors may represent a host defense mechanism against bacterial infection.[43]

COMBINED PANELS

The combination of multiple proteins may offer greater predictive ability of patient outcomes. The popularity of technologies allowing detection of a variety of proteins at a single time, such as a bead-based multiplex approach or mass spectrometry, has made the measurement of many proteins in small amounts of sample easy. As a result, it is now possible to collect the expression data for a panel of proteins to determine whether there is a correlation with patient outcome. By using these techniques, relationships between protein expression and burn injury or patient outcome can be established. Using these approaches, it has been shown that the risk of dying of sepsis is elevated in pediatric burn patients with increased expression of IL-6 and IL-12p70 alongside reduced TNF-α expression.[11]

Prediction of Patient Survival with Clinical Characteristics

The ability to accurately predict which patients have a reduced likelihood of survival will enable the clinician to develop a more aggressive treatment strategy in order to maximize the patient's chance of survival. Classically, age and percent TBSA burn were used in the initial trial for early assessment of patient outcome.[44] Furthermore, the additive influence of the presence of an inhalation injury or pneumonia could be accounted for in order to refine prediction of death.[45] With improvements in clinical care, such as resuscitation procedures, better control of

infections and septic episodes, and the development of new grafting techniques, mortality following a severe burn injury has significantly decreased. Three risk factors, however, are associated with increased mortality: age greater than 60 years, burn covering more than 40% of TBSA, and presence of inhalation injury.[46]

We have reported that the inflammatory and the metabolic responses are positively correlated with burn size[47] and that patients with massive burns have a higher incidence of sepsis, inhalation injury, mechanical ventilation requirement, myocardial infarction, and death.[48] To evaluate the effects of clinical complications on patient outcome, 952 severely burned pediatric patients were studied. A cutoff of 62% of TBSA burned was identified: patients above this threshold had an increased incidence of sepsis, MOF, and mortality.[48]

The assessment of protein expression panels has shown that these can be used to predict patient survival.[13,24] Although clinical characteristics are frequently used to evaluate the severity of the patient's health, we have found that the inclusion of proteomic data and assay results from the clinical laboratory can improve identification of patients who may have difficult clinical courses.[49] In this study of 322 severely burned children, a panel of biomarkers was identified, including burn size, presence of inhalation injury, age, blood urea nitrogen, α-2-macroglobulin, IL-4, and aspartate aminotransferase. Testing of this model showed that although prediction of death was only accurate 52% of the time when using burn size, age, and presence of inhalation injury, by including clinical chemistry and proteomic data, accuracy could be boosted to 81%.

Inhalation Injury and Mechanical Ventilation

The severity of burn injury is sometimes complicated by inhalation injury, which contributes to mortality. Patients with inhalation injury have an odds of dying nearly three times higher than those without inhalation injury.[48] Morbidity in patients with inhalation injury is further complicated by exposure to inhaled toxins and soot, exposure to which can predispose the patient to development of respiratory tract infections and/or ARDS. Mechanical ventilation is used to alleviate these symptoms. Biomarker studies have been performed in burn patients under various ventilation strategies, such as low tidal volume versus high tidal volumes. Shelhamer et al. reported that, in mechanically ventilated patients, an early increase in plasma IL-8 concentrations, among other cytokines (IL-1β, IL-6, IL-8, GM-CSF, and TNF-α), was associated with a several-fold increase in ventilator-associated pneumonia or death.[50] However a recent study compared serum concentrations of inflammatory cytokines, IL-6, IL-8, and TNF-α before and after using percussive ventilation in patients with minor burns and smoke inhalation to determine whether the plasma levels of these biomarkers are affected by the ventilation strategy.[51] Unexpectedly this study showed that high-frequency percussive ventilation (HFPV) increased blood oxygenation and did not further increase the serum levels of inflammatory cytokines,[51] as was hypothesized by the Shelhamer et al. study.[50]

Protein expression within the bronchoalveolar lavage fluid (BALF) can also be used to give insight into the effects of inhalation injury in the burned patient. Profiling of cytokine expression within the BALF from burned survivors and nonsurvivors revealed that expression of many inflammatory markers, including IL-1RA, IL-1β, IL-2, IL-4, IL-8, IL-10, IFN-γ, MIP-1β, and TNF-α was suppressed in nonsurvivors. Additional studies revealed differences in pulmonary immune hyporesponsiveness in the nonsurvivors that were responsible for decreased cytokine production. Correlation of the expression of these same cytokines in the serum with the clinical determination of the severity of inhalation injury demonstrated that IL-1RA, IL-6, IL-8, granulocyte colony-stimulating factor (GCSF), and monocyte chemotactic protein 1 serve as biomarkers for lung injury severity.[53] Within the BALF, the detection of raised concentrations of IL-10 alongside suppressed expression of IL-12p70 are significantly associated with postburn acute lung injury.[54] Furthermore early detection of increased IL-10, double-stranded DNA, and hyaluronic acid in the airway is associated with subsequent development of pulmonary bacterial infections.[54]

Resuscitation and Kidney Function

Fluid resuscitation is guided by the type of fluids to be administered, flow rate, volume, and frequency. The goal of fluid management is to correct the hypovolemic shock associated with the loss of the skin barrier function without overresuscitating. Formulae such as the Parkland formula or the Galveston formula are used to determine the burn patient's resuscitation goals. While overresuscitation is often reported,[5] no one protocol has been established for use by all burn centers. The most recent work by Cancio et al. promotes the use of computerized tools to assist providers in the resuscitation of burn patients.[55]

Volume requirements for resuscitation can be estimated by patient weight and TBSA burned.[56] Inhalation injury, burn thickness, and time since injury are also involved in these calculations.[57] The actual infusion rate is titrated over time based on urine output.[5] While several studies have suggested using intrathoracic blood volumes to guide resuscitation rates, higher ratios of serum pro- to antiinflammatory cytokines were found in these patients when compared to patients with urine output-guided resuscitation.[58] In the same study, granulocyte, lymphocyte, and monocyte CD markers were also higher in the urine-guided resuscitation group compared to patients who receive intrathoracic blood volume-guided resuscitation, suggesting a shift to an anti-inflammatory status in this group.

Studies to determine reliable biomarkers for intravascular volume and renal perfusion in critical care have pointed to neutrophil gelatinase-associated lipocalin (NGAL) and B-type natriuretic peptide (BNP) as useful markers to determine resuscitation strategies. Acute kidney injury was identified by measurement of NGAL 12 hours earlier than when using creatinine levels; in patients who had been overresuscitated, BNP levels were significantly higher.[59,60] During resuscitation following burn, measurement of creatinine, NGAL, and BNP at the point of care facilitate determination

of vascular volume and assessment of renal function.[59,61] Additional studies are needed to optimize the cutoffs for BNP and NGAL that will be used to guide resuscitation.

Wound Healing

Wound closure is predicted based on injury location, wound perfusion, and the gross appearance of the wound bed and granulation tissue.[62] In the absence of credible algorithms or biomarkers, quantitation of these factors is subjective. Therefore determination of biomarkers that can be used to monitor wound healing or be modulated to achieve optimal wound healing while avoiding hypertrophic scarring is of utmost importance in this field. Wound healing is accomplished via a precisely orchestrated cascade of interrelated cellular and biochemical events that lead to repaired tissue and is accomplished via the following events: inflammation, migration, proliferation, and remodeling. These phases are tightly regulated, and each phase overlaps with the previous one and is characterized by specific markers. The initial inflammatory phase of wound healing prevents wound infection through the early immune response and is characterized by vasodilation, fluid extravasation, edema formation ensured by neutrophils, monocytes, and macrophages, respectively. The second phase is the proliferative phase, characterized by activation of fibroblasts and keratinocytes, which leads to wound closure and revascularization. Finally the remodeling phase is characterized by collagen and elastin deposition and differentiation of fibroblasts into myofibroblasts to help with wound contracture and ultimately wound closure. Finally apoptosis of keratinocytes, myofibroblast, and immune cells will take place to terminate wound healing and avoid overgrowing extracellular components that may lead to unwanted hypertrophic scarring.

Acute wounds heal by an interdependent sequence of events mediated by pro- or antiinflammatory cytokines and chemokines. Determining the levels of these cytokines may reflect the status of the healing wound. Biomarker studies aim to determine specific markers that drive each phase of wound healing in order to tailor therapeutic strategies that will optimize functional recovery. Possible biomarkers have been identified by analyzing cytokine levels in the serum, wound exudate, blister fluid, and wound tissues. From these studies, increased serum levels of IL-3, IL-12p70, and PCT have emerged as biomarker candidates indicating delayed wound healing.[63] Hawksworth et al. analyzed the levels of proinflammatory cytokines in the serum, wound effluent, and biopsies of the wound bed collected during each débridement procedure.[64] Serum IL-6, IL-8, MIP-l α, and effluent inducible protein [IP]-10 protein were predictive of wound dehiscence.[64] Additionally, expression of mRNA transcripts for MCP-l, IL-lα, TNF-α, IL-8, MIP-lα, GM-CSF, IL-lβ, and IL-6 were also predictive of wound dehiscence.[64]

In elderly patients, delayed wound healing was associated with increased levels of CD44 and keratin-6.[65] Modulation of matrix metalloproteinase-9 in these patients accelerates wound healing.[65] IL-33, a member of the IL-lβ cytokine family, was shown to accelerate wound healing, increase extracellular matrix (ECM) production, facilitate the development of activated macrophages, and inhibit meticillin-resistant *Staphylococcus aureus* (MRSA) colonization by activating neutrophil proliferation while increasing expression of ECM-associated genes.[66] Leptin also improved wound healing by stimulating angiogenesis[40] and neovascularization in ischemic wounds as part of the autocrine/paracrine regulation of wound healing.[67] TNF-α is an important factor in wound healing due to its role in the early immune response when secreted by activated macrophages. TNF-α may also influence wound healing through direct action on keratinocytes and endothelial cells, thereby impacting epithelialization and vascularization.[68] Therefore TNF-α may be a good therapeutic target to improve wound healing in burns.

Conclusion

The utilization of proteomic, genomic, and clinical measurements to predict patient outcomes, monitor injury severity or organ recovery, or monitor wound healing following severe burn injury is the topic of much research. With current efforts to precisely define the patient population or injury severity (including defining sepsis), future efforts to identify biomarkers for patient outcomes should yield markers with greater specificity and utility. By pursuing these efforts, identification and validation of biological markers that can be used to guide clinical decisions or to monitor efficacy of therapy will be possible.

22 Hematology, Hemostasis, Thromboprophylaxis, and Transfusion Medicine in Burn Patients

DEREK CULNAN, KAREL D. CAPEK, CHARLES VOIGT, and KUZHALI MUTHUMALAIAPPAN

Introduction

Severe burn injury causes a myriad of hematologic perturbations. Burn excision as well as substantial in-hospital phlebotomy causes severe blood loss anemia and even hemorrhagic shock, requiring substantial transfusion. Large-scale fluid resuscitation and shock cause a significant coagulopathy. Surgical extirpation can similarly cause a significant dilutional coagulopathy requiring transfusion. Hematopoiesis, the generation of new blood cells, is directed away from red blood cell (RBC) production toward myeloid blood cell production by the hyperinflammatory cytokine cascade. The hyperinflammatory nature of burn injury further makes the patient hypercoagulable, generally requiring significant anticoagulation or thromboprophlyactic therapy. Providing total burn care requires knowledge of hematology, hemostasis, thromboprophylaxis, and transfusion medicine to overcome the substantial pathophysiology experienced by these patients.

Etiology of Anemia in Burn Patients

Anemia is the condition occurring when the RBC concentration, or hemoglobin (Hb) concentration, falls below normal laboratory limits for healthy adults. These normative values do not correlate with sufficient oxygen delivery. Weiskopf and Feiner classically demonstrated normal oxygen delivery despite dramatic acute anemias while examining Hb concentrations as low as 5 g/dL in euvolemic subjects.[1] Anemia is common in burn patients, especially in those with severe thermal injuries. Burn patients suffer from anemia due to acute surgical blood loss and the anemia of critical illness. This can occur in patients with as little as 10% total body surface area (TBSA) burned.[2] A mild reduction of RBCs mass is of little clinical significance[3]; when the concentration is significantly reduced, or total blood volume loss is beyond 30%, it becomes clinically relevant, leading to impaired end-organ perfusion and oxygenation.[4] The initial 2 weeks post-burn feature anemia mainly resulting from blood loss through the burn wound, dilution due to resuscitation, and surgical blood loss from repeated débridement to prepare the wound bed with well-vascularized tissue.[5] Subsequently, anemia is characterized as the anemia of critical illness and develops from inadequate nutrition,[6,7] stunted erythropoiesis,[8] or phlebotomy and dressing changes.[8] Specifically, bone marrow dysfunction leading to dampened erythropoiesis has been explored in autopsy studies and in the mouse model of burn injury in vitro.[8] In an autopsy study of patients who died from myocardial infarction, sepsis, or burns, the bone marrow of burn patients contained significantly fewer erythroblasts compared to the other groups.[9]

Acute blood loss results in at least 2% blood volume loss per percent body surface area excised; thus during major burn excisions, there is significant blood loss often requiring massive transfusions (MTs).[10] MT is defined as the transfusion of packed red blood cells (pRBCs) of 10 units or more within 24 hours of admission.[11] While acute surgical blood loss is obvious and prominent during the treatment phase, burn patients suffer a prolonged anemia of critical illness during their recoveries, which is insidious. The anemia of critical illness is the inability of RBC production to meet RBC demand and losses during critical illness.[12,13] More than 50% of transfusions during a burn patient's hospital course may be caused by the anemia of critical illness.[14] It has been equated to an acute form of the anemia of chronic disease[15–17] and anemia of inflammation in conjunction with nutritional deficiencies.[12] Acute blood loss anemia is controlled with surgical technique, while the anemia of critical illness can be restrained with reduced phlebotomy, decreased blood loss with dressing changes, improved nutrition, and resolving the critical illness by covering the patient with skin, thereby abating his disease. Prevention of anemia is accomplished through alteration of its sources, acute blood loss, and the anemia of critical illness, while the mainstay of treatment for both types of anemia is the transfusion of pRBCs.

Hemostasis in Burn Patients

Controlling blood loss and hemorrhage during burn care is important to prevent episodes of hemorrhagic shock and limit total transfusion need. While Barbosa and Rowel demonstrated that a 6-h RBC transfusion requirement is one of the mortality predictors in MT trauma patients, it is unclear

if these findings extend to controlled blood loss during a burn extirpation.[18] In these cases, a skilled anesthesiologist can match the transfusion rate and blood product mix to the bleeding rate, thus preventing hemorrhagic shock, maintaining euvolemia, and avoiding coagulopathy while the surgeon removes burned and diseased tissue and engrafts the patient.

As with burn-susceptible infections, preventing burn-derived anemia from developing is more optimal than treating the anemia or subsequent sequela. Several methods have been established to mitigate acute surgical blood loss, including epinephrine tumescence, thrombin-soaked dressings, and tourniquet use.[19] Additionally, excision with electrocautery at a fascial or subcutaneous level can limit blood loss significantly in large, full-thickness burns.[20] Regardless of excision methodology employed, many studies found the injection of dilute epinephrine into the subdermal space promoted vasoconstriction and reduced blood loss during surgical management of the wound.[21–24] In a pediatric trial, epinephrine tumescence alone decreased blood loss from 3.5% to 5% to 0.98% of total blood volume per percent of body excised and grafted.[24] Importantly sufficient time must be allotted for the epinephrine to take effect, with an ideal interval of 25 minutes.[25] Epinephrine tumescence has no significant hemodynamic consequences, nor does it alter wound healing.[26–30] A recent study confirmed that subcutaneous epinephrine injection had no adverse effect on perfusion, pain, or scar quality versus the saline-administered control group.[26] Of interest lately has been tumescent infiltration of lidocaine and epinephrine by clysis. Gumus showed that this technique resulted in more facile excision with diminished blood loss.[31] Similarly, clysis has been demonstrated to reduce the need for blood transfusions.[32] The use of thrombin-soaked pads for additional hemostasis support postoperatively has been studied in the context of epinephrine tumescence and provides supplementary hemostasis by reducing unnecessary ooze from the dressing site.[19,33–35] New silicone gel dressings also significantly reduced the amount of blood loss per percent excised and the amount of blood transfused.[36,37] We employ nonadherent dressings (Telfa) soaked with epinephrine intraoperatively. This facilitates hemostasis and does not restart the bleeding upon removal of the pads, as often occurs with epinephrine-soaked laparotomy pads that avulse the clots they helped induce on the wound surface when they are removed. Finally the use of an extremity tourniquet during excision and débridement can decrease acute surgical blood loss without compromising graft adherence.[19,38–41] Kragh et al. found tourniquet use efficacious in both adults[42] and children.[43] In combination, all three techniques (epinephrine tumescence, thrombin-soaked dressings, and tourniquet use) can reduce intraoperative transfusion from 3.3 to 0.1 units per operative case with 96% graft take and total units transfused from 15.7 to 7.9 units per patient.[34] However recent analysis indicates that utilizing the epinephrine-tumescent technique obviates the need for tourniquets.[44] Of note, administration of topical bovine thrombin must be avoided in burn patients with prior exposure because they have been shown to develop coagulation derangements and severe bleeding complications from an acquired factor V deficiency.[45] Mullins et al. reported safe and effective hemostasis through recombinant human thrombin applied as a spray.[46] Due to rampant overestimations of operative transfusion needs and the expenses incurred by blood typing and cross-matching,[47] a preoperative estimate of 1.78 units of pRBCs per 1000 cm^2 of burn wound excised best utilizes blood bank resources.[48]

Coagulopathy in Burn Patients

In addition to anemia, thermal injuries are associated with systemic coagulopathy, and the hemostatic changes seen in patients with severe burns appear similar to those in patients with other major traumas. The severity of the burn correlates with the extent of hemostatic changes[49,50]; typically only severely burned patients (≥30% TBSA) develop extensive coagulopathy.[51–53] However, no consensus currently exists on the definition of coagulopathy in burn injuries.[54] Despite being documented since the 1970s, the physiology of coagulopathy in burns is still ill-defined.[49] However, coagulopathy of thermal trauma does present with characteristics common to sepsis-induced coagulopathy: decreased levels of antithrombin and other native anticoagulants, elevated levels of activated factor VII, fibrinogen degradation products, plasminogen activator inhibitor-1 (PAI-1), and thrombin-antithrombin complex (TAT).[53] The three types often discussed in burn- and trauma-related literature are trauma-induced coagulopathy (TIC), disseminated intravascular coagulation (DIC), and acute traumatic coagulopathy (ATC).[54] Acute coagulopathy of trauma shock has largely been subsumed under TIC.[55] Caused by trauma, TIC is characterized by coagulation activation, hyperfibrinolysis, and consumption coagulation.[56] The main pathophysiology of TIC is DIC .[55,57,58] Specifically DIC presents as the fibrinolytic phenotype in the early, acute phase of trauma and burn[54,56,58,59], whereas the thrombolytic phenotype is associated with sepsis-induced DIC, which presents later in the clinical course of burn pathophysiology.[56] As defined by the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis, DIC is an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization originating from and causing damage to the microvasculature, potentially leading to multisystem organ dysfunction (MOD).[55,60] DIC is characterized not by the significant bleeding, transfusion requirements, and fourfold higher mortality associated with TIC,[54,61] but by excessive thrombosis, unchecked inflammation and MOD, insufficient anticoagulation mechanisms, and increased fibrinolysis.[58] Indeed, early coagulopathy is associated with increased incidence of ventilator-associated events among burn patients.[62] MTs are administered more frequently in patients with DIC.[63] ATC is associated with the depletion of fibrinogen, platelet dysfunction, and activation of protein C.[64] This particular coagulopathy is not secondary to other conditions, such as hypothermia, and markers for it can be discerned within 30 minutes of the inciting thermal event.[65,66] In the pediatric population, ATC is defined by an international normalized ratio (INR) of 1.3 or greater, and those who present with fibrinolytic shutdown are more likely to develop deep vein thrombosis (DVT), especially because prophylactic anticoagulant administration is not recommended in the pediatric population due to their lower rates of venous thromboembolism (VTE).[67] Coagulopathy seen in burns is mediated by

preexisting conditions (e.g., age and comorbidities) as well as environmental (e.g., ambient temperature) and therapeutic factors (e.g., pre-hospital fluid administration).[68]

As demonstrated in multiple studies, the timing and onset of coagulopathy correspond with the severity of the burn,[49,52,69,70], and TIC may present without initial hypercoagulopathy.[71] Few burn patients present with coagulopathy at admission, but a large number develop it within a day post-burn.[49] In fact, at admission, no statistically significant differences were observed between nonsurvivors and survivors in coagulation and fibrinolysis markers.[72] The inciting causes of coagulopathy in burned patients include tissue hypoperfusion from fluid resuscitation, systemic inflammatory response syndrome (SIRS), blood loss from surgical excision, hypothermia, endothelial damage, consumption and/or dilution of coagulation factors, and acidemia.[53] Tejiram et al. effectively reviewed the myriad of changes seen in the clotting dynamics of burn patients and related more subtle factor changes as possible markers of mortality than partial thrombin time (PTT) and INR, which were normal in their cohort.[73] Classically, hypothermia, acidosis, and coagulopathy are collectively known as the lethal triad,[71,74,75] corresponding to MTs and mortality in burn and trauma patients.

Prevention of hypothermia in the operative theater is completely within the purview of the operative team and the operating room in the same way that the temperature of a steak is completely within the purview of the chef and the oven. As a manifestation of the First Law of Thermodynamics, a patient cannot cool beyond the temperature of the operating room. The clinical practice guideline in many burn centers is to maintain the ambient temperature of the ICU and operating rooms at 86–104°F (30–40°C) as a component of standard of care in the treatment of burn patients.[76,77] Maintaining sufficient heat in the operating room to prevent hypothermia is essential. In patients undergoing surgery, inadvertent perioperative hypothermia resulted from 50% to 90% of the cases.[78] Singer et al. determined hypothermia to be associated with high mortality, although it was much more commonly found in patients with large burns.[76,77] In fact, it has been shown that hypothermia, the condition where the core temperature falls below 36°C (96.8°F),[79] is not associated with external factors at the time of the burn, but correlates to burn severity and patient physiological status.[80] Burn patients are most vulnerable during excisional surgery due to operative heat loss[81] concurrent with evaporative water loss[82] or massive fluid therapy.[53,77,83]

Acidosis is an ever-present threat for the recovering burn patient. Lactic acidosis from shock states occurs transiently during recovery and surgery and exacerbates bleeding, as does hypercarbia. Uremia causes an anion gap acidosis and reduces platelet aggregation, which can be reversed with desmopressin.[84] Hyperchloremia of normal saline administration is an effect of hemodilution or a decrease in renal excretion of H^+.[85] While administration of natural saline is associated with hyperchloremia-induced metabolic acidosis,[86] Ringer's lactate, the other crystalloid solution typically used, correlates with metabolic alkalosis.[87]

Diagnosis of coagulopathy depends on detection. The INR measured upon admission is the basis for the diagnosis of acute traumatic coagulopathy.[49,64] Initial Hb levels may mask bleeding, and repeated measurements are necessary to use Hb levels diagnostically as a marker for bleeding. Notably, low initial Hb is considered an indicator for hemorrhage-associated coagulopathy.[68] However, assessing specific coagulation markers has proved both time-consuming and expensive, and typical laboratory tests, such as PTT, are limited in diagnostic value.[52,53,88] The markers of the various coagulopathies seen in burns present similarly to the coagulopathy seen in patients with sepsis and severe trauma.[53,89,90] Among the coagulopathic changes are increased levels markers of thrombin activation, activated factor VII (FVIIa), thrombin-antithrombin complex (TAT) and inhibited fibrinolysis with increased levels of PAI-1, as well as decreased levels in proteins C and S, fibrinogen, and antithrombin.[53,90–93] In the first day post-burn, patients with severe burns show marked decreases in fibrinolysis[51,53,72] as well as platelet activity.[94] Lavrentieva et al. demonstrated that, in the early post-burn phase (day 3 to day 7 post-burn), survivors could be distinguished from nonsurvivors by the levels of natural coagulation inhibitors (i.e., proteins C and S and antithrombin), fibrinolytic factors (i.e., PAI-1 and tissue-plasminogen activator), and TAT, a marker of thrombin generation, but not at admission when both groups presented with statistically similar levels in all parameters.[72] While van Haren et al. also found that severely burned patients become hypercoagulable following admission despite pharmacologic thromboprophylaxis, they determined that thromboelastography (TEG) was a more reliable indicator of coagulopathy than were coagulation markers.[89] Interpretation of TEG data is reviewed in Fig. 22.1. Furthermore, TEG provides diagnostic answers in a much shorter time than standard laboratory testing, resulting in faster goal-directed therapies.[91,95] The majority of burn centers worldwide used standard coagulation tests,[96] but the move to using TEG is warranted. With the advent a portable fibrinogen analyzer, fibrinogen levels can be measured in mere minutes.[97] Low levels of fibrinogen have been shown to be predictors for MTs[98]; Hayakawa et al. demonstrated that fibrinogen reached critical diagnostic levels (150 mg/dL) sooner than other coagulation parameters,[63] making it a key factor in determining blood product needs as well as being a coagulation indicator. More recently, other studies showed higher levels of fibrinogen (211 mg/dL and 190 mg/dL) functioned as useful predictors of MT.[98,99]

Not only is there limited consensus on the diagnosis of the type of coagulation associated with burns, there is no agreement on the therapies used to respond to the condition when it presents.[96] It is accepted that the activation of fibrinolysis is inadequate to offset the excessive fibrinogen formation in the early post-burn phase in patients severely burned.[72] Hemostasis depends on fibrinogen for clot formation and platelet aggregation, and the depletion of fibrinogen correlates with poor outcomes.[100] While fibrinogen is the coagulation protein with the highest plasma concentration, plasma transfusions do not correct the fibrinogen depletion seen in TIC and ATC unless massive volumes are infused.[101] Current European Trauma Guidelines suggest the administration of fibrinogen concentrate or cryoprecipitate if a trauma patient presents with both significant bleeding and thromboelastometric signs of functional fibrinogen deficit or a fibrinogen concentration (FIB) of

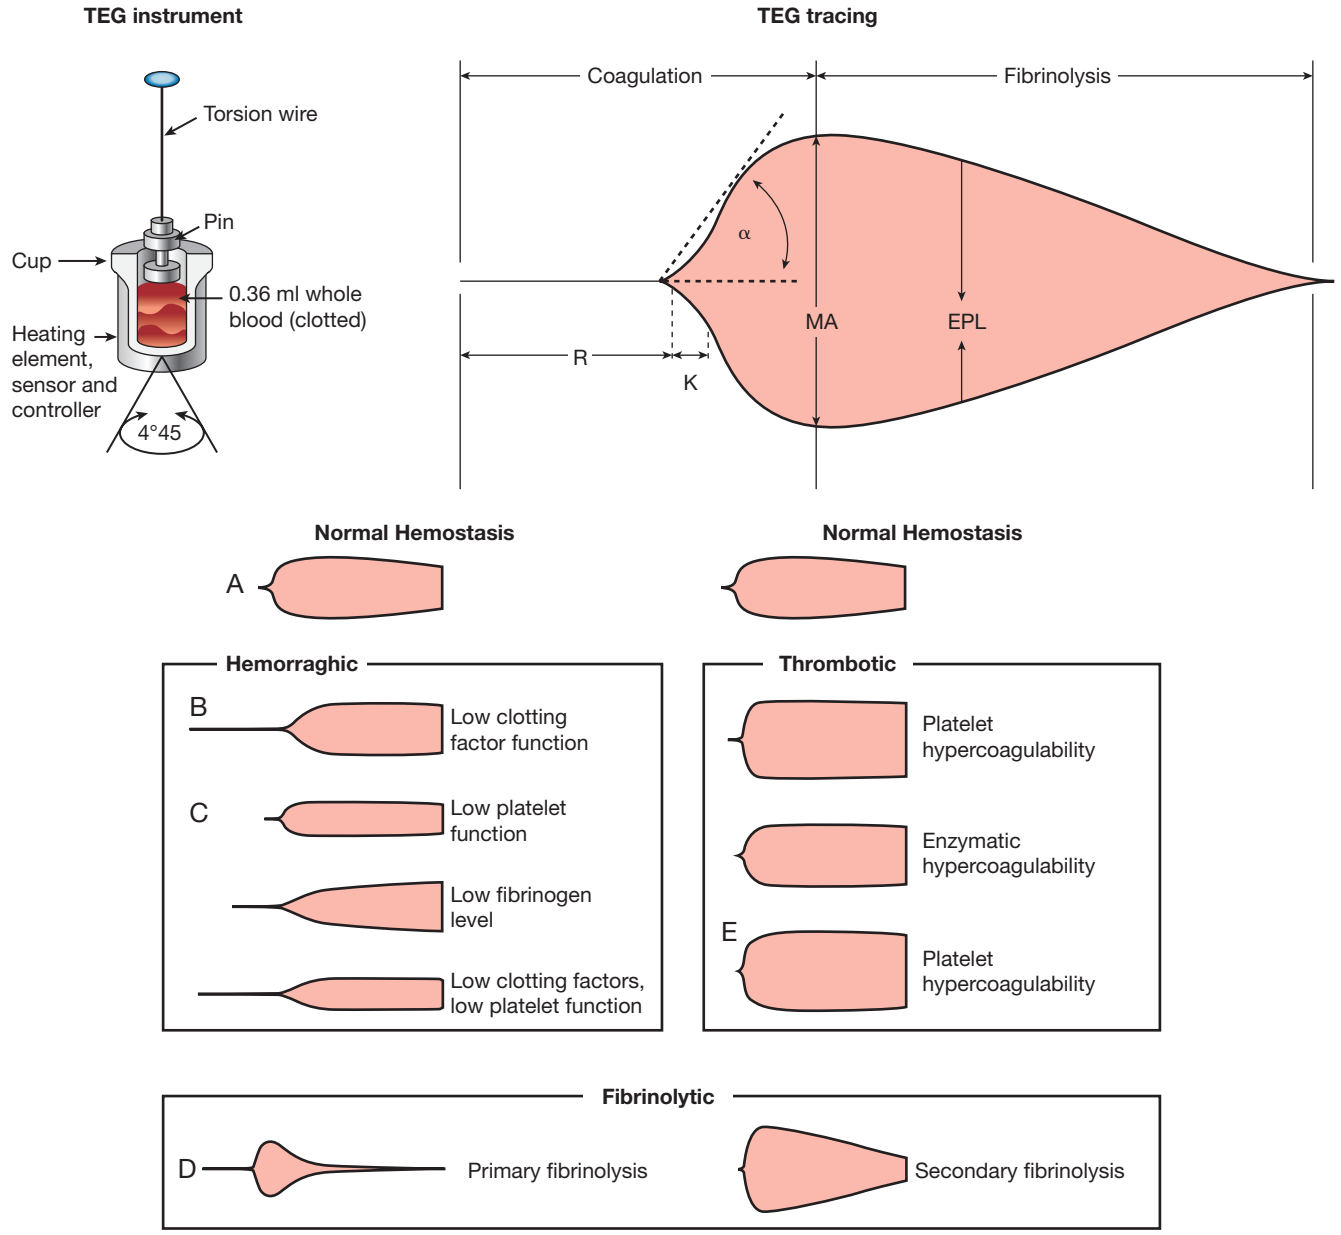

Fig. 22.1 Panel 1 depicts the thromboelastography (TEG) device, in which a cuvette of whole sample blood is incubated with a pin and torsion wire rotates within the sample. The tracing depicted in Panel 2 reflects the **force** required to **spin** the pin **over time** as the fibrin strands form a clot which resists pin movement. R (reaction time) in minutes reflects the latency time to initial fibrin formation. Elevations are typically treated with frozen fresh plasma (FFP) or reversal of anticoagulants, which delay initiation of clot formation. K (kinetics) is the time taken to achieve a clot strength of 20 mm. α is the angle between R and K and measures the speed of fibrin build up and cross-linking, which reflects the availability of fibrinogen; defects are typically treated with cryoprecipitate. TMA (time to maximum amplitude) is another measure of speed to fibrin build up. MA (maximum amplitude) represents the ultimate strength of the fibrin clot and overall stability and is a measure of platelet action and stabilization of the clot. Deficits in MA are typically treated with platelets or ddAVP to augment platelet aggregation. FPL, A30, or LY30 reflects the amplitude of the clot strength at 30 minutes as a measurement of fibrinolysis. Fibrinolytic patterns are treated with TXA typically. (A) Normal TEG tracing. (B) Low clotting factor availability causing a decreased α-angle. (C) various pathological hemorrhagic TEG tracings. (D) Fibrinolytic TEG tracings. (E) Various thrombotic TEG tracings. (From Mauffrey C, Cuellar DO, 3rd, Pieracci F, et al. Strategies for the management of haemorrhage following pelvic fractures and associated trauma-induced coagulopathy. *Bone Joint J.* 2014;96–B(9):1143–1154.[299])

less than 1.5–2 g/L.[68] Topical hemostatic agents such as thrombin spray rely on plasma FIB to effect hemostasis in operative wounds.

Limiting fibrinolysis is another important method to control blood loss during burn excisions. Tranexamic acid (TXA), a synthetic derivative of lysine, has found great utility in treating burn patients. In the landmark CRASH2 randomized controlled trial, Roberts et al. demonstrated a reduction of blood loss and mortality with TXA use in trauma patients.[102] Not only does TXA safely and significantly reduce the mortality rates of trauma patients with, or at risk of, substantial bleeding when administered early in the course of treatment,[103] but its de minimis side-effect profile in conjunction with its low cost and ease of use have

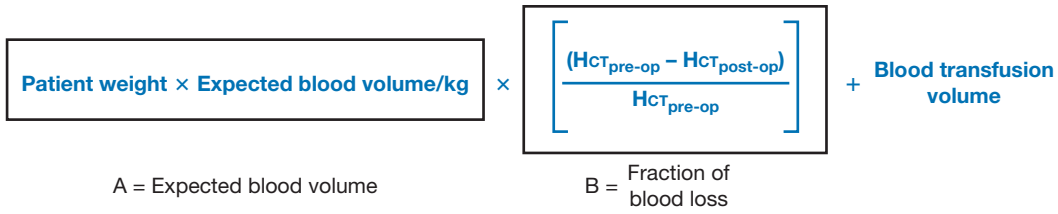

Fig. 22.2 An algebraic formula to estimate surgical blood loss. In the first group of terms, labeled A, the patient's weight is multiplied by the expected blood volume for age: adult men 75 cc/kg, adult women 65 cc/kg, infants 80 cc/kg, term infants 85 cc/kg, and premature neonates 95 cc/kg. The second portion of the equation utilizes preoperative and postoperative hemocrit (Hct) to derive the fraction of blood lost to account for the observed change in Hct. Finally, blood transfused is added in to account for intraoperative transfusion effects.

made it an integral component of resuscitation protocols worldwide.[104] However, the benefits of TXA are seen only when administered within 3 hours of injury; after that window, it has been shown to increase mortality.[65,105] Thus it is most efficacious to treat acute traumatic coagulopathy. Fibrinolysis is less likely to be fully activated the sooner patients receive TXA; fibrinolysis continues unceasingly once activated, and only restoration of endogenous antifibrinolytic elements can then abate the activity.[106] Some practitioners feel that the potential risk is too great for use in patients whose bleeding is not life threatening.[107] Although reports exist highlighting the prothrombotic effects resulting from each antifibrinolytic drug,[65] we advocate the use of TXA perioperatively for large burn excisions.

Transfusion of Blood Cells

Burn patients have many disparate indications for transfusion. In the setting of active operative hemorrhage, the rapid transfusion of pRBC, plasma, and other products is essential to prevent hemorrhagic shock. In the postoperative period, transfusion is necessary to treat blood loss anemia, coagulopathies, and consumptive thrombocytopenias. As a component of resuscitation, plasma transfusion is often required to treat coagulopathies resulting from consumption and under-production of factors, as well as for volume expansion, as discussed in Chapter 8 on the pathophysiology of burn shock and burn edema and in Chapter 9 on fluid resuscitation and early management. Understanding the vastly disparate indications for transfusion in burn patients allows clarity in the urgency and aggressiveness of transfusion used in these patients with ever-changing status.

The first major indication for transfusion is intraoperative blood loss during burn wound excision. The anesthesia team must monitor overall preload while estimating blood loss to prevent hypovolemia and hemorrhagic shock. Surgical control of hemorrhage is critical, but large blood loss is expected, especially in the setting of large burns. Surgical blood loss has been estimated and measured in a variety of ways,[33,108–112] but reports based on surgical and anesthesia team estimates[113] are simple and reliable. Following serial hematocrit value along with hemodynamic markers is a standard method of monitoring blood loss and transfusion success. Various formulae have been developed to calculate the estimated blood loss. Total blood volume is estimated using the patient's weight, preoperative and postoperative Hb, and presumed normal adult Hb of 70 cc/kg. Generally accepted and employed constants are adult men 75 cc/kg, adult women 65 cc/kg, infants 80 cc/kg, term infants 85 cc/kg, and premature neonates 95 cc/kg. Gross initially described the mathematics of the formula in 1983[114]; we have derived an equation estimating allowable operative blood loss with which we estimate blood loss for all our operations.[115] Fig. 22.2 reflects the formula we utilize, and, although patient conditions, such as venous capacitance and changes in vascular tone, can significantly alter blood volume of distribution, this formula has proved the best estimator of blood loss in our experience.

Due to blood type and cross-match expenses and overestimation of operative transfusion needs[47] a preoperative estimate of 1.78 units of pRBCs per 1000 cm^2 of burn wound excised best utilizes blood bank resources.[48] However, even since publication of the prior edition of this book, studies show 25% of patients received cross-match orders exceeding national guidelines, with surgeons being most responsible for this overestimation.[116] Interestingly, change in hematocrit, not Hb, is considered the most reliable indicator for continuing blood loss,[117] and, at admission, is the best predictor of 24-hour blood product requirements,[118] as well as being associated with signs of shock and hemorrhage in trauma patients, both adult[119] and pediatric.[120] Additionally multiple studies have found massive blood transfusion in trauma, surgery, and critical care to be a predictor of SIRS, multiple organ failure, and increased infection and mortality,[74] although it is unclear if the need for significant transfusion is a marker for disease severity rather than the transfusion itself being the etiologic cause.

In the setting of active operative hemorrhage, transfusion rates should match the rate of blood loss. Estimation of ongoing rates of bleeding and matching transfusion rates requires careful coordination between the anesthesia and operative teams. MT protocols have been demonstrably life-saving in these cases.[121] In the setting of operative hemorrhage, the standard transfusion ratio is 1 pRBC to 1 flash frozen plasma (FFP).[121] Electrolytes must be monitored to prevent hypocalcemia instigated by the citrate anticoagulant in the blood products. As was demonstrated in the PROPPR study, major trauma centers were unable to deliver adequate amounts of thawed plasma for MT sufficiently quickly, so a burn team anticipating significant blood loss intraoperatively is well advised to order appropriate amounts of blood products prior to initiating the surgery.[122] With modern rapid infusers, such as the Belmont, capable of transfusing warmed, mixed blood products at rates of 500 cc/min, there is little reason for insufficient transfusion rates during a burn extirpation.

In the ICU, blood transfusions are typically unnecessary to treat or prevent hemorrhagic shock; rather, they are warranted for less emergent indications, such as blood loss anemia, coagulopathy, or volume expansion. Traditionally a defined Hb trigger of 10g/dL or hematocrit of 30%, the "10-and-30" rule, has guided transfusion practices.[123] These triggers continue in many centers worldwide.[123] However large-scale works in critical care literature[124] and smaller, retrospective reviews of adult[125] and pediatric[126] burn patients have established the benefits of a lower, more restrictive transfusion trigger, indicating that some patients had been receiving blood to no benefit.[123] The Society of Critical Care Medicine addressed transfusions in the intensive care setting. For critically ill patients, a restrictive strategy was found as efficacious as the conventional liberal one, so in patients with evidence of hemorrhagic shock, hemodynamic instability, or acutely bleeding, an Hb trigger of less than 7 g/dL indicates for transfusion, and this should be given as single units in the absence of acute bleeding.[127,128] Recent research supports the theory that pRBC transfusions should not rely on the use of standardized triggers, but rather be tailored to the burn patient's blood volume status, acuity of blood loss, and perfusion requirements.[2]

Transfusion needs increase with burn size,[5,47,129,130] as do complications. Each 1% increase in TBSA of burn has a corresponding 6% increase in mortality risk.[131] In a large study of transfusion trends in burn patients, those with 20% or greater TBSA required 13.7 ± 1.1 units, whereas those with 50% or greater TBSA required more than 30 units of pRBCs.[129] Burn patients often receive multiple transfusions; in one study, more than half the transfusions resulted from anemia of critical illness (nonsurgical).[5] While pRBC transfusion rapidly and reliably corrects anemia, it is associated with many of the consequences of bloodborne transmission, including hepatitis B, hepatitis C, and HIV. While the infectious transmission rate has significantly decreased with improved screening methods,[132,133] it is markedly higher in low- and middle-income countries than in high-income countries like the United States (0.1% and 0.003%, respectively).[134] More importantly, pRBC transfusion is associated with immunomodulation, including increased infectious morbidity,[135] with a 13% increase in risk of developing an infection per unit of blood transfused.[129] Muszynski et al. nicely reviewed the extensive hyperinflammatory and severe immunosuppressive effects of blood transfusions and related these data to critical care outcomes.[136]

Other significant consequences include transfusion-related acute lung injury (TRALI), which is difficult to diagnose in burn patients because simultaneous lung injury from resuscitation or inhalation injury may contribute to TRALI diagnostic criteria,[137] and ABO incompatibility, which can be rapidly fatal.[138] Implementation of restrictive-transfusion strategies in which pRBCs are transfused only for hemodynamic instability or at lower Hb concentrations has reduced overall transfusion and infection rates, benefitting both cost and survival.[68,125,126] FFP transfusion is also associated with TRALI[139] in burn patients, and early transfusion of FFP correlates with increased incidence of other deleterious effects post-burn.[140] However by not administering plasma from women with a history of pregnancy, the risk of TRALI from FFP is significantly mitigated,[141] and using pathogen-inactivated plasma reduces the risk of transmitting infectious diseases.[68] The indicators for increased transfusions of FFP and pRBC were high TBSA and use of argatroban anticoagulation.[142]

Except in the setting where MTs are indicated, greater ratios of FFP and platelets to pRBCs correlate to longer ICU stays and higher mortality rates.[143] When high ratios of FFP to pRBC are unable to be transfused, it has been demonstrated that resuscitating patients with a minimum of 1 L crystalloid per unit pRBC leads to improved mortality rates.[144] However, a recent study showed that TBSA burn and patient age independently correlated to mortality, not RBC or plasma transfusions.[142] Blood product resuscitation was not hemostatic, and coagulopathy and thrombocytopenia combined may contribute to intraoperative hemorrhage, which blood product transfusions would be inadequate to correct.[145] Brakenridge and coworkers showed that, despite prior reports of associations between FFP and large-volume crystalloid transfusions with MOD, it was the MT volumes of pRBC that correspond to MOD, not blood products.[146] Blood component ratios failed to predict inflammatory complications, whereas injury severity, sex, and total pRBC volume did.[147] Additionally transfusion of stored pRBC correlates with increased complications due to microparticles released from RBCs able to induce cellular dysfunction.[148] The poor quality of stored erythrocytes has been documented with dynamic microscopy.[149] Furthermore, recent data would suggest different protocols for transfusion in the operating room (acute blood loss) versus in the setting of critical illness (bedside).[150] A series of studies examining different ratios of FFP to pRBC transfusions have yet to demonstrate any difference in transfusion volume for burned pediatric patients.[10,151] Last, it has been demonstrated that transfusion protocols for adults are not efficacious in children;[152] a new score should be developed for transfusions in the burned pediatric population.

Recently, platelet-rich plasma (PRP), in which the platelet concentration is above baseline in blood plasma, has come under consideration for use in transfusing burn patients because its hemostatic antimicrobial effects have shown promise in wound healing in animal studies.[153] The concentration of growth factors and number of platelets dictate the clinical efficacy of PRP.[154] It is not transfusions of pRBCs but rather of platelets that have recently been correlated to nosocomial infections in the critically ill.[155] Platelet transfusion is not without complications because platelets are stored at room temperature, thereby facilitating higher rates of bacterial contamination than for other blood products. One in 1000–3000 platelet units may be bacterially contaminated;[156] one-sixth of these episodes result in a septic event.[157] In a study of blood bank utilization by a burn unit, 15% of all admitted patients received platelets with either pRBCs or FFP.[47,156] Given that cryopreserved platelets demonstrate superior hemostatic activity over liquid platelets, studying the efficacy of storing platelets at cold temperatures for burn units is warranted.[158,159] Last, immediate administration of pRBCs, plasma, and platelets upon admission has been shown to benefit patient outcome.[121]

Commonly coincident with sepsis,[160] thrombocytopenia requiring platelet transfusion is rare in burn patients. Often platelet counts and function are stable unless there is an infectious or septic event. In coagulopathic patients

with hemodynamically significant oozing from wound and donor sites, the administration of platelets and recombinant factor VIIa has been shown to improve hemostasis.[161,162] Of interest, recombinant factor VIIa seems most efficacious at lower temperatures.[163] Prothrombin complex concentrate (PCC) is gaining utility in treating coagulopathies derived from medications such as warfarin or argatroban and now has an expanding role in treating trauma and perioperative coagulopathies.[164] PCC is also gaining use as an adjunct or replacement for FFP to reverse factor-deficient coagulopathies and expedite operative intervention.[165,166]

Venothromboembolic Prophylaxis

Once burn patients recover from TIC they develop an elevated risk of venous thrombosis and thromboembolism. A recent study indicated that platelet-derived microparticles (PMPs) are responsible for the hypercoagulability seen immediately post-burn, particularly the decline in platelets, and that an ADP-induced platelet activation was crucial to the enhanced clotting seen a week post-burn.[94] Additionally, Levin et al. showed that thermal trauma incites an increase in the number of erythrocyte-derived microvesicles. These, in turn, increase the procoagulant activity while reducing the antithrombin and fibrinolytic activity of erythrocytes, thereby contributing to post-burn hypercoagulability.[167] Furthermore, the typically defined criteria for hypercoagulability described in Virchow's triad exist in all major burn patients: venous stasis from reduced activity such as bed-rest, endothelial activation or injury from shock state and inflammation, and hypercoagulability from acute-phase reactants.[168,169] Meizoso recently characterized the detailed pathophysiology of hypercoagulability in burn patients, concluding that larger-scale studies are needed to protocolize safe and effective thromboprophylaxis.[170] A typical burn ICU patient will be high or highest risk based on the American College of Chest Physician guidelines and Caprini score, indicating both mechanical and chemical prophylaxis.[168] In a 2005 survey of 84 U.S. burn centers, 76.1% routinely provided VTE prophylaxis, 31 utilizing subcutaneous unfractionated heparin (UFH), 16 low-molecular-weight heparin (LMWH), and 1 a heparin infusion.[171] In a 2013 review of their institution's patients in a single year, Mullins et al. reported an incidence of 113 DVTs in 86 patients for an incidence of 5.92%.[172]

The modalities that underlie VTE prophylaxis are mechanical and pharmacological prophylaxis. Mechanical treatments, such as intermittent pneumatic compression, aim to prevent venous pooling and mechanically pump blood from the extremities. These devices also stimulate fibrinolytic pathways, which further decreases the risk of venous thrombosis.[173,174] Chemical prophylaxis, such as heparin, is intended to reduce thrombosis by interfering with the coagulation cascade. Prophylaxis is often complicated in the burn population. For instance, mechanical prophylaxis is often impractical or impossible due to donor sites or wounds on the legs. Pharmacoprophylaxis agents can have inconsistent effects due to altered pharmacokinetics and pharmacodynamics leading to either venous thrombosis or hemorrhage.

Pharmacologic anticoagulants fall under four major classes: antithrombin-III (AT-III) activators, such as UFH; factor X inhibitors, such as LMWHs; direct thrombin inhibitors (DTIs), such as argatroban; and vitamin K antagonists, such as warfarin. The ideal phamacoprophylactic agent for a burn patient has a short half-life allowing dose titration and operative interventions, the ability to monitor resulting effects with laboratory values, an available reversal agent, and limited nursing workload. Warfarin is not used for prophylaxis in hospitalized burn patients due to its long half-life, which requires days to take effect and reestablish normal coagulation, all of which complicates operative management.[175] DTIs carry a high risk of bleeding and are irreversible so typically are employed only in the rare setting of antibody-confirmed heparin-induced thrombocytopenia (HIT) when treating burn patients.[176] Most VTE prophylaxis and treatment in burn patients are carried out using UFH or LMWH.

UFH exerts the principal part of its action by binding to and activating AT-III, the most abundant anticoagulant in the plasma. AT-III, in turn, breaks down activated thrombin, thereby terminating the propagation of coagulation. A minor portion of AT-III's action is attributable to inactivating factor X, the central factor joining the intrinsic and extrinsic coagulation cascades. Anticoagulant activity can be monitored, with a PTT targeting time of 30–41 seconds for prophylaxis and 60–80 seconds for therapeutic anticoagulation.[53] UFH can be administered either subcutaneously or via a continuous intravenous infusion. Subcutaneous dosing of 5000 units every 8 hours is considered an effective prophylactic dose; however in burn patients with unpredictable subcutaneous absorption and variable creatinine clearances due to hypermetabolism, this route is far less predictable. In our critical care population, we prefer a low-dose UFH infusion targeting a PTT of 30–41 seconds. With this protocol, we are able to provide a verifiable prophylactic effect regardless of the physiological state of the patient, although this comes at the cost of greater nursing utilization. UFH also has the benefit of a short half-life, and, in the setting of hemorrhage, it is reversible with protamine. There is a risk of development of HIT with this medication, and platelet levels must be monitored. Should thrombocytopenia develop in a burn patient, all heparin administration should be held until antibody titers can be returned. Because there are a myriad of causes of thrombocytopenia in burn patients, conversion to a secondary agent, such as a DTI, ought to be considered carefully on a case-by-case basis given the increased risk of bleeding associated with these medications and their lack of reversal agents.[177]

LMWH exerts its principal effect by inactivating factor X. Anticoagulant activity can be monitored with an anti-factor Xa level target of 0.2–0.5 IU/mL for prophylaxis and 0.5–1.2 IU/mL for therapeutic anticoagulation. In a review of practice at a large academic medical center, levels were determined to be insufficiently monitored and frequently outside the intended range in patients weighing less than 45 kg, more than 150 kg, or with impaired renal function.[178] These medications are delivered by subcutaneous injection and, as such, carry pharmacodynamic concerns regarding inconsistent absorption. There are also oral factor Xa inhibitors; however, there is not currently sufficient data nor experience to advocate their prophylactic

use in the acute burn patient for VTE prophylaxis. The half-lives of these agents are longer than UFH, and they only require dosing every 12–24 hours, which reduces nursing workload but increases the duration of bleeding, should it occur. In particular, Fondaparinux has a 17- to 21-hour half-life and thus is particularly prone to cause bleeding in our experience with burn patients; the use of fondaparinux is ill-advised. When these medications are chosen for burn patients, factor Xa levels should be monitored due to unpredictable subcutaneous absorption and large changes in creatinine clearance from hypermetabolism or renal impairment, although these pharmacologic issues are most often studied related to antibiotic dosing.[179] There are currently no reversal agents for this class, although scant data suggest that PCC may limit bleeding.[180]

There are circumstances in which VTE prophylaxis may need to be held in a major burn patient, such as bleeding. In these instances, an inferior vena cava (IVC) filter should be considered to reduce the risk of fatal pulmonary embolism. Furthermore, several centers routinely monitor patients for DVT formation with a weekly Doppler exam.

Hematopoiesis

Given the myriad of risks incurred to glean the benefits of transfusion, it is preferable for patients to generate their own replacement blood. Hematopoiesis is the production of the more than 10 distinct mature peripheral blood cell types.[181] Well-regulated hematopoietic differentiation is vital to generate all blood cells necessary for defense against invasive pathogens, gas exchange, and wound healing.[182] This process begins in the yolk sac, continues in the placenta and the aorta-gonad-mesonephros region, progresses to the fetal liver until finally occurring throughout postnatal life in the bone marrow.[183,184] Table 22.1 details the roles of growth factors and cytokines in directing hematopoiesis. Unfortunately, production is often insufficient to meet a burn patient's RBC requirements in the setting of large excisions and grafting procedures combined with critical care. This stems from the large volume of blood loss seen in burn surgeries as well as the fact that thermal trauma directs hematopoiesis away from erythropoiesis and toward immune cell production.

Two pathways exist for hematopoiesis: myeloid and lymphoid. The myeloid lineage ultimately produces RBCs and the cells comprising the innate immune system (e.g., platelets,[185] macrophages, neutrophils, eosinophils, and basophils). The lymphoid lineage forms the cornerstone of the adaptive immune system by generating B and T cells. Dendritic cells (DCs) and natural killer (NK) cells develop from either lineage. While only half the bone marrow is hematopoietically active,[186] an estimated 200 billion erythrocytes (0.5–2% of total RBCs),[187,188] 100 billion leukocytes, and 100 billion platelets (~7% of total platelets) are nonetheless produced daily in a healthy adult.

Accounting for one in every 10^5 nucleated cells in the bone marrow of a healthy adult, hematopoietic stem cells (HSCs) are the fountainhead of the hematopoietic hierarchy. Significantly they are the only cells in this system able to be both self-renewing and multipotent (able to differentiate into all potential blood cells).[181,189–192] The two variants of HSCs, long-term (LT) and short-term (ST), are distinguishable by more than their divergent self-renewal and differentiation capacities.[193–195] Aptly named, LT-HSCs remain permanently self-renewing cells with minimal response to physiologic stress and exhibit a total dearth of lineage-specific surface markers.[182] ST-HSCs derive from LT-HSCs and affect their production and differentiation depending on the existing pathologic state in their niches. ST-HSCs give rise to multipotent progenitor cells (MPPs),[196] which lack self-renewal potential but remain able to differentiate

Table 22.1 The Roles of Growth Factors and Cytokines in Hematopoiesis

Growth Factor or Cytokine	Role in Hematopoiesis
Stem cell factor	Essential for hematopoietic stem cell proliferation and differentiation Activates the c-*kit* receptor
Flt-3 ligand	Enhances multipotent progenitor, early lymphoid, myeloid, natural killer, and dendritic cell proliferation Activates the Flt-3/flk-2/CD135 receptor
IL-3	Plays a role in hematopoietic stem cell, myeloid, and erythroid cell line expansion
IL-6	Increased production following burn injury and infection Essential for expansion of hematopoietic stem and progenitor cells
G-CSF	Stimulates granulocyte proliferation in the bone marrow and augments immune activity of cells in blood Increased immediately following burn injury and in response to infection RhG-CSF use is not indicated for use in burn patients
CSF-1 or M-CSF	Essential for monocyte and macrophage differentiation Increases the survival of monocytes and macrophages
GM-CSF	Regulates the proliferation and differentiation of hematopoietic progenitors Enhances antigen presentation by DCs and macrophages Prophylactic administration accelerates bacterial clearance and killing
IL-7	Necessary for both engagement into lymphoid lineage and maintenance and expansion of lymphoid cells
Erythropoietin	Stimulates erythroid proliferation and prevents apoptosis to increase erythrocyte production May have a role in tissue protection via a related receptor rhEPO has not been shown to benefit burn patients
Thrombopoietin	Enhances megakaryocyte proliferation and reduces apoptosis to increase platelet production May increase following burn injury and contribute to thrombocytosis Evolving role in stem and progenitor cell proliferation

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-monocyte colony-stimulating factor; *IL*, interleukin.

into every hematopoietic lineage.[183,197,198] The progression of hematopoiesis, from stem cells to progenitor groups to terminally differentiated cells (Fig. 22.3), allows for the rapid amplification of cell production by the upstream proliferation of stem cells.[199] The hematopoietic hierarchy is not without controversy; other suggested hematopoietic progressions[200,201] differ in the branch points at which certain progenitor populations lose lineage potential[202] or advocate that select cell groups have the potential to dedifferentiate and enter a different lineage.[203] MicroRNAs (miRNAs), growth factors, and cytokines present in the bone marrow influence the commitment patterns of these progenitor cells, yielding mature, fully differentiated bone marrow cells that later populate the bloodstream.

Up-regulation of fetal liver kinase-2 (Flk2) is a shared feature of all lineages of HSC differentiation[203] as is the epigenetic regulation exerted by microRNAs on every stage of hematopoiesis.[204] The expression of a limited set of transcription factors, controlled by growth factors, cytokines, and miRNAs present in the bone marrow milieu, control lineage commitment, cell fate,[205–207] and, ultimately, the composition of cells in the bloodstream. As patients age, there is an HSC shift toward myeloid potential.[208]

Bone marrow hematopoiesis demonstrated an overall increase in the HSC population (identified as LSKs [Lineage^{negative}, Sca-1^{+} cKit^{+}] in mice) as early as 48 hours following burn injury,[209] and the expansion of LSKs persisted for at least 21 days post-burn.[210] Despite their multilineage potential (Fig. 22.3), LSKs do not differentiate evenly across all lineages. Only ST-HSCs and MPPs increase, with no significant change in LT-HSCs.[211] In the progenitor compartment, there is a significant increase in granulocyte-monocyte progenitors (GMPs) with a concomitant decrease in megakaryocyte-erythroid progenitor (MEP) production. Given the hierarchical nature of hematopoiesis, changes in ST-HSC and MPP production, and the lineage shift toward greater GMP and lesser MEP production may herald the overall problems present after burn injury: erythropoietic production (anemia) and myeloid function (immune dysfunction).[209,210] In a recent work, myelo-erythroid commitment following thermal insult was shown to be under β-adrenergic control via MafB regulation, indicating that burn injury perturbs the hematopoietic paradigm.[212] For more details please refer to Chapter 23 on the significance of the hormonal, adrenal, and sympathetic responses to burn injury. Further work on HSCs and progenitor cell responses may provide avenues for early therapeutic intervention, which may ameliorate the negative hematopoietic consequences of burn injury.

HSCs have considerable potential in treating blood disorders.[213–215] The utilization of these cells as a possible therapy for the anemia or immune dysfunction present in severely burned patients is currently not in progress. Rea and colleagues assayed the cells present in the healing burn wound, finding that hematopoietic cells were merely transient and predominantly present only in the acute inflammatory phase, with a small number persisting in the healing dermis.[216] Ascertaining the long-term hematopoietic response to various degrees of burn wounds will be crucial in developing HSC-based therapies for burn injuries.

Due to burn-associated anemia, erythropoietin (EPO) levels should be increased during treatment and recovery from the burn injury. However, contrary to the expected EPO response to anemia, there is limited increase in EPO following burn. Earlier studies had small sample sizes, used unreliable urine bioassays, and could not overwhelmingly support an appropriate EPO response, leading to contradictory results.[217,218] Later comparison of serum bioassays and radioimmunoassays showed no correlation between the two methods, and their results suggested significant differences between the sensitivity of these tests.[219,220] More recent larger studies using serum radioimmunoassays demonstrated an increase in EPO in response to decreased Hb concentrations but inconsistent erythropoietic response to this EPO increase.[130,221]

While only erythroid-committed cells in the bone marrow possess the EPO receptor, a related EPO receptor and response to EPO have been identified in nonhematopoietic tissues, including neurons, glial cells, retina, heart, skeletal muscle, kidney, ovary, uterus, testis, and endothelial cells.[222–225] Consequently the ability of EPO to reduce apoptosis and prevent damage to these tissues has been explored. RhEPO in particular can reduce apoptosis after cerebral ischemia[226]; protect the myocardium and promote remodeling following myocardial ischemia, allowing for restoration of cardiac function;[227,228] and protect against renal injury from ischemia, improving renal function.[229] Despite these findings and the expected erythropoietic response to rhEPO, its use in burn patients has not been substantiated.

Recombinant human erythropoietin (rhEPO) helps augment erythropoiesis in patients with chronic anemias (e.g., end-stage renal disease and HIV with antiretroviral use), decreasing transfusion rates and improving quality of life. To decrease transfusion rates and correct the anemia of critical illness, multiple trials have explored rhEPO use in the critically ill, including burn patients. Unfortunately both large clinical trials and meta-analyses of critically ill medical, surgical, and trauma patients show no significant reduction in transfusion rates with rhEPO use.[230,231] JM Still and others performed a study of rhEPO in burn patients resulting in no significant increase in hematocrit percentage or decrease in transfusion rates.[232–234] Critically ill patients may possess a resistance to EPO,[235] which may be a function of antierythropoietin antibodies[236] or a relative reduction in erythropoietic response due to less EPO-responsive erythroid precursors after burn-induced hematopoietic hierarchy shift.[237] As such, rhEPO is not indicated for use in burn patients. However a recent study showed that rhEPO significantly reduced the markers of multisystem organ failure and, in the lung, specifically reduced apoptosis and histological signs of tissue injury in mice with second-degree scald burns.[238] While the use of rhEPO has been shown to increase the rate of reepithelialization in scald injury and decrease time to close the wound when injected directly into the injury site,[239] we still cannot recommend the use of rhEPO in burn patients to decrease transfusion rates. These new data highlight the potential use for other burn-induced complications beyond the purview of this chapter.

MYELOID GROWTH FACTORS

Granulocyte Colony-Stimulating Factor

Granulocyte colony-stimulating factor (G-CSF) is the primary growth factor responsible for the proliferation and

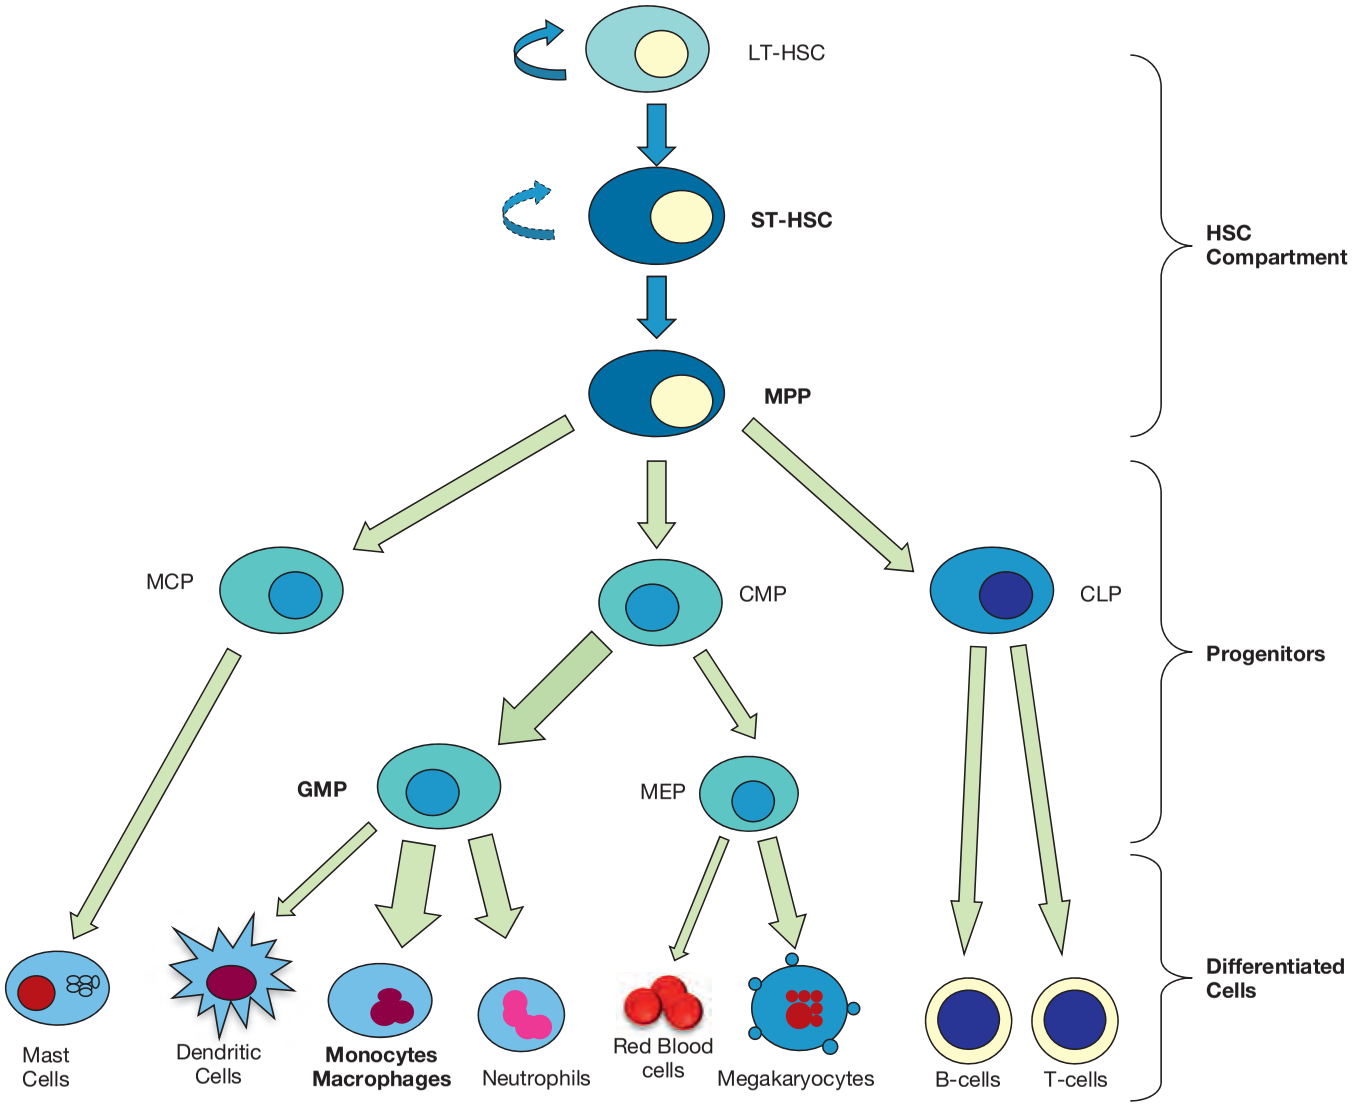

Fig. 22.3 A Hierarchical Model of Hematopoiesis The model here shows the three compartments of hematopoietic cells: stem cells, lineage-commited progenitors, and terminally differentiated cells. The first step in lineage commitment occurs at the branch point from multipotent progenitors (MPPs) to myeloid (CMP, common myeloid progenitor) or lymphoid lineages (CLP, common lymphoid progenitor) or MCP, mast cell progenitors). CLPs differentiate into T and B cells. The CMP population can branch in to GMPs (granulocyte-monocyte progenitors) or MEPs (megakaryocyte-erythroid progenitors), which then lead to their respective terminally differentiated populations.

differentiation of bone marrow granulocyte progenitors into mature granulocytes.[240,241] G-CSF is produced by monocytes, fibroblasts, and endothelial cells stimulated to produce G-CSF in response to inflammatory cytokines (tumor necrosis factor-α [TNF-α], interleukin-6 [IL-6], IL-1).[222] Although it stimulates the production of neutrophils in the bone marrow, in the periphery G-CSF augments the bactericidal activity of neutrophils by priming the oxidative burst, increases neutrophil half-life by preventing apoptosis, and down-regulates the overall inflammatory response by decreasing the cytokine production of monocytes and macrophages.[242] In various animal models of burn and burn sepsis, the benefits of G-CSF were shown to be the killing of translocated bacteria,[243] regulating the pro-inflammatory response to injury,[244] enhancing neutrophil chemotaxis,[245] and improving survival in combination with antibiotic therapy.[246,247]

At baseline, there are very low levels of G-CSF present in the blood. However following an inflammatory or infectious process, G-CSF levels dramatically increase. Following a burn injury, G-CSF levels in the blood are initially increased and then gradually decline to baseline 3–4 weeks following injury.[248–250] The initial increase in G-CSF may prime the neutrophilic component of the immune response for future bacterial insult. However, the immune dysfunction seen following burn injury or burn sepsis may be related to hyporesponsiveness of bone marrow progenitors and peripheral neutrophils to G-CSF.[251] Recent studies suggest that the increase in serum G-CSF post-burn corresponds to an increase in the resistance to infection, activation of innate immune responses, and prioritization of bone marrow responses, indicating that it plays a central role for burn patient survival, especially in the setting of infection.[252]

Administration of recombinant human G-CSF (rhG-CSF) to burn septic animals prior to the initiation of septic insult has been shown to improve the survival rate of burn septic mice.[245,246,253] However administration of G-CSF 24 hours after the onset of septic insult had little effect on survival.[254,255] Despite the potential benefit of exogenous G-CSF administration on the inflammatory and infectious response during burn injury, the use of rhG-CSF (Filgrastim)[256] is not indicated in the treatment of burn patients.

CSF-1

CSF-1 (M-CSF) is a preeminent growth factor for the differentiation, proliferation, and survival of monocytes and macrophages.[257] It also stimulates chemotaxis, cytokine, and superoxide production in macrophages.[258,259] Hume et al. first demonstrated that administration of CSF-1 to mice resulted in monocytosis and an increase in peritoneal and tissue macrophages.[260] In response to burn injury, CSF-1-responsive GM-CFU are increased in the bone marrow and this results in enhanced monocytopoiesis.[261] The underpinning of this monocytopoiesis post-burn arises from increased expression of CSF-1 receptors in ERMP-20$^+$ bone marrow compartment, which comprises monoblasts and promonocytes,[261] which begins to be initiated much earlier at progenitor level in GMPs[209] and CMPs.[210] Additionally burn injury and sepsis also alter the inflammatory cytokine phenotype of CFU-GM-derived macrophages in that they predominately result in hyporesponsive macrophages.[262,263] Similar hyporesponsiveness in monocytes has been demonstrated in trauma patients.[264] These findings provide a plausible mechanism and a role for CSF-1 and its cognate receptor interactions in monocyte/macrophage biology following burn injury.

GM-CSF

Granulocyte-monocyte colony-stimulating factor (GM-CSF) regulates proliferation and differentiation of hematopoietic progenitor cells, as well as modulating the function of mature leukocytes.[265] GM-CSF enhances the antigen-presenting capacity of macrophages and DCs, increases complement-mediated phagocytosis, and augments bacterial killing by both innate immune cells[266,267] and chemotaxis of leukocytes.[268,269] GM-CSF is produced by a variety of cells, including macrophages, B lymphocytes, pulmonary epithelial cells, neutrophils, and stromal cells.[270,271] In response to burn injury, bone marrow GM progenitors respond by producing more GM-CFU colonies .[261] Administration of GM-CSF prior to burn injury and *E. coli* sepsis enhanced bacterial clearance and survival of experimental animals.[272] Similarly, GM-CSF improved the survival of neonatal rats when administered prophylactically prior to *S. aureus* infection.[273] However, GM-CSF administration after the onset of infection did not provide a survival benefit.[274] While the inactivation of GM-CSF or GM-CSF receptor genes in mice did not alter the number of granulocytes and monocytes, these animals exhibited significant alveolar macrophage dysfunction. Furthermore GM-CSF-deficient mice are very susceptible to pulmonary group B streptococcal infection.[271] Cioffi et al. studied the effects of GM-CSF in burned adults. They found a 50% increase in mean leukocyte counts after the first week post-burn in treated patients. Application of GM-CSF did increase myeloperoxidase activity (cytosolic oxidative function) 1 week post-burn, but these levels returned to unburned control levels during weeks 2 and 3 of treatment, while remaining elevated in the untreated patients. Extracellular oxidative function, measured by superoxide production, was initially depressed in both burned groups compared to nonburned controls, although GM-CSF-treated patients demonstrated a return to nonburned control levels after week 1, while these levels remained below control levels in the untreated burn patients.[275] In a multicenter clinical trial, administration of rhGM-CSF in hydrogel to deep second-degree burn wounds has been shown to be both safe and to accelerate wound healing.[276,277] A subsequent study found topical application of GM-CSF reduced healing time of partial-thickness burn wounds by 5.1 days compared to standard treatment with no significant increase in adverse effects. The same study examined two other growth factors, fibroblast and epidermal, and found a decrease in healing time by 5.02 and 3.12 days, respectively, as well as improvement in scar color, height, pliability, and vascularity.[278] Further research examining the efficacy of topical administration of rhGM-CSF on deep partial-thickness burn wounds similarly found accelerated wound healing with no difference in adverse reactions.[279] These data corroborated other studies that likewise found accelerated wound healing with application of topical rhGM-CSF and no difference in adverse reactions in adult[280] and pediatric burn patients.[281] Given the promising data,

cautious increasing use as a topical treatment to promote wound healing is warranted, but further examination of rhGM-CSF, along with fibroblast and epidermal growth factors, is also recommended.

LYMPHOID GROWTH FACTORS

Several growth factors/cytokines contribute to the formation of lymphoid cells; the most prominent and well studied is IL-7. The IL-7 receptor is unique to lymphoid cells. Thus IL-7 is the cytokine/growth factor that influences the expansion of this cell line. IL-7 receptor engagement is essential not only for lymphoid cell proliferation and survival but also for HSC differentiation into the lymphoid lineage. The IL-7 receptor enhances lymphoid cell survival through maintenance of Bcl-2.[282] Bone marrow stromal cells and the thymus predominantly produce IL-7. T cells are unique since their maturation takes places in the thymus as opposed to the bone marrow, and they undergo a process of positive and negative selection dependent on both IL-7 activation and expression of the transcription factor Notch1.[283] Alterations in IL-7 production, in addition to other cytokines, can negatively impact survival after inhalation injury.[284] Additional growth factors/cytokines contributing to lymphopoiesis include IL-2, IL-15, and IL-23.

MEGAKARYOCYTE GROWTH FACTORS

Megakaryocyte and platelet production are regulated by thrombopoietin. Similar to EPO, thrombopoietin enhances megakaryocyte progenitor proliferation by amplifying cell-cycle regulators and preventing apoptosis.[222] It is the only growth factor necessary for proliferating megakaryocytes and their progenitors.[285] Unlike erythropoietin, thrombopoietin has a synergistic role with other growth factors and cytokines in the maintenance and proliferation of HSCs[286] and can be used in their expansion.[287] Thrombopoietin stimulates platelet release from the bone marrow and in the periphery, thereby up-regulating platelet function and aggregation.[288] Produced in the liver, kidney, skeletal muscle, and stromal cells of the bone marrow,[222,289] thrombopoietin production may be increased in response to increased IL-6 production.[290] Given the elevated IL-6 levels present following burn injury, IL-6-induced thrombopoietin release may be responsible for the thrombocytosis often seen immediately post-burn.[291] Elevated levels of thrombopoietin, and subsequently platelet activation, may be present following burn injury.[292] The evidence from a recent study would support the notion that thrombopoietin blockade could help prevent organ damage in burn patients with sepsis.[293]

TRANSCRIPTION FACTORS

While growth factors control hematopoietic cell fate, the development of terminally differentiated cells is under the control and coordination of a limited set of transcription factors. Ultimately specific sequential and temporal gene expression patterns dictate hematopoietic commitment. These genetic processes are governed though modulations in the rate of gene transcription, which are accomplished through the binding of DNA-binding proteins or transcription factors to specific regions on a gene.[294] Transcription factors are nuclear proteins that act as control points in the conversion of a gene to a functional protein.[294] Since many key proteins are turned over rapidly to meet the changing needs of the tissues, a complex system of cell signaling architecture, with the final common pathway of gene transcription, must exist to produce bioactive proteins on demand. Since cells respond to several signals simultaneously, and many ligand–cell interactions stimulate similar proximal signals, tight control of transcriptional initiation must exist for the proper orchestration of cellular responses.

The role of transcription factors in hematopoietic cell fate is an evolving topic of study. The lineage-restricted proliferation and differentiation program of hematopoiesis is achieved through switching on and off specific sets of genes in response to cell signals. Since thermal injury and sepsis are accompanied by hematologic and hematopoietic changes that determine the overall pathophysiological response of burn patients, it is reasonable to assume that transcriptional regulation of hematopoietic developmental genes play a significant role. It is known that GATA-1, sct/tal1, and Klf1 form the transcriptional core of the erythroid lineage and are all expressed by the earliest hematopoietic progenitors.[295] The relationship between transcription factors is complex because they are not independent of one another but demonstrate antagonism. In fact, the inability of one transcription factor to suppress the other has been linked to the development of hematologic malignancies. However little is known about hematopoietic transcription factor changes following pathologic injury, even though they may control the dramatic hematopoietic shifts following severe trauma and burn injury. Given the importance of these transcription factors to cell fate and the significant shifts in lineage commitment patterns, knowledge of these transcription factors and their roles in hematopoiesis may help in providing a foundation for future reference. Furthermore recent studies indicating the poor correlation of animal models to humans with regards to transcriptional response after burn/trauma/endotoxemia highlight the need for medical research to shift from a reliance on animal models,[296] especially mouse models,[297] although the clinical translation efficacy is debated.[298]

Conclusion

Hematology plays a major role in burn care. Patients suffer from anemia due to RBC losses in surgery as well as the anemia of critical illness. Operative hemostasis is important both to limit RBC loss and prevent shock. Coagulopathies develop due to factor consumption and insufficient production as well as hypothermia. Transfusion of various blood products is critical to the management of patients. Hematopoiesis is directed away from erythropoiesis to the production of the immune cells vital to fight off invading microbes and heal wounds. Venous thrombosis becomes a major risk in these critically ill patients, adding another mortality risk. Hematologic management is a central component of burn critical care and ought to be carefully considered.

23 Significance of the Hormonal, Adrenal, and Sympathetic Responses to Burn Injury

DEREK CULNAN, CHARLES VOIGT, KAREL D. CAPEK, KUZHALI MUTHUMALAIAPPAN, and DAVID HERNDON

Introduction

The endocrine system is central to coordinating the systemic response to burn trauma (Table 23.1). Pathological and compensatory changes are seen in the hypothalamic-pituitary-adrenal (HPA) axis, thyroid, pancreatic, and gonadal hormonal secretions. These changes act in concert with the humoral effects of cytokines and immunological mediators discussed in the chapters on burn edema (Chapter 8) and multisystem organ failure (Chapter 31). They mediate the innate adaptive (stress) response critical to survival in patients, particularly those who recover sans medical treatment. However in patients receiving medical treatment, they often prove maladaptive. Understanding these fundamental responses is critical to the appropriate application of critical care to burned and traumatized patients.

Normal Hypothalamic-Pituitary-Adrenal Axis

The physiologic response of the HPA axis begins with the hypothalamic release of corticotrophin-releasing hormone (CRH) into the hypophyseal portal system, which mediates the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary. This, in turn, stimulates the synthesis and release of cortisol from the adrenal cortex. The situation is more complex because the hypothalamus's afferent and efferent connections are numerous and diverse in physiological effect. The hypothalamus is the fountainhead of the autonomic nervous system, being its most rostral component. Hypothalamic nuclei originate central outflow, primarily via the dorsal longitudinal fasciculus, to numerous caudal central autonomic centers (pain modulation, heart rate, respiration, blood pressure, salivation, and the dorsal motor nucleus of the vagus) and to the intermediolateral cell column of the thoracic cord, which includes sympathetic nervous system (SNS) afferents to the adrenal glands. Hypothalamic stimulation thus initiates the release of epinephrine and norepinephrine from the chromaffin cells of the adrenal medulla, which essentially are modified postsynaptic neurons. The action of these hormones and neurotransmitters is traditionally thought to facilitate adaptation to changing conditions. As the terminal signal transducer of the global stress response, the adrenal glands function as two distinct parts: the cortex that produces corticosteroids and the medulla that secretes catecholamines. Both are critical to orchestrating the systemic "storms" required to survive a massive injury.

The cellular and biochemical pathways through which catecholamines work these organism-level alterations are an area of active study. We will discuss the pathological alterations in these systems and how they relate to modern critical care and the remainder of the endocrine response.

Strong Sympathetic Activation Following Burn Trauma

The catecholamine surge following burn trauma was delineated in landmark papers in 1957 demonstrating marked elevations in 24-h urine levels of norepinephrine and epinephrine proportional to burn size, highest in the first 3 days and remaining elevated for weeks.[1,2] Herndon et al. repeated these studies, finding sustained elevation in urinary epinephrine and norepinephrine levels past 35 weeks in pediatric burn patients.[3,4] Jeschke et al. subsequently demonstrated that cortisol, catecholamines, and hypermetabolism are significantly elevated up to 3 years after severe burn injury.[5] In light of the decades of evidence for sympathetic activation following thermal injury, it is critical to understand the resultant physiologic effects.

CARDIOVASCULAR RESPONSE

The chapters on multisystem organ failure and shock describe the physiology of the "ebb" phase from distributive shock and myocardial depression in which cardiac function is depressed. By 48 h post-burn the myocardium becomes hyperdynamic in a β-adrenergic–mediated manner transitioning to the "flow phase."[4,6] Even small burns are associated with significant changes in cardiac function and long-term pathologic changes.[7] One sympathetic reflex arc begins when hypotension stimulates baroreceptor (carotid sinus and aortic arch) afferent nerve activity, with resultant increases in efferent sympathetic outflow. This sympathetic signal for peripheral vasoconstriction and consequent increase in peripheral vascular resistance is mediated in part by the nerve-stimulated release of norepinephrine. Angiotensin II (AII) and arginine vasopressin (AVP) also act to

Table 23.1 Influence of Catecholamines on Cardiovascular, Metabolic, and Immune Response to Thermal Injury

Physiologic Variable	Sympathetic-Mediated Change Following Burn Injury
Resting metabolic rate	Increase[238] Increase[29] Increase[25] Increase (in vitro)[171]
Proteolysis	No change (urea production)[30] No change (protein oxidation)[238] Decrease[39]
Glucose production and oxidation	Decrease secondary to increase in lipid catabolism[29,239] No change[238]
Glycogenolysis	Increase (indirect evidence via cAMP)[240]
Gluconeogenesis	Increase (indirect evidence via cAMP)[240]
Lipolysis	Increase[30] Increase[238] Increase[29] Increase[32]
Cardiac output	Increase[29] Increase[30]
Peripheral vascular resistance	Unknown
Heart rate	Increase[39] Increase[30]
T-cell number and function	Unknown
B-cell number and function	Unknown
Neutrophil number and function	Decrease[71]
Monocyte number and function	Increase (indirect; clonogenic potential)[241] Increase (indirect; clonogenic potential)[242] Increase[71,243]

Citation of studies from the current literature suggesting that sympathetic activation is involved in changing the listed physiologic variables following thermal injury.

increase vascular tone.[8,9] Additionally a complex interplay of AII and catecholamines further modulates vascular tone.[10] Concurrently AVP has been shown to reversibly depress myocardial function in the isolated heart. AVP and catecholamine overstimulation may thus contribute to myocardial depression following burn injury early in the compensation of the "ebb phase."[11,12]

As the heart transitions to the "flow phase" within 48 h after insult, sympathetic outflow is likely an important driver in maintaining supranormal cardiac function during recovery from thermal injury. In a group of burned patients undergoing visceral blood flow and metabolic measurements, the average cardiac index was 8.2 +/−0.5 L/m^2 min.[13] In the same study, liver and kidney metabolic and blood flow measurements were also conducted, and all were found to be elevated. These data allude to a supraphysiologic circulatory need requisite for recovery from severe burn injury. Guillory and Finnerty reviewed the menagerie of animal studies demonstrating the centrality of β-receptor dysfunction in mediating this cardiac pathophysiology and have given mechanistic insight into the efficacy of modern burn therapy with β-blockade.[6]

The sympathetic surge continues long after volume status is restored and baroreceptor signaling ends. Despite elevated levels of circulating norepinephrine and epinephrine, there is a paradoxical decreased peripheral vascular resistance during the hyperdynamic "flow" phase. Accompanying reduced cardiac afterload is increased cardiac preload and thus increased cardiac output. There is abundant evidence that mediators of neural, humoral, and metabolic origins are involved in driving the decrease in vascular resistance following thermal injury. The significance of β_2-adrenergic receptors in vasodilation has been demonstrated using knockout mice,[14] thus pointing to the significance of epinephrine. The situation is complicated in the burn patient by the increase in nerve-stimulated release of norepinephrine, which can potentially mediate vasoconstriction. However evidence exists that the local distribution of adrenergic receptors mediating either vasodilation or vasoconstriction will determine the effect of circulating epinephrine and nerve-stimulated norepinephrine release on peripheral vascular resistance.[15] Blood flow regulation to the burned extremity remains intact: even in legs with 85% surface burned, increasing the surface temperature causes increases in blood flow comparable to unburned legs.[16] In addition, increased tissue metabolism has been recognized to produce metabolites that mediate increased blood flow by reducing vascular resistance.[17] With markedly increased metabolism in major burns, these metabolites, along with catecholamines, nitric oxide (NO),[18] and atrial natriuretic peptide,[9] may contribute to decreased vascular resistance.[19]

When decreases in peripheral vascular resistance compromise tissue perfusion and lead to end-organ damage (e.g., the urinary granular casts of tubular necrosis), pressor agents may be required to maintain adequate tissue perfusion in the setting of adequate volume status. Epinephrine is the drug of choice, providing optimal vasoconstrictor and inotropic effects. In cases of resuscitated burn shock, the additional inotropic support of epinephrine is essential to maintain tissue perfusion without overly constricting the cutaneous vasculature needed to heal burn injuries. For example dobutamine, a β-adrenergic inodilator, is an important inotrope in select burn patients, and the novel non-adrenergic inodilator, levosimendan, may find utility in treating cardiac failure in burn patients.[20]

CATECHOLAMINE RESISTANCE

Acidosis is the most common cause of catecholamine resistance. Macarthur et al.[21] described inactivation of catecholamines by superoxide anions contributing to the observed hypotension of septic shock in rat models. They found treatment with superoxide dismutase not only abrogated endotoxin-induced hypotension in anesthetized rats, but also elevated circulating levels of catecholamines. These findings suggest that compensatory sympathetic activation, which counteracts hypotension during conditions of sepsis, may be blunted by inactivation of catecholamines

by superoxides in the extracellular milieu. In a conscious rat model of sepsis, superoxide inhibition enhanced plasma levels of catecholamines, increased blood pressure, and improved survival.[22] They also found that NO reduces the biologic activity of norepinephrine without altering nerve-stimulated release.[23] Case et al. showed increased superoxide release for T cells in a norepinephrine-stimulated manner.[24] These findings may provide insight into the clinical observations involving critically ill patients in which pharmacologic norepinephrine administration is ineffective in correcting hypotension.

CATECHOLAMINES AND HYPERMETABOLISM

Despite myriad factors reported to promote or inhibit the development of the post-burn hypermetabolic state, many investigators have demonstrated sympathetic catecholamines (norepinephrine more so than epinephrine) to be the effector limb of the transition to and maintenance of this hypermetabolic state.[25] Herndon et al. clearly showed this using a 50% full-thickness scald burn rodent model, with groups pretreated with thyroidectomy, adrenalectomy (+/− dexamethasone replacement), and reserpine depletion of catecholamines.[26] Adrenalectomy or reserpine blunted more than half of the hypermetabolic response. Wilmore et al. demonstrated catecholamines to be the mediator of the human hypermetabolic response to thermal injury.[25] Several key findings were generated by that study: the β-adrenergic (but not α-adrenergic) blockade reduced metabolic rate, pulse, blood pressure, and free fatty acids. Additionally the investigators documented the "nonliving" response to thermal injury: poikilothermia. They noted that when burned patients were placed in cooler environments (21°C), their metabolic rates generally increased, with urinary catecholamine excretions increasing in parallel, excepting four nonsurvivors who showed less catecholamine elaboration, became hypothermic, and did not elevate their metabolic rates. The reason these patients failed to develop sufficient hypermetabolic responses to permit survival remains only partially understood. Burned patients consistently selected a higher room temperature (~30°C) and also had skin and core temperature increases of 1.7°C –2°C above controls.[27] Elevations in energy requirements could be partially modulated through adjustments in environmental temperature. Burn patients treated in warm environments of 32°C exhibited reduced metabolic rates compared to those treated at 25°C, although both groups remained hypermetabolic. After injury, and concurrent with an elevated hypothalamic temperature set-point and cardiac index, qualitative and quantitative changes occur in the flow of biological energy and mass (substrate) through the patient.[28]

Experimental studies of Wolfe and Durkot[29] suggest that the adrenergic drive following burn facilitates lipolysis, influencing fatty acid oxidation. The importance of adrenergic drive on lipid metabolism in burn was shown in human patients through the use of stable isotopic studies as well as adrenergic antagonists.[30–32] The profile of the plasma lipids is dramatically changed as well.[33] These results indicate that not only is lipolysis following thermal injury mediated by β_2-adrenergic receptors, but also suggest increased intracellular and extracellular triglyceride–fatty acid cycling, with resultant heat production. Elijah et al. further elucidated the effects of peroxisome proliferator activated receptor (PPAR) on lipolysis and hyperglycemia in the severely burned.[34]

Wilmore developed experimental paradigms suggesting the role of catecholamines in mediating the hypermetabolic response to thermal injury.[25] Findings included a positive correlation of increased plasma catecholamines and whole-body oxygen consumption following thermal injury,[25] as well as demonstrating that adrenergic blockade lowers the burn-induced increase in metabolic rate and cardiac output to control levels in animal models.[25,29]

Experimental findings in rats suggested that the adrenal medulla, while essential for high rates of heat production following thermal injury, is not the primary driver of the hypermetabolic response.[35,36] Animals with hypothalamic lesions did not increase metabolism following thermal injury and were chronically hypothermic,[37] not unlike experiments in which the adrenal medulla was removed prior to thermal injury.[35] These results are consistent with clinical observations of burn patients in whom reductions in heat loss were achieved with occlusive dressings and for whom elevated environmental temperatures demonstrate partial reductions in metabolic rate and catecholamine secretion.[38]

β-BLOCKADE

Building on findings that catecholamines drive post-burn hypermetabolism, Herndon et al.[39,40] demonstrated that pediatric patients could be treated with the β-adrenergic blocker propranolol to successfully reduce metabolic rate without compromising cardiovascular function. In a more recent study by this group,[41] β-adrenergic blockade in pediatric patients for 4 weeks during recovery from severe burns reduced the elevation in resting energy expenditure and reversed the reduction in net muscle–protein balance by 82%. Such treatment also prevented fatty liver and loss in fat-free whole-body mass and provided for a more efficacious recovery in these children.[42,43] Subsequent studies built on these findings demonstrated improvements when dosing was continued for 1 year post-burn.[44] Recent animal studies have further established a cyclooxygenase-2 role in inflammatory proliferation in the liver.[45] Downregulation of fructose-1,6-bisphosphatase-2 mRNA has been observed in muscle tissue following treatment with propranolol; this enzyme may play a role in gluconeogenesis, although the metabolic significance of this tissue-specific transcriptional alteration remains to be determined.[46] Propranolol leaves α-adrenergic receptors unopposed, resulting in peripheral vasoconstriction and increasing vascular resistance. Reduced blood loss has been observed, with postoperative hematocrit 5–7% higher with propranolol.[47] The exercise-induced enhancements in muscle mass, strength, and VO_2 peak were not impaired by propranolol; instead, aerobic response to exercise was improved in massively burned children.[48] β-Blockade in nonburned septic patients has become an area of active research and, based on these findings in burned patients, demonstrates value for some patients, although the overall indications and patient selection have yet to be fully elucidated.[49,50]

SYMPATHETIC INFLUENCES ON IMMUNE FUNCTION

New data have clarified the interconnections between the immune and sympathetic nervous systems and are well reviewed by Pedro et al.[51] Understanding these interactions may be important to comprehending the implications of our pharmacologic treatments with β-adrenergic antagonists and agonists on immune function.

Immunohistochemical staining demonstrates substantial sympathetic innervation of all primary (thymus and bone marrow) and secondary (spleen and lymph nodes) lymphoid organs.[52–55] Innervation has been shown to reach immune cell compartments of the spleen (the white pulp), periarterial lymphoid sheath, marginal zone, and marginal sinus areas, as well as the splenic capsule and trabeculae.[56–59] Sympathetic nerve terminals have been described in direct apposition to T cells, interdigitating dendritic cells, and B cells.[60]

Immune modulation by adrenergic signaling was recently reviewed by Sanders.[61] Lymphocytes (including activated and resting B cells, naïve $CD4^+$ T cells, T-helper [T_H1] cell clones, and newly generated T_H1 cells) express β-adrenergic receptors, but they are not expressed in newly generated T_H2 cells.[62–64] Furthermore there is significant evidence that norepinephrine can modulate the function of $CD4^+$ T cells, which in turn can modulate antibody production of B cells.[65] Sympathetic neurons suppress $CD8^+$ T-cell receptor response and cytotoxic activity.[66] In addition, norepinephrine can directly influence B-cell antibody production depending on the time of exposure following activation.[67] The physiologic importance of these in vitro findings is supported by a series of in vivo experiments involving severe combined immunodeficient (*scid*) mice depleted of norepinephrine prior to reconstitution with antigen-specific T_H2 and B cells. These experiments demonstrate that norepinephrine is necessary to maintain a normal level of antibody production in vivo.[62] Furthermore other whole-animal experiments also involving *scid* mice provide evidence that the immune response itself stimulates the release of norepinephrine from adrenergic nerve terminals in bone marrow and the spleen, which in turn can influence antibody production by B cells.[68] β-Blockade in 20 pediatric burn patients significantly reduced serum tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β).[69] The parasympathetic system further conditions the immunomodulatory role of the SNS. Recently it was shown that the vagal synapses trigger acetylcholine release from memory T cells, in turn reducing TNF-α through α-7-nicotinic acetylcholine receptor.[70] These findings suggest the potential of sympathetic/parasympathetic activation in mediating immune responses.

In animal models, blocking β-adrenergic receptors soon after injury partially restored the lipopolysaccharide (LPS)-stimulated TNF-α secretory potential of circulating monocytes lost during the course of burn injury and sepsis.[71] Apart from adrenergic inhibition of LPS-stimulated TNF-α release in isolated macrophages,[72–75] similar inhibition of LPS-stimulated TNF-α production has also been demonstrated in human mast cells,[76] microglial cells,[77] astrocytes,[78] and cytotoxic T lymphocytes.[79] In contrast to adrenergic stimulation of TNF-α release, experiments with isolated atria,[80,81] myenteric plexus,[82] and brain tissue[83] have proved that TNF-α can negatively affect the release of norepinephrine.

Although the precise mechanisms of the negative modulation of proinflammatory cytokines by catecholamines are poorly understood, it may be achieved through the ability of catecholamines to induce the antiinflammatory cytokine IL-10.[84–87] Whole-animal studies involving assessment of circulating levels of IL-10[87] as well as studies of human whole blood and mononuclear cells stimulated with LPS in the presence of adrenergic agonists[84,86,88] support this premise. Immunomodulatory effects were further elucidated by Takenaka et al. demonstrating the effects on T-cell differentiation to CD4+ via a dendritic cell-mediated pathway.[89] Additionally experimental neurotrauma resulted in increased IL-10 consequent to endogenous adrenergic stimulation in the absence of LPS or other evidence of infectious challenge.[90]

SYMPATHETIC RESPONSE TO SEPSIS

Burn injury is commonly complicated by transient bacteremia, infection, and sepsis (see chapters on Infection [Chapter 12] and Multisystem Organ Failure [Chapter 31]). Infection causes a marked sympathetic response proportional to the degree of insult[91] in which there are simultaneous and opposing forces of hyperinflammation versus immunosuppression. Sepsis is accompanied by an enormous catecholamine surge leading to changes in cardiovascular output, immunomodulatory effects, and catabolism. Propranolol has been shown to attenuate those changes.[92] The use of an adrenergic blockade as an immunomodulator has found further utility in other traumatic injuries.[93] Furthermore animal models of septic peritonitis suggest that initial sympathetic activation, as measured by elevated levels of plasma norepinephrine and greater norepinephrine turnover, persists for many hours.[94,95]

Collectively these data clearly support a complex trophic interconnection between the SNS and immune system. Burn- and sepsis-induced sympathetic responses exert significant influence on bone marrow cellular events. Evidence for norepinephrine regulation of myelopoiesis in experimental thermal injury with sepsis is detailed in Chapter 22 on hematology.[212]

Role of Thyroid Function

An early rat study showed that thyroidectomy did not alter the post-burn increase in metabolism, although adrenalectomy or catecholamine depletion with reserpine did reduce post-burn metabolic rates.[26] Subsequent human studies demonstrated generally normal total triiodothyronine (T3) and thyroxine (T4), free T3 and T4, and thyroid-stimulating hormone (TSH) levels in uncomplicated burn patients. However in those patients with infection or sepsis, decreased amounts of free T4 and T3 were observed.[96] T3 replacement did not alter metabolic rate or mortality post burn[97] but may have decreased circulating levels of norepinephrine and epinephrine. These and other studies suggest that the hypermetabolic response to burn is independent of thyroid hormones.[98] More importantly, these data, in

conjunction with more recent work by Senel et al., allude to a post-burn shift in metabolic control away from thyroid signaling in favor of other mediators.[99]

SEX STEROIDS FOLLOWING BURN TRAUMA

Androgens

Release of C_{19} Steroids. In the normal physiologic state, dehydroepiandrosterone sulfate (DHEAS), a weak androgen, is the major secretory product of the adrenal cortex. In burn patients, there is an increase in cortisol secretion and a distinct decrease in serum DHEAS levels[100] owing to a reduction in synthesis.[101] Testosterone and androstenedione levels decrease abruptly. In burn patients, subnormal testosterone levels persist for 3–18 months post burn, whereas cortisol levels normalize earlier.[101] The decrease in testosterone secretion may be the direct effect of excessive cortisol levels on the testes.[102,103] Wilmore, Long, Mason, and Pruitt wrote a masterful review of the coordinated hypothalamic response to injury in 1976: "Stress in Surgical Patients as a Neurophysiological Reflex Response."[104]

Burned men exhibit hypogonadism and Leydig cell failure following thermal injury, resulting in depressed testosterone levels. Plymate et al. measured levels of sex hormones (e.g., sex hormone-binding globulin [SHBG] and luteinizing hormone [LH]) and thyroid hormones in the weeks following burn injury. They showed an increase in estradiol levels and a concomitant decrease in the secretion of bioactive LH following burn injury, suggestive of an alteration in hypothalamic control of the gonadal axis leading to suppression of testosterone release. SHBG also exhibited significant changes, with an initial decrease and subsequent rise in concentration as compared to controls. This increase in SHBG results in a further suppression of testosterone by reducing the amounts of the unbound hormone. The levels of SHBG strongly correlated with levels of T3 and free T3 as well. This study helped elucidate the complex relationships of alterations in hypothalamic, thalamic, and gonadal regulation in the burned male.[105] Taken together, these studies allude to a pervasive shift from normal hypothalamic function to a post-injury "mobilization" that remains but partly understood.

It appears that synthesis of C_{19} steroids by the adrenals and testes is compromised as a result of enhanced production of C_{21} steroids, such as cortisol. Aldosterone levels are also subnormal, despite elevated plasma renin activity. This suggests a shift in pregnenolone metabolism away from mineralocorticoid and adrenal androgen pathways toward the glucocorticoid pathway.[100] DHEAS also has a profound influence on the immune response, and a role for DHEAS as a modulator of the immune response is now well established.[106–109] Given that immunostimulatory properties of T_H1 cells are low during severe illness,[100] DHEAS deficiency may be a contributing factor to the immune suppression in burn patients. In vitro treatment of human T cells with DHEAS increases IL-2 production (which is required for clonal expansion) and IL-2 mRNA synthesis.[109] Interestingly this effect was seen only in $CD4^+CD8^-$ and not in $CD4^-CD8^+$ cells. DHEAS-treated cells were also able to mediate a more potent cytotoxic effect than were untreated cells.

Under conditions of severe physical stress and chronic illness, dopamine levels have been shown to be elevated;[110,111] consequently dopamine may also influence immune status and adrenal steroid secretion in burn patients. Exogenous dopamine is often used in the treatment of critically ill patients because of its vasopressor, renal vasodilator, and cardiac inotropic properties. Povoa et al. reviewed vasopressor use in septic shock and found a need for a multimodal selection of these agents.[112] However several other studies indicate that dopamine treatment may undermine an already depressed immune system. This effect appears to act via the suppression of prolactin release from the anterior pituitary. Dopamine suppresses serum prolactin and DHEAS levels but not cortisol levels.[113,114] In vitro, prolactin has a synergistic effect on ACTH-induced DHEAS secretion by human adrenal cells.[115] Thus it is possible that the dopamine-induced suppression of prolactin is responsible for lowering DHEAS levels and hence suppression of the T-cell proliferative response. The in vitro proliferative

Table 23.2 Influence of Glucocorticoids on Metabolic and Immune Response to Thermal Injury

Physiologic Variable	Glucocorticoid-Mediated Change Following Burn Injury
Resting energy expenditure	Increased[152,176,179]
Oxygen consumption	Increased[244,245]
Primary fuel	Lipids, glucose[190]
Proteolysis	Increased in skeletal muscle[160,161,163,164,246]
Acute-phase protein synthesis	Increased[133,247,248]
Nitrogen excretion	Increased[244]
Glycogenolysis	Increased via effect on glucagon[157,158]
Gluconeogenesis	Increased[153,154,247]
Lipolysis	Increased[191]
Ketone body formation	Normal[193]
Triglyceride level	Increased[193,247]
Thymic changes T-cell population T-cell proliferation B-cell population	Involution[218] Decreased[217,249] Inhibited[219,220,248] Not conclusive from current data
Neutrophil population —chemotaxis —demargination —bactericidal activity	Increased[223,249,250] Suppressed[223] Increased[223,226] Suppressed[228]
Monocyte population	Increased transiently with corticosteroids but decreased in burn patients[250–252]
—chemotaxis	Suppressed[224]
—bactericidal activity	Suppressed[224,227]
Bone formation	Decreased[200]

Citation of studies from the current literature suggesting that glucocorticoid release is involved in changing the listed physiologic variables following thermal injury.

response of T cells from patients on dopamine therapy is diminished,[113] and cells treated with DHEAS mediate a more potent T-cell cytotoxic effect.[109]

Extensive studies and clinical experiences were undertaken over the past decade with androgen supplementation using oxandrolone. Reeves and Finnerty detailed the 5-year outcomes of long-term oxandrolone treatments following a 24-month administration in severely burned children. They found significantly increased bone mineral content, greater height velocity, reduced cardiac work, and augmented muscle strength.[116] This is described in greater detail in the chapter on hypermetabolism (Chapter 30). Overall there is a hypoandrogeneric state post burn, and supplementation with the anabolic steroid oxandrolone is effective at both ameliorating hypermetabolism as well as shifting the patient toward anabolism.

Estrogens

The impact of xenoestrogens on mortality in burned patients has been investigated. Found in insecticides used from the 1950s to the 1970s, xenoestrogens are compounds that can act as estradiol receptor agonists or antagonists and that are stored in fat. During the hypermetabolic state following thermal injury, the xenoestrogens are released along with mobilized lipids from these fat stores. In older burn patients who were more likely to have higher concentrations of these compounds in their bodies, it was discovered that nonsurvivors had significantly increased levels of two xenoestrogens, heptachlor epoxide and oxychlordane. It was suggested that these compounds may induce the inactivation of estradiol, progesterone, testosterone, and glucocorticoids via the induction of steroid hydroxylases, as well as antagonizing estradiol receptors, which may result in decreased inflammation and cytokine release.[117]

ADRENAL CORTICAL STEROIDS FOLLOWING BURN TRAUMA

Adrenocortical response is critical to coordinating the systemic response to thermal injury. The glucocorticoid surge following burn injury has long been measured by both serum and urinary excretion markers. Regulation of glucocorticoid secretion is complex, with multiple determinants of the adrenal cortex secretion of cortisol, including pituitary ACTH, but also afferent neural control and hyperthermia, which blunts the adrenal response to ACTH. Furthermore the usual circadian rhythm of cortisol secretion is dampened after burn injury. In 1982, Vaughn et al. showed elevated circulating and urinary cortisol, with a weak correlation to the level of ACTH. Superior correlations were noted between cortisol and total body surface area (TBSA), metabolic rate, and average body temperature. These observations in burned patients indicate that adrenal hypersecretion of cortisol is in response to temperature, circulating mediators of hypermetabolism, direct adrenal innervation, and a decrease in adrenal cortex responsiveness to ACTH. As a result, the authors concluded that cortisol may play a secondary role in permitting and promoting the changes seen in post-injury hypermetabolism.[118] On this basis, they attributed post-injury metabolic and thermal changes primarily to sympathetic tone and circulating catecholamines (norepinephrine and epinephrine).

Danner and colleagues carefully mapped the HPA axis response to a massive septic insult in their lethal canine pneumonia model as they attempted to define the "critical illness-related corticosteroid insufficiency" (CIRCI). They found a massive surge in total, bound, and free serum cortisol and in ACTH. Additionally they determined that ACTH failed to promote a further increase in cortisol and that dexamethasone did not suppress cortisol, possibly because the adrenals were already maximally stimulated. Significantly in sepsis-surviving animals, the HPA axis recovered to normal levels whereas ACTH and dexamethasone responsiveness recovered by 10 h compared to nonsurvivors. In contrast, the mineralocorticoid response with hyperaldosteronism remained past 72 h and did not regain dexamethasone suppression. Thus mineralocorticoids are ACTH-independent in the setting of sepsis. These data support the adrenal exhaustion hypothesis.[119]

In a postmortem study of adrenal glands of ICU patients, it was found that the adrenocortical structure was disrupted following critical illness. These patients tended to have adrenal glands that weighed less than controls, with significantly less protein content and greater fluid content. There was also considerable downregulation of ACTH-regulated genes.[120]

Elevated plasma-cortisol levels have been shown during critical illness, especially during an episode of systemic inflammatory response syndrome (SIRS). However cortisol production during the day in patients with SIRS, although elevated, is less than doubled. ACTH is suppressed in these patients, implying a non-ACTH-driven response. It has been demonstrated that during critical illness clearance of plasma cortisol is significantly reduced, playing a significant role in the hypercortisolism of the critically ill stress response.[120] Other investigators determined in the setting of septic shock that only serial hormonal measurements and provocative testing were useful for HPA axis function assessment. They further identified high aldosterone levels in a population with poor outcomes from sepsis.[119]

Norbury et al. followed urinary cortisol levels in 212 severely burned children, finding three- to fivefold increases in cortisol excretion up to 100 days post-burn. Urinary norepinephrine levels were significantly increased up to 20 days,[4] as shown in Fig. 23.1. Hypercortisolemia has been suggested as a driver of whole-body catabolism following severe burn. To test this hypothesis, Jeschke et al. blocked cortisol production with ketoconazole in 55 severely burned children. They found normalization of the eightfold elevation in urine cortisol in the treatment group. Counterintuitively, no change was seen in inflammatory response, acute-phase proteins, body composition, muscle protein breakdown or synthesis, or organ function. Their data suggest that post-burn hypercortisolemia does not play a central role in the catabolic response.[121]

Jeschke and Herndon characterized the long-term inflammatory and acute-phase responses in 977 pediatric burn patients with greater than 30% TBSA with 24-h urinary excretion. They found significant elevations of cortisol, catecholamines, cytokines, and acute-phase proteins for up to 3 years, as seen in Fig. 23.2. They also observed insulin resistance, increased fracture risk, hepatomegaly, increased cardiac output and cardiac dysfunction, and impaired strength over the same period.[4,5]

Free versus Total Cortisol

Glucocorticoids circulate in the body bound to cortisol-binding globulin (CBG), such as transcortin, as an inactive complex. Only 1–10% of total plasma cortisol circulates unbound and is responsible for the biological activity of glucocorticoids. Free plasma cortisol is a surrogate for the difficult-to-measure tissue cortisol.[122,123] Burn injury shifts the equilibrium between unbound and total cortisol toward an elevation in the unbound fraction.[124] Serum CBG and CBG-binding capacity are low in burn injury, severe infection, and septic shock.[124–126] In burn patients, CBG levels have been shown to decrease markedly, with the lowest values occurring 48 h after injury.[127] Even a minor burn, such as 3% TBSA, results in a reduction of serum CBG levels by 30%,[128] which return to normal levels 1–2 weeks later. The net effect of the decrease in CBG levels following thermal injury may not only result in increased levels of free cortisol but also in the amount of excreted cortisol, which is reflected in high urinary corticosteroid levels. The urinary cortisol concentration was observed to increase progressively with burn size, with the highest levels in the 60–99% TBSA burn groups.[129] Additional explanations for increased levels of corticosteroids in burn patients may be due to the direct inhibitory effect of corticosteroids on the biosynthesis of CBG.[130–132] Furthermore IL-6 elevation associated with massive burns has also been implicated in reducing CBG synthesis.[133]

Evidence exists suggesting that cortisol elevation with corresponding decreased ACTH may be driven by endothelin or atrial natriuretic peptide/hormone (ANP/H). Vermes et al.[134] demonstrated significant elevation in both plasma endothelin and ANP levels for 8 days following hospitalization in severely ill patients with sepsis or trauma. Fittingly endothelin has been shown to be a modulator of the sympathetic response.[135] In addition, infusion of ANP in humans has been demonstrated to block CRH-stimulated secretion of ACTH and cortisol,[136] while endothelin-1 and endothelin-3 enhance secretion of steroid hormones from the adrenal cortex.[137] However endothelin-3 has been reported to elevate ACTH and corticosterone levels in rats,[138] whereas endothelin-1 results in elevated ACTH in humans.[139] Based on this, Vermes et al.[134] suggest that endothelin may be responsible for stimulating steroid secretion, whereas ANP's action on the HPA axis may suppress ACTH secretion, thereby explaining the paradoxical increase in cortisol with concomitant low ACTH levels in severely stressed patients.

By precisely measuring cortisol, Cohen et al. found no significant correlation between total plasma, free plasma, and tissue microdialysis cortisol levels. Tissue microdialysis cortisol levels were significantly increased in burned patients compared with healthy controls. Furthermore via subcutaneous microdialysis of cortisol levels in burned and non-burned tissue of severely burned patients, they discerned no significant difference in local cortisol concentrations. This indicates that local microenvironmental changes in burned tissue, such as more cortisol cleaved from CBG by the neutrophil elastase, failed to significantly affect local cortisol levels. They concluded that free cortisol demonstrated a better correlation with TBSA than total cortisol.[140] Given the sensitivity of cortisol to pain and stress as well as diurnal variations, Brown et al. advocate the utilization of salivary α-amylase as a surrogate in the setting of outpatient investigations.[141]

SUBSTRATE CYCLING

Influence on Metabolic Pathways

Elevated energy expenditure and hyperglycemia are hallmarks of thermal injury. The heavy demand for energy stems from the increase in essential functions, such as the synthesis of proteins required for wound healing, the synthesis of acute-phase proteins, and inflammatory mediators. The increase in substrate cycling is partly responsible for the elevation in resting energy expenditure in burn patients. This occurs when enzymes catalyzing opposing reactions of the same pathway are simultaneously active. For example, in the conversion of glucose to glucose-6-phosphate and back to glucose, the demand for energy increases to resynthesize adenosine triphosphate (ATP) used in this and similar reactions. In burn patients, the rate of glucose production and glycolysis, as well as of lipolysis and re-esterification of triglycerides, is elevated.[31] This cycling of substrates generates heat through the hydrolysis of high-energy phosphate bonds in ATP, thereby contributing to thermogenesis as well as increased energy requirements in burn patients.[142] Concurrently muscle mitochondrial decoupling and fat browning adaptions occur to increase thermogenic capacity.

Hormonal Determinants of Glucose Utilization

In 1986, glucose and alanine fluxes were studied in adult burn patients with stable isotope tracer infusions, somatostatin infusion (suppressing insulin and glucagon), and insulin + glucose replacement (isolated glucagon suppression). Insulin and glucagon levels were both significantly elevated above those in unburned individuals. Somatostatin infusion reduced both insulin and glucagon levels and induced a stable decrease in glucose production at 30 min with a progressive decrease in glucose uptake over the course of 30–180 min. When glucagon was selectively reduced via the reinfusion of insulin to restore basal levels in conjunction with glucose infusions to maintain euglycemia, glucose production was suppressed significantly below levels when somatostatin was infused alone, and glucose clearance was restored to pre-infusion levels. This study provided evidence for glucagon control of hepatic glucose production (HGP) in the post-burn state, with basal levels of insulin further suppressing HGP while exerting greater influence to increase (peripheral) glucose uptake. Glucagon reduction (via somatostatin + insulin infusion) did not alter the alanine clearance or flux rates; however suppression of insulin and glucagon (from somatostatin infusion alone) increased the alanine flux rate, consistent with increased peripheral protein catabolism when the insulin signal is diminished. The authors noted prior observations indicating tachyphylactic hepatic gluconeogenesis in response to glucagon. However in the setting of hypercortisolemia (observed in these patients), prolonged HGP in response to glucagon signaling manifests.[143]

A concurrent study of unburned adults differentiated the response to endogenous insulin infusions from the response to a proximate glucose infusion using somatostatin suppression of endogenous insulin and glucagon + insulin replacement to basal levels during the glucose infusion. This study established that glucose infusion (1 and 4 mg/kg per minute), independent of endogenous insulin effect, suppresses endogenous glucose production, stimulates alanine

production, and suppresses urea production.[144] A further analysis of data collected as part of the T3 replacement trial described earlier showed that the metabolic rate increased proportionally with and was independently predicted by plasma glucagon.[145]

In the setting of an adequate, constant nitrogen intake, increasing carbohydrate feeding spared protein catabolism and mitigated negative nitrogen balance, whereas intravenous fat emulsion did not affect nitrogen balance independently.[146,147] These studies indicated the primary determinants for nitrogen excretion were carbohydrate intake and metabolic rate. Nitrogen excretion was minimized when the carbohydrate intake approximated the metabolic rate. Insulin was additively anabolic to carbohydrate intake in further decreasing nitrogen excretion when patients were provided constant and sufficient protein intake.[148]

GLUCOCORTICOIDS FOLLOWING BURN INJURY

In burn patients likely to recover, plasma glucocorticoid levels are moderately elevated or in the upper normal range, can persist beyond a month,[124,149] and return to normal as healing progresses.[150] In contrast, patients with severe thermal injury (90% TBSA) have markedly lower levels of glucocorticoids, suggesting that they are unable to mount an adequate response.[124]

Glucocorticoids and Carbohydrate Metabolism

Glucocorticoids contribute to hyperglycemia by enhancing endogenous production of glucose in the liver.[151–154] Following burn, elevated glucose levels are sustained through gluconeogenesis and impaired glucose utilization. The increased plasma lactate produced by peripheral tissues following burn, as documented by Wolfe et al.,[155] is an essential substrate for gluconeogenesis by the liver. Burn injury causes intrinsic alterations in the liver, which increase the conversion of pyruvate to oxaloacetate at the expense of nontricarboxylic acid cycle sources.[156] Efficient mobilization of glucose from glycogen and skeletal muscle amino acids for gluconeogenesis requires glucagon secretion,[145,157] which is stimulated by glucocorticoids.[145,157,158] Glucocorticoids sustain the action of glucagon and prevent the usual development of tachyphylaxis from high levels of glucagon. In addition to gluconeogenesis, impaired glucose utilization and insulin resistance can also play a role in sustaining high circulating levels of glucose in burn patients.[152]

Glucocorticoids and Protein Metabolism

Protein catabolism is a part of burn hypermetabolism, resulting in negative nitrogen balance. Cuthbertson's[159] landmark studies were the first to suggest the important concept that nitrogen loss is a whole-body rather than a local burn wound response. The increase in proteolysis seen in burn injury is at least partly mediated by glucocorticoids. In humans[160] and in animal models,[161] administration of glucocorticoids enhances muscle proteolysis. Furthermore burn injury-induced muscle proteolysis can be inhibited by a glucocorticoid receptor antagonist.[162] Amino acids mobilized from peripheral tissues are transported to the liver where, unlike in other tissues, cortisol stimulates protein synthesis. The increased hepatic protein synthesis in response to cortisol can drive the new synthesis of gluconeogenic enzymes and acute-phase proteins in response to burn injury.

The complete details of the mechanisms involved in burn-mediated alterations in protein metabolism are unknown. However some information can be gleaned from studies on other states of excessive catabolism. In conditions such as metabolic acidosis, adrenalectomy halts muscle proteolysis and does not increase expression of components of the ubiquitin–proteasome pathway.[163,164] These effects can be reversed by dexamethasone administration. Further support for this premise is provided by in vitro studies, which show that dexamethasone-induced increases in proteolytic degradation in myocytes can be abolished by the glucocorticoid inhibitor RU486.[165] Ding and coworkers[166] suggest that partial inhibition of the ubiquitin–proteasome pathway may be beneficial in enhanced catabolic states. Taken together, these data suggest that interaction of glucocorticoids and the ATP-requiring ubiquitin–proteosome system may play an important role in burn-induced proteolysis.[167–171]

Another aspect of protein catabolism following burn is the generation of gluconeogenic amino acids. Plasma levels of alanine are increased following burn.[172] Nitrogen produced as a result of transaminating alanine to the gluconeogenic intermediate, pyruvate, is subsequently converted into glutamine and then to urea for excretion by the liver. In muscle tissue, alanine aminotransferase (ALT/SGPT) transfers an amino group from glutamine to pyruvate, forming alanine and α-ketoglutarate. Alanine is then dumped into the bloodstream, taken to the liver, and returns to the muscle as glucose (the glucose–alanine cycle). This is one reason why plasma alanine increases after burn. By contrast, in the liver, glutamine enters the mitochondria, and eventually nitrogen is processed via the urea cycle.[173] Glutamine is one of the major participants in the translocation of amino acids from peripheral tissues to the liver for nitrogen excretion. Expression of glutamine synthase is increased to compensate for glutamine depletion in peripheral tissues. Following burn injury, glutamine synthase mRNA is increased first in the lung and later in muscle.[174] Adrenalectomy partially reduces burn-induced glutamine synthase mRNA[174] in a tissue-specific manner, with no such effect in the kidney or liver. There is evidence suggesting that glucocorticoids may augment glutamine synthesis in lung and muscle tissues.[175] Mobilization of protein from peripheral tissues is also indicated by the increase in phenylalanine in the blood of burn patients.[172] Phenylalanine is the only amino acid not degraded by peripheral tissue; hence it accumulates in the circulation when uptake by the liver is compromised.

The hypermetabolic and catabolic states seen in thermal injury remain long after the burn wound completely heals:[152,176–179] reduction in protein catabolism and enhancement of lean body mass were seen only 9–12 months following the initial injury.[177] Therefore the post-burn treatment of growth deficiency must be prolonged beyond wound healing.

Many treatment algorithms to modulate this growth retardation and hypermetabolism have been examined and subsequently reviewed by Diaz.[180] Indirect effects of glucocorticoids on glucose levels in burn include modulation of insulin-like growth factor-1 (IGF-1), an important mediator of growth hormone (GH) action.[181,182] Marked depression of all components of the IGF-1 complex is seen following burn.[183–187] Elevated glucocorticoid levels in burn patients

may contribute to the suppression of the acid labile subunit (ALS) of the IGF-1 complex. Treatment of rats with dexamethasone results in low levels of serum ALS as well as liver ALS mRNA.[188,189]

In addition to amino acids released from peripheral tissue,[190] free fatty acids are released from adipose tissue by cortisol.[191] In burned children and adults, increased lipolysis is reflected in the elevated plasma levels of palmitic and oleic acids.[32,192,193] Collectively these effects lead to hepatomegaly and a cushingoid phenotype.

Glucocorticoids on Bone Metabolism

Aside from combating the increased demand for energy, glucocorticoids also affect bone development. Abnormal bone metabolism in burn injury has been demonstrated in animals and humans.[194,195] In children, the reduction in bone mineral density persists for at least 5 years after severe burn injury (>40% TBSA) and results in permanent retardation of linear growth.[196,197] The reasons for loss of bone mineral density include increased production of endogenous glucocorticoids, the inflammatory response, immobilization, aluminum loading, and production of cytokines (e.g., IL-1 and IL-6) that facilitate bone resorption.[198] In an animal study, Hoscheit et al. found increased markers of bone resorption, particularly RANKL, in the first 2 weeks after burn, suggesting that the decreased bone mass after burn injury results from increased resorption and decreased bone formation.[199]

Glucocorticoids have potent effects on bone formation and resorption, resulting in loss of bone mass. Weinstein and coworkers[200] investigated the long-term (equivalent to 3–4 human years) effects of glucocorticoids on bone metabolism in an animal model and reported a reduction in osteoclastogenesis and osteoblastogenesis leading to reduced bone turnover and reduced bone formation, respectively. Enhanced osteoclast and osteoblast apoptosis was observed in mice subjected to long-term glucocorticoid administration, as well as in patients with glucocorticoid-induced osteoporosis.[200] In addition, glucocorticoids directly downregulate expression of type I collagen and upregulate expression of collagenase-3 in chondrocytes.[201] On the other hand, IGF-1 enhances expression of type I collagen and suppresses the expression of collagenase-3.[202] Thus the massive increase in glucocorticoids and the corresponding decrease in IGF-1 in burn injury have the ability to profoundly alter bone and cartilage formation.

The mechanisms by which glucocorticoids mediate bone resorption are unclear. Glucocorticoids may mediate bone resorption by their dual capacity to initially inhibit osteoclast synthesis and later stimulate osteoclast synthesis, coupled with an increase in bone resorption.[203] Another mechanism by which cortisol may influence bone resorption is by suppression of IGF-1 or GH-induced chondrocyte proliferation.[204] The antiproliferative effect of glucocorticoids may be mediated through downregulation of the GH receptor and binding affinity, as well as suppression of the local production of IGF-1 by these cells.

Supplementation with exogenous recombinant human GH (rhGH) was studied by Herndon et al.[180,205,206] and was found to have a profound anabolic effect on the muscle and skin. Breederveld et al. reviewed trials of GH in burn patients, noting more rapid healing of burn wounds and donor sites as well as reduction of hospital stay without increasing mortality or scarring.[205] IGF-I supplementation was also examined and had an even greater anabolic effect but with less resultant hypoglycemia or hyperglycemia.[206] However Takala et al.[207] ascertained increased morbidity and mortality in trauma patients, and the use and further study of these hormones has since been restricted.[208] In a subsequent study, Herndon and Voigt employed a combination treatment of oxandrolone and propranolol that significantly ameliorated growth arrest in pediatric burn patients without the risks associated with IGF-1 treatment.[209] Rojas et al. reviewed the current pharmacotherapy for hypermetabolism in burn patients and cover these issues in detail.[210]

Glucocorticoids on Immune Suppression

Severely burned patients are susceptible to opportunistic infections, and sepsis is a major cause of death associated with burns. Burn injury leaves the patient vulnerable to opportunistic infections via skin, GI, respiratory, and urinary tracts.[211] The glucocorticoid response to thermal injury appears to play an important role in immune dysfunction, with impairment of both specific and nonspecific defenses. Corticosteroids reduce lymphocyte, eosinophil, and basophil numbers; alter lymphocyte subpopulations; depress immunoglobulin production by B cells; and suppress neutrophil and monocyte/macrophage activity.

Acute thymic involution[212,213] and a reduction of the total T-cell population occur soon after burn injury.[212–215] During initial thymic involution in an animal model, there is marked depression of $CD4^{+/}CD8^{+}$ lymphocytes. Thymic involution is a common response to various types of stress and trauma.[216] In humans, the depression of T lymphocytes is reflected by the reduction of both $CD4^{+}$ and $CD8^{+}$ cell numbers.[214] In an animal model,[212] $CD4^{+}CD8^{-}$ cells are reported to be more sensitive to the effects of thermal injury than are $CD4^{-}CD8^{+}$ cells. Unsurprisingly $CD4^{+}CD8^{-}$ cell numbers remain suppressed during the initial 2-week period following burn injury.

Thymic changes following exogenous administration of glucocorticoids are similar to those seen in burn,[217,218] in that both noninjury exogenous hypercortisolism states and burn injury are associated with decreased $CD4^{+}CD8^{+}$ and increased $CD4^{+}CD8^{-}$ thymocytes.[213] The reduction in $CD4^{+}CD8^{+}$ cell numbers during the first 24 h after burn is due to glucocorticoid-mediated apoptosis because burn-induced thymocyte apoptosis is suppressed by adrenalectomy or the administration of a glucocorticoid antagonist.[213] Other factors contributing to lymphocyte dysfunction and immunosuppression resulting from elevated corticosteroid levels may include direct inhibition of T-cell proliferation, IL-2 production,[219,220] apoptosis,[221] and altered lymphocyte membrane fluidity.[222]

Apart from these effects on lymphocytes, glucocorticoids also enhance susceptibility to infections by modifying monocyte and neutrophil function. Movement of circulating inflammatory cells to the site of infection is suppressed by the ability of glucocorticoids to reduce the cellular response to chemotactic stimuli,[223–225] diminish neutrophil adherence,[226] and induce a shift from marginal to circulating cells.[223] Glucocorticoids also suppress the bactericidal activity of monocytes[227] and neutrophils,[228] perhaps through impairment of lysosomal function.[229]

Although severe burns are associated with alterations in B-cell production and function, there is considerable inconsistency in the literature.[230–235] For example, in rats subjected to 30% burn injury, splenic lymphocytes respond poorly to LPS, and immunoglobulin synthesis is reduced in comparison to control animals.[236] Others have found an increase in circulating B cells early after burn injury.[232] Administration of methylprednisolone to normal volunteers for 2–4 weeks also reduces serum immunoglobulin levels.[237]

This review provides a glimpse of how the catecholamine and hormonal responses to thermal injury support compensatory cardiovascular, metabolic, and immunologic changes. Although adrenergic mechanisms are important for their ability to influence intracellular signaling pathways, their roles as modulators of gene expression are still being explored. While alteration of gene expressions by glucocorticoids is well described, less is known about the interplay of glucocorticoids with the complex post-injury signaling milieu seen with severe thermal injury or other forms of trauma.

24 The Hepatic Response to Thermal Injury

MARC G. JESCHKE, OMAR NUNEZ LOPEZ, and CELESTE C. FINNERTY

Introduction

The extreme hypermetabolic and hypercatabolic stress responses induced by a severe burn injury are characterized by increased proteolysis, lipolysis, and production of endogenous glucose via glycogenolysis and gluconeogenesis. The critical organ controlling these processes is the liver. With major roles in metabolism, inflammation, immunity, and the acute-phase response, the liver orchestrates the basic functions that modulate survival and recovery in severely burned patients. The function of the liver following a severe burn injury has been elucidated, demonstrating that the preservation of liver function is associated with survival. The strong correlation between postburn survival and the expression of cytokines and acute-phase proteins (APPs) produced by the liver further supports this contention.

Worldwide, the World Health Organization (WHO) attributes approximately 265,000 deaths each year to burn injuries and their sequelae, with the vast majority of these injuries occurring in low- and middle-income countries.[1] In the United States alone, burns result in approximately 4000 deaths, 24,500 hospitalizations, and more than 745,000 nonhospitalized injuries per year, with an incidence rate of 280 burns (per 100,000 people).[2,3] The effects induced by burns are not limited to the injured area alone. A severe burn injury has devastating effects on the injured patient by affecting almost every organ system, resulting in greater morbidity and mortality.[4] Amplified glucose availability leads to increased protein catabolism and lipolysis, initiating the postburn hypermetabolic stress response.[4–6] Systemic inflammation, including pathophysiologic regulation of cytokines, hormones, and APPs, drives the hypermetabolic response.[7–9] Prolongation or amplification of the hypermetabolic or inflammatory responses may result in dysregulation of counterregulatory stress hormones (catecholamines, cortisol, glucagon), thereby exacerbating postburn hypercatabolism, multiorgan failure, and death.[10,11]

For more than 20 years, reductions in morbidity and mortality have resulted from research efforts focused on improving postburn resuscitation, hypermetabolism, infection control, ventilation, and wound healing.[5] Greater advances in clinical care, however, are needed to reduce morbidity and mortality even further. With a series of studies, we have concluded that the liver plays a fundamental role in the systemic response to burn.[12–16] Through the modulation of immune, inflammatory, metabolic, and acute-phase response signal transduction pathways, the liver contributes greatly to survival and recovery following a severe burn injury.[11] This chapter discusses liver function under normal conditions and following a severe insult such as a burn injury.

Anatomy and Physiology of the Liver

ANATOMY

In an average-sized adult, the liver weighs approximately 1500 g, making up almost 2% of the total body weight. Following a severe burn injury, the liver size can increase significantly to meet additional demands. The Couinaud's segmental system, the preferred anatomy classification system, divides the liver into eight independent functional units (termed segments) rather than relying on the traditional morphological description based on the external appearance of the liver. Roman numerals (I–VIII) delineate the segments based on the dual vascular inflow, biliary drainage, and lymphatic drainage within each segment.[17]

PHYSIOLOGY

A broad spectrum of biological functions is orchestrated by the liver. The interrelated physiologic-anatomic units of the liver direct the following processes:

a. *Energy homeostasis and nutrient metabolism*: the synthesis, degradation, and coupled interconversion of amino acids, carbohydrates, and lipids are closely linked to hepatic energy metabolism.
b. *Protein synthesis and amino acid metabolism*: The liver uses amino acids directly for protein synthesis and as a source of organic nitrogen for nonessential amino acid synthesis. The overall balance of amino acid synthesis, degradation, dietary supply, and body distribution is reflected by plasma amino acid levels.
c. *Carbohydrate metabolism*: The liver plays an important role in maintaining carbohydrate homeostasis, principally through glucose catabolism, production, and storage. The ability to use, store, synthesize, and release glucose gives the liver a central role in maintaining stable serum glucose levels. Compromise of this function can result in hypoglycemia or hyperglycemia.[18]
d. *Lipid metabolism*: Hepatic metabolic energy requirements are met principally through β-oxidation of free fatty acids (FFA). Fatty acids synthesized in the liver or derived from peripheral fat depots combine with glycerol in the liver to form triglycerides (TG). Through

the production of very-low-density lipoproteins (VLDL), the liver provides peripheral tissues with indirect access to the convergent metabolic processes in the hepatocyte that lead to triglyceride synthesis. Following synthesis by the liver, high-density lipoproteins (HDL) circulate in the plasma, where they scavenge free cholesterol released from aging cell membranes. The liver also produces apoprotein CII, which is required for the peripheral activation of lipoprotein lipase, and cholesterol.[19,20]

e. *Biotransformation*: Many environmental compounds (including drugs) and endogenous metabolic products are lipid soluble and nonvolatile, precluding their efficient excretion in urine or feces. Through biotransformation reactions, the liver transforms these substances into more water-soluble analogs and enhances their excretion via urine or bile.[21]
f. *Excretion*: The biliary tract is the principal excretory route for numerous exogenous and endogenous substances. Six hundred to eight hundred milliliters of bile are secreted daily, using a canalicular surface area of approximately 10 m^2. Inorganic ions account for most of the osmotic activity in bile, keeping it approximately isotonic with plasma. Organic solutes present in bile include conjugated bile acids, phospholipids (lecithin), cholesterol, bile pigments, hormones, and small amounts of protein.[22,23]
g. *Immunologic functions*: A major portion of the mononuclear phagocyte system is centered in hepatic sinusoids. Kupffer's cells use phagocytosis and pinocytosis to clear bacteria, particulate matter, and old erythrocytes from sinusoidal blood. Kupffer's cells are also the major site of lipopolysaccharide (endotoxin) detoxification. The liver also contributes to the humoral arm of body defense through uptake and secretion of IgA.[24]
h. *Vitamin metabolism*: Vitamin uptake, storage, and mobilization are additional important functions of the liver. The absorption of fat-soluble vitamins (A, D, E, and K) is dependent on bile salts. Because vitamin A is stored exclusively in the liver, excess ingestion may be associated with significant hepatic injury. Hepatic stellate cells play a role in vitamin A storage as well. The initial vitamin D activation step, conversion of vitamin D_3 to 25-hydroxycholecalciferol, occurs in the liver. Coagulation factors II, VII, IX, and X are dependent on vitamin K, which is essential for the γ-carboxylation and activation of these factors. Vitamin E has recently garnered much attention due to its potent antioxidative properties. Following a severe thermal or traumatic injury, vitamin E might reduce oxidative stress and subsequent damage.[25–27]
i. *Hormonal system*: The liver is an important site of hormonal synthesis, secretion, or interaction. Growth factors that are important for growth and development such as insulin-like growth factor-I (IGF-I) and the IGF binding proteins (IGFBPs) are made and secreted by the liver. Production and secretion into the bloodstream of angiotensinogen occurs within the liver. Synthesis of hepatocyte growth factor (HGF), a major hepatic regenerative growth factor, occurs in the liver.[28]

The Hepatic Response to a Severe Thermal Injury

LIVER DAMAGE AND MORPHOLOGICAL CHANGES

Burn-induced liver injury is variable and is typically proportional to the severity of the burn injury. Hepatomegaly, or a fatty liver, is a common postburn finding (Fig. 24.1). These changes can be reversed; however the significance of these alterations is related to the extent of fat deposition and its etiology.[29] Autopsies of deceased pediatric burn victims revealed that fatty infiltration of the liver is associated with hepatic failure and endotoxemia.[30] Increased hepatic edema, typically observed within 12 hours after burn injury, is associated with damage to the liver. Both liver and body weight significantly increase at 2–7 days postburn, as compared to nonburned liver/body weight.[13] In burned rats, total hepatic protein concentrations are reduced significantly, suggesting that the increase in liver weight is due to edema and not to increased protein levels or hepatocyte numbers. Hepatic edema may induce release of hepatic enzymes into the circulation as a result of cellular damage or by altering membrane permeability. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are typically detected only at low levels in plasma. Therefore, detection of elevated levels in the circulation indicates possible hepatocyte injury. Severe hepatic damage can also be detected by elevations in serum glutamate dehydrogenase or alkaline phosphatase (ALKP). Elevations in ALKP provide insight into the function of the extrahepatic biliary tract and are frequently elevated in hepatobiliary disease. The liver damage induced by thermal injury is secondary to edema formation, hypoperfusion, and inflammation. Following a severe burn, elevations between 50% and 200% of AST, ALT, and ALKP are observed (Fig. 24.2). These serum markers peak early during the first 24 hours after the burn injury, indicating that burn-induced liver damage is a rapid phenomenon.[14,31]

Increased hepatocyte death, both by apoptosis and necrosis, is associated with liver damage.[13] Two distinctly different pathways result in cell death: programmed cell death (apoptosis) and necrosis.[32] Cell shrinkage, uniform fragmentation of DNA, and membrane blebbing characterize apoptotic cells. Necrosis, on the other hand, is characterized by cellular swelling, fragmentation of the DNA in a random manner, activation of lysosomes, and complete breakdown of the cellular membrane enabling cellular contents to be extruded into the interstitium. These final steps induce an inflammatory response by attracting inflammatory cells, causing the release of free radicals and proinflammatory cytokines, leading to additional tissue breakdown. The morphological hallmarks unique to each process are used to differentiate between apoptotic and necrotic cells. At the time of autopsy, 10–15% of severely burned decedents had signs of liver necrosis, as determined by pathological examination.[33]

Apoptosis also occurs in the liver following a cutaneous thermal injury (Fig. 24.2).[13] The liver tries to maintain homeostasis when hepatocyte apoptosis increases by a compensatory increase in hepatocyte proliferation. Despite

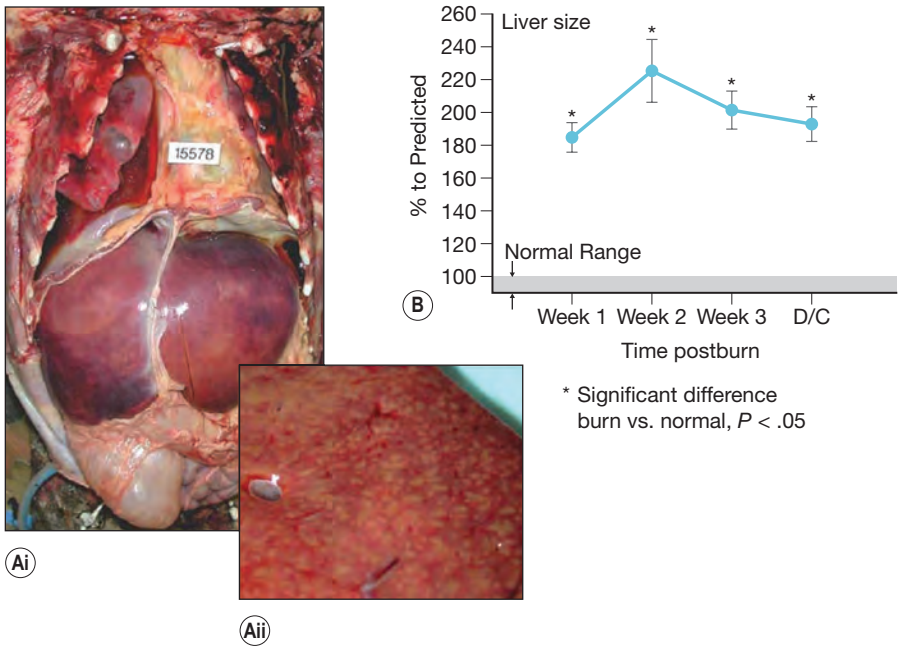

Fig. 24.1 A, Massive hepatomegaly (i) and hepatic fatty infiltration (ii) of a burn victim at autopsy. B, Liver size increased throughout acute hospitalization by over 200% in 242 surviving burn patients. (From Jeschke MG. The hepatic response to thermal injury: is the liver important for postburn outcomes? *Mol Med*. 2009;15:337–351.)

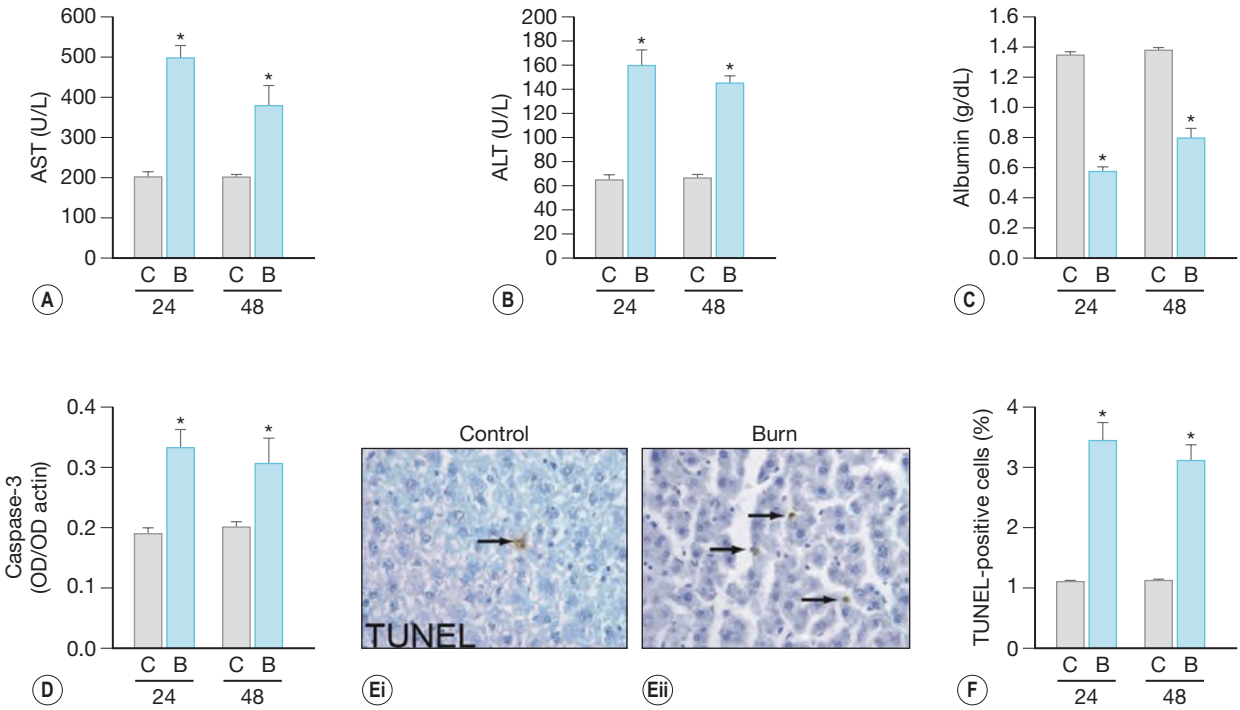

Fig. 24.2 Hepatic dysfunction of the rat burn model mimics the postburn human disease state. A, Serum aspartate amino transferase (AST) 24 and 48 hours after thermal injury. B, Serum alanine amino transferase (ALT) 24 and 48 hours after thermal injury. C, Serum albumin 24 and 48 hours after thermal injury. D, Caspase-3 activity in liver lysates as determined by successive Western blotting with active caspase-3 and actin antibodies. The data are expressed as a ratio of the two band intensities. E, TUNEL staining of a liver section before (i) and 24 hours after (ii) thermal injury. F, Quantified TUNEL-positive cells 24 and 48 hours after thermal injury. Time after injury in hours is indicated. *C,* Control; *B,* burn. Data presented are mean ± SEM. *$P < 0.05$ (Burned animals n = 8 and controls n = 4 per time point). *Significant difference between burn and control, $P < 0.05$. (From Jeschke MG. The hepatic response to thermal injury: is the liver important for postburn outcomes? *Mol Med*. 2009;15:337–351.)

the attempt to maintain homeostasis in overall hepatocyte number, the liver is unable to immediately regain mass or maintain protein concentration. The molecular mechanisms that initiate and propagate hepatocyte apoptosis following a cutaneous burn are not known.[34–37] Blood flow to the bowel is decreased by approximately 60% for up to 4 hours following a thermal injury.[38] Hepatic blood flow is likely decreased as well, and this may be one of the early events inducing programmed cell death. Apoptotic signals, including interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α), increase systemically during this same time frame.[39–42] Additional studies have revealed that the elevations of proinflammatory cytokines are not limited to the serum. Local elevations also occur after a thermal injury, as seen with increased concentrations of hepatic IL-1α, IL-1β, IL-6, and TNF-α.[43–45] Taken together, these events are probably early events in the induction of hepatocyte apoptotic signaling.

Underlying Molecular Mechanisms

The induction of hepatocyte apoptosis and dysfunction following a severe burn (Fig. 24.3), involves specific reductions in endoplasmic reticulum (ER) calcium that lead to increases in cytosolic calcium.[46] Mitochondrial damage occurs as a result of increased cytosolic calcium, leading to the release of cytochrome c, which then binds to the inositol triphosphate receptor (IP3R), causing a reduction in the amount of calcium stored in the ER. In addition, ER stress triggers apoptosis by activating c-Jun N-terminal-kinases (JNK). The serine on the insulin receptor substrate 1 (IRS-1) protein is then phosphorylated, blocking the tyrosine on the same protein from being activated by phosphorylation. At the same time, the prosurvival phosphoinositide 3-kinase (PI3K)/serine-threonine protein kinase (Akt) signaling pathway is blocked, amplifying the ER stress response by further activating the inositol triphosphate receptor (IP3R). If the unfolded protein burden can be limited through the use of chemical chaperones, this discovery may be of therapeutic significance as a method to promote hepatocyte survival.[47] Alternative pharmacologic agents are being developed to block proapoptotic ER stress signaling pathways, and, looking ahead, these alternatives may prove beneficial by improving clinical outcomes.[48,49]

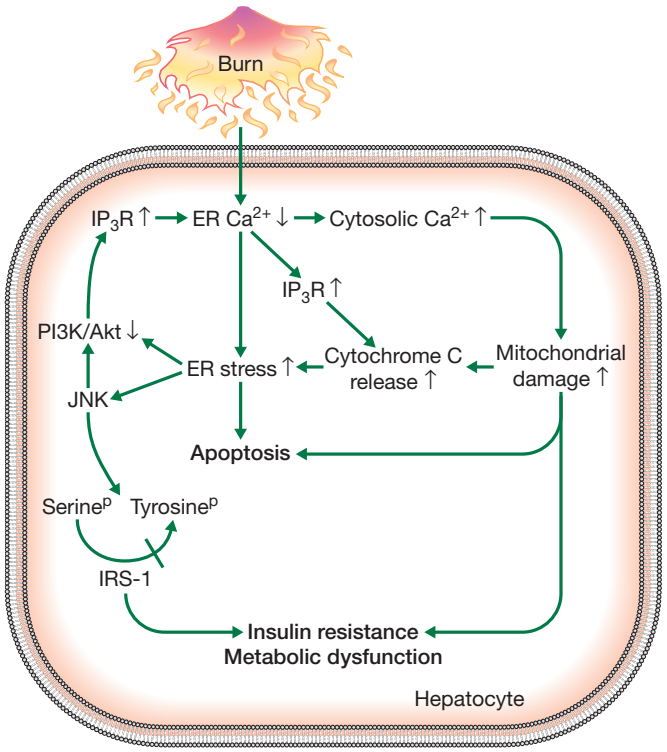

Fig. 24.3 Schematic of suggested pathways involved in the hepatic response postburn. Thermal injury leads to gross alterations in endoplasmic reticulum (ER) calcium with increased cytosolic calcium concentration. Increased cytosolic calcium induces mitochondrial damage, which releases cytochrome c. Cytochrome c increases the existing ER stress/Unfolded protein response (UPR) but also binds to the IP_3R, augmenting the depletion of ER calcium stores. ER stress/UPR leads to cell apoptosis and activation of JNK, which phosphorylates the 612 serine of IRS-1, blocking phosphorylation of tyrosine IRS-1. ER stress/UPR also impairs the prosurvival PI3K/Akt signaling, resulting in increased activation of the IP_3R, increasing ER stress/UPR. (From Jeschke MG. The hepatic response to thermal injury: is the liver important for postburn outcomes? *Mol Med.* 2009;15:337–351.)

EFFECTS ON THE BILIARY SYSTEM

Intrahepatic cholestasis frequently occurs following trauma or sepsis without demonstrable extrahepatic obstruction. Drug toxicity, total parenteral nutrition, and hypoxia are also associated with this phenomenon.[50] The occurrence of intrahepatic cholestasis is associated with impaired bile acid and organic anion transport in basolateral and canalicular hepatocytes.[51,52] Intrahepatic cholestasis occurs in approximately 26% of patients.[33]

MONONUCLEAR PHAGOCYTE SYSTEM (MPS)

The immune system is severely compromised following a major thermal injury, resulting in heightened susceptibility to infections and sepsis.[51,53,54] The phagocytic functions of the mononuclear phagocyte system (MPS) are depressed postburn,[55] although the mechanism by which this occurs is unknown. Investigations have demonstrated that MPS dysfunction may be related to hemolysis. By regulating the production of APPs and proinflammatory cytokines, the liver modulates the immune response.[43,56,57]

Glucose, Protein, and Lipid Metabolism

Hypermetabolic stress is induced by large burns covering in excess of 40% of the total body surface area (TBSA), and this response is accompanied by inflammation, the development of hyperdynamic circulation, temperature elevation, and increased glycolysis, gluconeogenesis, glycogenolysis, proteolysis, and lipolysis.[58–60] These massive alterations affecting major physiologic processes occur following traumatic injury and critical illness as well, although the duration, severity, and the magnitude of these responses are far greater in severely burned patients.[5] Exaggerated elevations in catecholamines, glucocorticoids, glucagon, and dopamine trigger the hypermetabolic response via a highly complex cascade of events.[4,31,61] Additional factors in this response, however, have been identified, including proinflammatory cytokines (IL-1 and IL-6, TNF), platelet-activating factor, endotoxin, neutrophil-adherence complexes, free radicals (reactive oxygen species and nitric oxide),

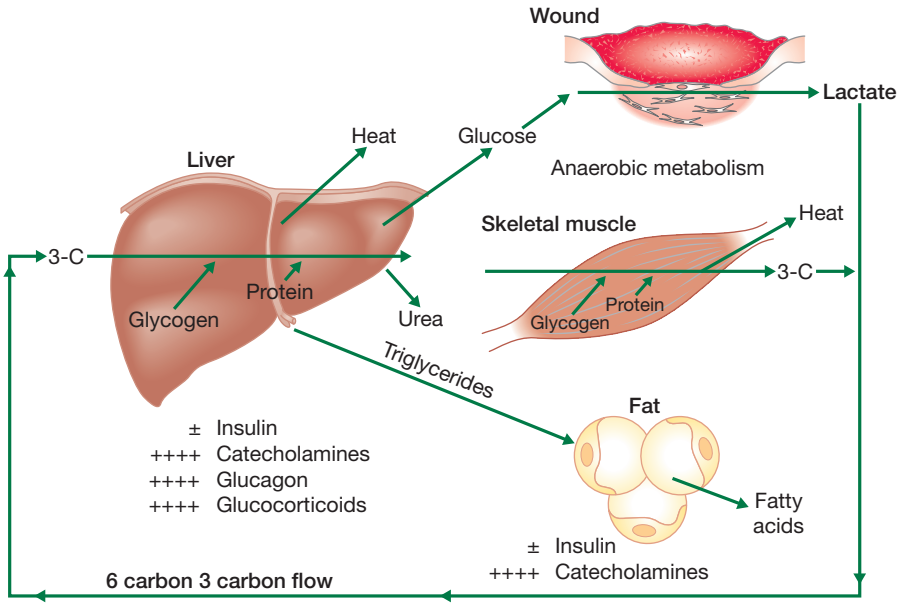

Fig. 24.4 Metabolic changes postburn with the liver playing an essential role. (From Jeschke MG. The hepatic response to thermal injury: is the liver important for postburn outcomes? *Mol Med.* 2009;15:337–351.)

and factors involved in the coagulation and complement cascades.[62] Following activation of the biological processes, these mediators and the resulting byproducts contribute to the increased metabolic rate and altered glucose metabolism that occurs following thermal injuries.[63]

The precise temporal occurrence of the modulation of these postinjury metabolic events has led to the classification of two events: the "ebb phase" and the "flow phase."[64] The first 12–14 hours following a severe burn injury are called the "ebb phase."[65,66] Events characterizing this period include decreased cardiac output, reduced oxygen consumption, attenuated metabolic rate, and hyperglycemia with impaired glucose tolerance. These metabolic processes slowly increase to a plateau over the next 5-day period, termed the "flow phase."[64] During this time, insulin release in response to glucose challenge is twice that seen in nonburned volunteers. Insulin resistance characteristically develops concurrent with elevation in plasma glucose levels during this period[67] (Fig. 24.4). Although these metabolic alterations were assumed to resolve as soon as wound closure was complete, impaired glucose metabolism has been demonstrated in approximately 12% of pediatric burn injury survivors 24–36 months after severe thermal injuries; burn size, age, lean mass, and adiposity are predictors of insulin resistance in burned children.[68]

Because the metabolic alterations that accompany critical illness have the potential to modify energy substrate utilization, glucose availability must be maintained. Stress mediator release acts in opposition to the anabolic actions of insulin by augmenting hepatic glucose production[69] to increase gluconeogenic substrates such as glycerol, alanine, and lactate by increasing lipolysis of adipose tissue and proteolysis of skeletal muscle.[70–74] The release of hepatic glucose is not suppressed by hyperglycemia, and the physiologic inhibitor property of insulin on glycogenolysis is impaired, inducing posttrauma hyperglycemia.[75,76] The hyperglycemic response to stress is further aggravated by catecholamine-induced enhancement of glycogenolysis in the liver and direct sympathetic stimulation of glycogen breakdown.[72] Peripheral insulin resistance occurs in the muscle and adipose tissue when glucose disposal is impaired by catecholamines following alterations in insulin signaling and glucose transporter type 4 (GLUT-4) translocation.[71,77] At 7 days postinjury, IRS-1 activation is impaired at the tyrosine binding site, leading to Akt inhibition in muscle from severely burned children.[67] Protein farnesylation (a posttranslational lipid modification of cysteine residues) has been identified as an additional pathophysiologic mechanism involved in the metabolic dysfunction observed after burn injury.[78] Interference with the insulin signaling pathways in liver and muscle has also been linked to a reduction in mitochondrial oxidation in both tissues and altered lipolytic rates, resulting in attenuation of insulin's action on glucose production in the liver and glucose uptake in the liver.[76,79] Glucose production via gluconeogenesis and glycogenolysis is increased by glucagon and epinephrine, which, in concert with cortisol and growth hormone (GH), act to sustain this response.[69,80] Release of the aforementioned stress hormones is initiated by the action of proinflammatory cytokines, resulting in an indirect effect of these inflammatory mediators on postburn hyperglycemia.[81–84] These same proinflammatory cytokines, including IL-6, monocyte chemotactic protein-1 (MCP-1), and TNF, have been found to directly modify the insulin signal transduction pathway, further exacerbating postburn insulin resistance in the liver and skeletal muscle.[85,86] Throughout the acute and convalescent periods following the burn injury, breakdown of lean muscle protein is prolonged by the supraphysiological expression of proinflammatory cytokines and perturbations in the metabolic pathways.[8,87,88] Thermal injury impairs the body's ability to use fat as an energy source. Significant variation in the expression of the counterregulatory hormones glucagon and cortisone occurs postburn. While burn injury decreases glucagon, there is a

marked increase in cortisone levels that lasts for at least 3 years postinjury.[61,89] Although the likelihood that perturbations of the hormonal system drive postburn hyperglycemia is low, impairment of insulin receptor signaling at the molecular level is the more probable instigator.[90]

Soon after injury, marked lean body mass wasting is driven by the increase in energy requirements, which are mainly satisfied by degradation of proteins in skeletal muscle in severely burned individuals.[5,91] Stable isotope infusion studies have confirmed that this muscle breakdown is associated with pronounced negative nitrogen balances that persist for up to 9 months postinjury.[58] Significant reductions in muscle mass probably contribute to whole-body postburn insulin resistance, as the majority of insulin-stimulated glucose uptake occurs in the skeletal muscle.[92] Stable isotope studies using leucine to monitor whole-body protein flux confirmed the relationship between hyperglycemia and muscle protein catabolism and even showed that hyperglycemia increases proteolysis.[93] Significantly elevated rates of infection and delayed wound healing are associated with reductions in lean body mass of 10–15%.[94] The growth delay in severely burned pediatric patients that lasts for up to 2 years may be accounted for by this persistent protein catabolism.[58,95–97]

During the acute response to burn, there are significant changes in the metabolism of fat, which lead to elevations in serum TGs and FFA, along with changes in body fat content and distribution.[98] This massive mobilization of fat tissue results in fatty deposits in the liver and other organs, most likely due to decreased expression of fat-transporting proteins coupled with elevations of serum TGs and FFA. Hepatomegaly with hepatic steatosis is associated with increases in septic episodes and ultimately with greater mortality,[30] further supporting the notion that impaired liver function in the severely burned patient is closely linked to survival. The hepatic accumulation of TGs occurs both in critically ill patients and in severely burned patients.[99–101] In fact, liver size is increased by more than fourfold in severely burned patients.[30,102] Despite the similar deposition of TGs in the liver following critical illness, the rate of TG accumulation in the postburn liver is far greater than that of any other pathological condition with hepatic steatosis as a sequelae. Hepatic TGs accumulate following a severe burn, resulting from lipolysis induced by β-adrenergic stimulation that releases excessive amounts of fatty acids into the circulation.[103,104] Although insulin typically suppresses lipolysis, the burn-induced insulin resistance is apparent by the diminished effectiveness of insulin in this capacity.[100] Uptake of fatty acids from the circulation by the liver is proportionate to the amount of FFAs available,[20,105] as lipolysis increases FFA delivery, hepatic uptake is increased, and the fatty acids are either oxidized or synthesized into TGs. Because oxidation is a rate-limited step, there is a marked acceleration in the rate of TG synthesis and deposition when large amounts of fat are available either due to lipolysis or diet.[106] Synthesis of hepatic TGs is considered to be a direct metabolic response to a severe burn injury. Excessive intake of glucose and consequent hyperglycemia also lead to postburn hepatic steatosis.[107] Under normal conditions, increases in VLDL-TG secretion accompany accelerated synthesis of hepatic TGs, which reduces the accumulation of TGs in the liver. However, in severely burned patients, there is a reduction in secretion of VLDL-TGs, which is not responsive to the increased synthesis of liver TGs.[104] It would therefore be expected that reducing FFA availability could minimize accumulation of TGs in the liver.

The liver is clearly a key player in the orchestration and modulation of burn-responsive metabolic processes postburn. Alterations in the metabolism of glucose, fat, and protein can result in poor outcomes, and these processes are controlled by the liver. Therefore, we propose that the liver is an essential organ in the response to severe burn injury and that liver function may determine outcomes of severely burned patients.

Acute-Phase Response

There is a shift in hepatic protein synthesis following a major trauma such as a severe burn injury. Hepatic constitutive protein production is downregulated while production is shifted to increase APPs.[11,31,57] This shift in production of APPs represents a reprioritization of liver function to meet new metabolic demands, heighten the immune and inflammatory responses, and support coagulation and wound healing.[57] Traditionally APPs have been divided into two subcategories based on whether they were mediated by IL-1-like cytokines such as IL-1 or TNF (type I APPs, e.g., haptoglobin or α1-acidglycoprotein) or IL-6-like cytokines, including IL-6 or IL-11 (type II APPs, e.g., α2-macroglobulin and fibrinogen).[11] As more evidence supports frequent communication between the type I and type II APPs, this strict division appears to be an artificial categorization that is no longer representative of function or response. While acute-phase protein synthesis is upregulated, constitutive hepatic proteins, including albumin, transthyretin, transferrin, and retinol binding protein, are downregulated.[108–111] Relative to normal levels, albumin and transferrin expression decrease by 50–70% following a severe burn. Two mechanisms downregulate the production of these proteins: the liver shifts from synthesizing constitutive proteins to APPs, coupled with extensive loss of constitutive proteins due to capillary leakage. These proteins are lost into the massive extravascular space and burn wound. The loss of these proteins following trauma, however, may negatively impact clinical outcomes. Albumin and transferrin are important transporter proteins and contribute to regulation of both osmotic pressure and plasma pH. Due to the exclusive roles that these proteins play, reduction in their synthesis has been used to monitor recovery and predict mortality.[111–113]

As noted earlier, cytokines also mediate the acute-phase response. The temporal, biphasic modulation of proinflammatory cytokine expression is highly regulated and predictable. Immediately following a burn, there is an increase in IL-1, IL-6, IL-8, and TNF expression that peaks between 2- and 10-fold above normal levels. After approximately 12 hours, there is a slight decrease in expression, followed by another increase before the overall levels begin to decline. As a testament to the extreme nature of a burn compared with other traumatic injuries, both animal and human studies have revealed that, following a traumatic injury, cytokines return to normal levels within 2 days, whereas the elevation can last for more than 2 weeks after thermal injury.[114,115] The signaling cascade modulating this response includes a multitude of pro- and antiinflammatory signal transcription

factors including nuclear factor-κ B (NF-κB), c-jun, tyrosine phosphorylation and activation of intracellular tyrosine kinases (JAKs), CCAAT/enhancer-binding proteins (C/EBPs), signal transducer and activator of transcription (STAT) 1, STAT3, STAT5, latent cytoplasmic transcription factors, and mitogen-activated protein.[56,108,109,116–119] Transcription, translation, and expression of APPs are initiated by the action of these signaling molecules. IL-6 in particular is suspected of being a major—if not the primary—mediating cytokine. Amplification of the IL-6 signal occurs by activation of glycoprotein 130 (gp 130) and the JAK-kinases (JAK-1) and propagation of the signal via translocation of STAT1 and STAT3 to the nucleus, where transcription and translation of APPs occur. This rapid initiation of the acute-phase response serves a single purpose: to protect the body from further damage. When the acute-phase response occurs in a balanced fashion, the body is protected and returns to a homeostatic existence. When there are prolonged amplifications of proinflammatory cytokines and APPs, however, hypercatabolism results, leading to increased incidence of sepsis, multiorgan failure, morbidity, and mortality.[8,10,112]

Vitamin Metabolism

Vitamins are requisite components of many biological functions including energy production and utilization, inflammation, wound healing, metabolism, and antioxidation. Vitamin deficiencies are caused by the burn-induced hypermetabolic response, so supplementation is required to maintain crucial biological functions.[120,121] Vitamin A is reduced in burn patients, perhaps related to reduced levels of its transporter—retinol binding protein. Without vitamin A, dermal wound repair is suboptimal, and supplementation with this vitamin may enhance wound healing. Vitamin E is a critical antioxidant that has profound effects in reducing lung injury.[27] Because this vitamin is also depleted in the serum and in the tissue following a burn injury, supplementation is also recommended. Vitamin D, a necessary nutrient to maintain bone health, is also reduced following a burn injury, contributing to postburn osteopenia and increasing the risk of bone fractures; vitamin D_3 supplementation after burn injury and beyond the acute period is advocated to counteract the trajectory of low vitamin D levels and associated morbidity.[122–124] Riboflavin and thiamin, also reduced by burn injury and trauma, are important participants in energy generation, protein metabolism, and wound repair. Thiamin is a key co-factor for energy generation in the Krebs cycle, for glucose oxidation, and for the formation of collagen. Riboflavin decreases postburn; due to its role as a coenzyme in oxidation-reduction reactions, this vitamin should also be supplemented.[120] Postburn reduction of folic acid negatively impacts DNA and RNA synthesis. Folate utilization is also impaired by inadequate availability of vitamin B_{12} and methionine. Folate deficiency therefore can also occur as a result of deficient levels of these two nutrients. Energy-generating and protein metabolic processes rely on the coenzymes vitamin B_6 and B_{12}. Supplementation should be in the form of a multivitamin in order to have adequate levels of these necessary components. Additional functions of these vitamins include fatty acid catabolism (vitamin B_{12}) and metabolism of amino acids (vitamin B_6). The antioxidant/free radical scavenging properties of vitamin C are crucial following a burn injury. As part of the hypermetabolic response, an elevation in free radicals including superoxide, peroxide, and hydroxyl is thought to increase burn-induced vascular permeability. Administration of vitamin C may reduce microvascular permeability, which would reduce the need for fluid replacement, in turn improving patient outcomes.[125]

Coagulation and Clotting Factors

A severe burn injury alters the coagulation cascade and activates thrombotic and fibrinolytic responses. During the early shock phase following the burn, there is a decrease in most of the homeostatic markers due to dilutional effects associated with fluid resuscitation and loss or degradation of plasma proteins to the extravascular space or the wound. Once resuscitation is achieved, clotting factors typically return to normal levels. Thrombogenicity increases later during the postburn course as a result of decreases in antithrombin III, protein C, and protein S levels resulting in an increase in the risk of thrombosis. The risk for developing disseminated intravascular coagulation (DIC) is considerably heightened by this hypercoagulable state. Postmortem DIC has been discovered in 30% of all examined cases, indicating another association between liver damage and poor outcomes.[126]

Hormones

The liver is a major site for hormone synthesis and action. In vitro and in vivo studies have demonstrated that HGF accelerates hepatic regeneration, improves hepatic function, and modulates the acute-phase response.[127–129] Elevation of plasma HGF occurs within 30–60 minutes following injury, presumably signaling the hepatocytes to begin dividing in order to meet the anticipated burden. The initiating signal that stimulates plasma HGF upregulation, however, is currently unknown, although it has been hypothesized that there is either an increase in extrahepatic production of HGF by the spleen, lung, gut, or kidney or a decrease in excretion of hepatic HGF. Hepatocyte DNA synthesis is stimulated by this rapid increase in HGF.[28] HGF only has this effect under specific conditions; when administered to noninjured rats, only a small number of hepatocytes were induced to initiate DNA synthesis. This study demonstrated that priming events—such as those experienced following a burn injury—are required to enable hepatocytes to respond to mitogenic signals.[28]

IGF-I is also synthesized in the liver.[130] In the body, approximately 99% of IGF-I is bound to one of the six binding proteins, IGFBP 1–6, for transport.[131] These hormones are synthesized in the liver following GH stimulation.[132] The effects mediated by IGF-I are similar in burn and other pathological states—improvements in cell proliferation, cell repair mechanisms, increased protein expression in the muscle, and restored normal functioning of intestinal and immune cells.[133–135] In the immediate posttrauma and postburn periods, IGF-I is a key player in regenerating the liver and modulating the acute-phase response to restore hepatic homeostasis and function.[135,136] The influence of hormones on hepatic recovery and regeneration is an important consideration when trying to restore hepatic function.

Importance of the Liver for Postburn Outcomes

We have described liver function under normal and severe stress conditions. In addition, it is important to emphasize that it is not known whether liver function and integrity are essential for favorable outcomes following a severe burn. Price et al. found an association between impaired liver function and integrity, and unfavorable postburn outcomes, in a retrospective study.[137] Our group and others have conducted several studies to determine the relationship between liver function and burn outcomes. In a review of autopsies from severely burned children, Barret et al. reported the incidence of hepatomegaly, fatty liver, and sepsis. Approximately 80% of the patients had hepatic fat infiltration, whereas 100% of the patients had hepatomegaly.[30] Additionally the incidence of sepsis was greater in patients with severe fatty infiltration of the liver. In a study of 102 severely burned children, burn injury was associated with liver enlargement in all patients regardless of outcome.[14] During the first week following a burn injury, liver size was significantly increased (+185 ± 5%), peaked during the second postinjury week (+226 ± 19%), and remained significantly enlarged (+189 ± 10%) at the time of discharge. Prolonged alteration of the hepatic structure was indicated by the continued increase in predicted liver weight (+140–150%) even 6, 9, and 12 months postburn. Synthesis of hepatic proteins was impaired for at least 12 months following the burn injury. Based on this study, it was concluded that a severe burn injury induced significant enlargement of the liver concurrent with impaired hepatic protein synthesis.

Mittendorfer et al. determined the contributions of hepatomegaly and hepatic steatosis to outcomes following a severe burn in the well-established rodent model.[106] Following a burn covering 60% TBSA, nutritional manipulation was used to induce fatty liver in a subset of rats. Hepatomegaly and hepatic steatosis were induced by consumption of a high-fat diet. If both hepatomegaly and fatty liver were present, postburn mortality increased to 40% (compared with 0% in the control group). Based on these findings, we concluded that the integrity and function of the liver were crucial for survival after a severe burn injury because hepatomegaly, hepatic steatosis, and liver dysfunction were associated with increased postburn mortality. Other models have been used to demonstrate the importance of liver function for survival after critical illness.[138] In a murine sepsis model, Deutschman et al. found that IL-6 knockout mice were more likely to die as opposed to their littermates with normal IL-6 expression. Hepatic alterations were apparent in the IL-6 knockout animals following cecal ligation and puncture. Cholestasis, steatosis, and hepatocellular injury were not found in the normal mice but were apparent in the IL-6 knockout animals; liver regeneration was absent in the septic IL-6 knockout animals, while apparent in the control group. The investigators demonstrated that IL-6 is a key regulator of the pathological changes of the liver observed after sepsis. The most interesting finding, however, was the association of a three- to fourfold increase in mortality in animals with hepatic damage or dysfunction.[138] Hepatic failure and concomitant hepatocyte apoptosis have been linked to the signaling pathway involving Fas and Fas ligand (Fas/FasL).[139] Through a series of RNA interference studies, Song et al.[140] elegantly demonstrated that reduction in the expression of Fas is protective during fulminant hepatitis. Silencing Fas prevented death, leading to the conclusion that hepatic dysfunction contributes to mortality and restoration of hepatic function reduces mortality. Although investigation of the role of Fas/FasL in burns is still in its early stages, evidence supports the postburn induction of Fas/FasL[141] possibly hinting at the mechanism underlying burn-induced hepatocyte apoptosis and dysfunction.

Because animal models do not fully recapitulate the human clinical response, prospective clinical studies are necessary to determine the relationship between liver function and postburn outcomes. In a study conducted as part of the Inflammation and the Host Response to Injury Collaborative Research Program, we used discovery proteomics to compare plasma protein expression in survivors and nonsurvivors of severe burn injuries.[142] A total of 32 patients, including 16 nonsurvivors and 16 survivors were matched according to burn size and injury severity. Discovery proteomics techniques were used to determine plasma protein expression. In burn patients, 43 proteins were associated with mortality. The main activity of the associated proteins involve the complement cascade, coagulation cascade, acute-phase response pathway, and cytokine signaling suggest that the response of the liver may be crucial to survival following a burn injury.[142]

Another study involving 330 burned children determined whether proteomics could be used to augment clinical parameters as predictors of mortality in pediatric burn patients. The study showed that the combination of both clinical and proteomic variables improved the outcome prediction accuracy from 52% to 81%. The panel of 38 potential biomarkers included hormones, proteins, and cytokines, and most of these biomarkers are produced by the liver. Taken together, the data in severely burned children and adults indicate that the liver is crucial for determining survival and postburn outcomes.[143]

Conclusion

To summarize, the widespread effects of a burn injury impact almost every organ system, resulting in significant morbidity and mortality.[5] This chapter has explored the liver's central role in the response to severe thermal injury. Myriad functions of the liver are essential for survival (Fig. 24.5), and the burn injury alters all of these hepatic responses. Available data provide strong evidence that the concentrations of hepatic proteins in the circulation can serve as biomarkers predictive of postburn morbidity and mortality. We therefore interpret these findings as supporting the central role of the liver in determining patient outcome and propose that attenuation of liver damage and restoration of hepatic function will result in a reduction of postburn morbidity and mortality.

25 Importance of Mineral and Bone Metabolism after Burn

JEFFREY LISIECKI, BENJAMIN LEVI, and GORDON L. KLEIN

Metabolic Actions of Calcium, Phosphate, and Magnesium

As insoluble elements, minerals are major inorganic components of bone tissue and confer weight-bearing properties to the skeleton. Soluble calcium (Ca), phosphate (PO_4), and magnesium (Mg) play important roles in metabolic pathways, acting as cofactors and regulators of numerous biochemical systems.

CALCIUM

Calcium functions in neurotransmission, cell depolarization, impulse propagation, and muscle contractility. In intracellular pathways, after capture by Ca-binding protein or protein kinase C, Ca serves as a second messenger. In extracellular metabolism, Ca activates several factors in the coagulation cascade.[1]

PHOSPHATE

Phosphate has an integral role in the storage and transfer of energy. Inorganic phosphate groups are exchanged in multiple metabolic reactions that allow energy-demanding activities in the human body (e.g., adenosine triphosphate [ATP] metabolism). Phosphorylation reactions represent the mainstay of cellular respiration. In the form of phospholipid, PO_4 is a major structural component of cell membranes.[1]

MAGNESIUM

Magnesium is essential to the cell and mitochondria. It is a cofactor in the transfer of PO_4 groups, and it is necessary in reactions involving purine nucleotide metabolism.[1] Mg also functions in plasma membrane excitability, stabilizing conditions characterized by abnormal nerve excitation or vasospasm.

Homeostasis of Calcium, Phosphate, and Magnesium

CALCIUM

Intestinal efficiency to absorb Ca is inversely related to Ca intake, varying from 20% to 70%.[2] The regulatory mechanism is shown in Fig. 25.1. With high Ca intake, transient hypercalcemia occurs followed by suppression of parathyroid hormone (PTH) secretion and PTH-stimulated renal conversion of 25-hydroxyvitamin D to calcitriol (1,25-dihydroxyvitamin D). With low Ca intake, the opposite occurs.

These mechanisms are likely mediated by the parathyroid chief cell Ca-sensing receptor (CaR). The CaR is a membrane-bound G protein-coupled protein that may be up- or down-regulated.[3] In patients with CaR downregulation, higher circulating Ca is required to suppress PTH production and secretion, giving rise to primary hyperparathyroidism.[4] In patients with CaR upregulation, less circulating Ca is needed, leading to hypoparathyroidism.[5]

Parathyroid hormone normally increases bone resorption and renal tubular Ca reabsorption to raise serum Ca concentrations. Furthermore, it stimulates the renal enzyme 25-hydroxyvitamin D-1α hydroxylase to convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D or calcitriol. Calcitriol then binds to intestinal epithelial cells and increases transcellular Ca absorption.

Intravenous (IV) administration of Ca bypasses the intestinal control mechanism and suppresses PTH and calcitriol production.

PHOSPHATE

In contrast to Ca, the intestine plays no significant regulatory role in the absorption of PO_4. Approximately 80% of dietary PO_4 is absorbed, and the bone stores approximately 90% of the body's PO_4. Homeostatic control appears to rest primarily within the kidney.[6,7] Thus, the renal excretory rate of PO_4 primarily regulates serum PO_4 concentrations and maintains them within a normal range. Fibroblast growth factor (FGF)-23 is a key regulator of PO_4 and vitamin D metabolism in humans.[8] FGF-23 gene mutations cause autosomal dominant hypophosphatemic rickets, a phosphate-wasting disorder. FGF-23-mediated renal phosphate wasting occurs through downregulation of the type II sodium–phosphate co-transporters NPT2a and NPT2c.[8]

MAGNESIUM

Approximately 60% of the body's Mg is stored in the skeleton[1] but not at sites where matrix is calcified. Mg absorption varies with dietary intake, with about 40% of an average daily load being absorbed.[1] The relationship between Ca and Mg absorption is described as inverse, but the mechanism of this is unclear. Renal excretion is the main route of Mg elimination, and it may vary with Mg

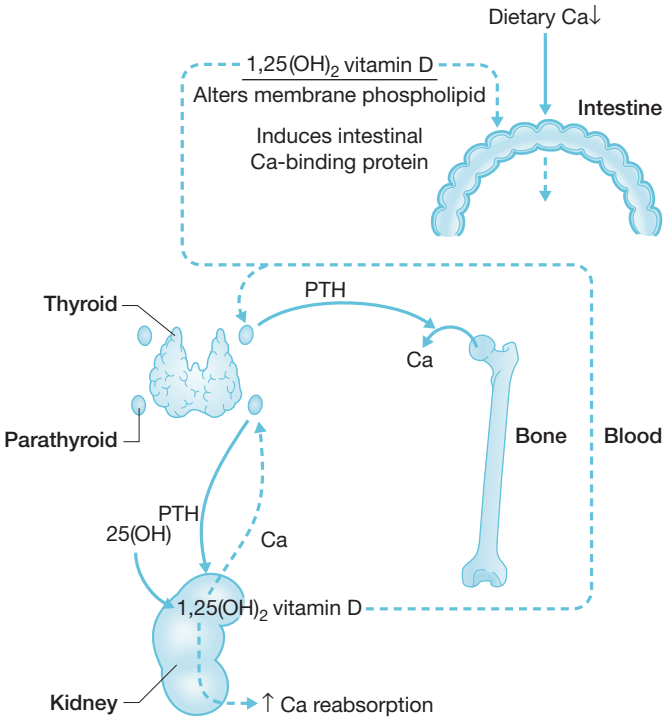

Fig. 25.1 Vitamin D and calcium metabolism. *PTH,* Parathyroid hormone.

concentration in serum. A large paracellular pathway for the intestinal absorption and secretion of Mg exists and is dependent on luminal Mg concentrations. The Mg ion channel, TRPM6, is located in intestinal brush border epithelial cells and may participate in Mg homeostasis in the gut. Mg is 70% ultrafiltrable in the serum.[1] About 70% of filtered Mg is reabsorbed along the cortical afferent limb of the loop of Henle.[1] Whereas hypermagnesemia increases urinary Mg excretion by activating the renal CaR,[9] hypomagnesemia increases loop of Henle Mg reabsorption and reduces urinary Mg excretion. Loop diuretics increase urinary Mg excretion. Because little distal tubular Mg reabsorption occurs, an IV fluid bolus decreases Mg reabsorption and increases urinary Mg excretion.[1]

Effect of Burn Injury on Calcium, Phosphate, and Magnesium Homeostasis

Significant burn injuries trigger a cascade of effects that lead to alterations in the body's metabolism of bone and minerals. These effects can be thought of in two distinct phases: the inflammatory phase and the subsequent stress response, although they occur concurrently. The inflammatory response after burn injury leads to high levels of cytokines, including interleukin (IL)-1β and IL-6, which stimulate the osteocytic and osteoblastic production of the ligand of the receptor activator of NFκB (RANKL). RANKL stimulates the differentiation of marrow stem cells into osteoclasts, stimulating bone resorption and releasing mineralized Ca into the serum.[10,11] The concomitant stress response is marked by increases in urine free cortisol, which is responsible for longer-term alterations in mineral metabolism and longer-term bone loss.[11]

Although the effects of burn injury on mineral ions are not fully understood, studies from the University of Texas Medical Branch and Shriners Hospitals for Children in Galveston describe some of the developments in this area. In children with greater than 30% total body surface area (TBSA) burns, ionized Ca is, on average, 5% below the lower normal limit.[12] In addition, serum PTH levels are too low for ionized Ca levels, indicating hypoparathyroidism. Administration of a standard amount of PTH does not increase urinary cyclic AMP and PO_4 excretion,[12] pointing to PTH resistance. Mg depletion, encountered in all the burn patients studied,[12,13] impairs hypocalcemia-induced PTH secretion and imparts resistance to PTH infusion. The prevalence of Mg depletion may result from resuscitation of patients with IV fluids lacking Mg.[12] Aggressive parenteral Mg supplementation produces repletion in 50% of patients. However, it does not improve hypoparathyroidism,[13] making the cause of postburn hypoparathyroidism unclear. Sheep studies revealed that an approximate 50% upregulation of parathyroid CaR occurs at 48 hours after burn injury,[5] associated in humans with decreased circulating Ca necessary to suppress PTH secretion.[3] The proposed mechanism underlying this phenomenon, known as a reduced set point for Ca suppression of PTH secretion, is shown in Fig. 25.2. Cytokines, especially IL-1β and IL-6, are highly produced after the systemic inflammatory response. These cytokines stimulate parathyroid cell production of CaR in vitro.[14-16]

The upregulation of parathyroid CaR decreases PTH release, lowering the blood's ionized Ca concentration.[10] This is believed to represent an effort by the body to modulate the duration and intensity of the inflammatory response after burn injury. It has been demonstrated in vitro that mononuclear cells in the peripheral blood produce chemokines in response to the medium Ca concentration. Chemokines may then attract more inflammatory cells via the production of Macrophage inflammatory protein 1 alpha (MIP-1α) and RANTES. Therefore, it appears that the inflammatory response to burn injury increases bone *re*sorption via RANKL, which in turn augments the inflammatory response, and the CaR pathway may act as a modulator of this response.[10]

In a study of 11 adult burn patients, serum concentrations of PO_4 and Mg were low, consistent with abnormalities observed in Ca homeostasis.[17] Six patients had low serum ionized Ca concentrations, three of them manifesting hypocalcemia during the first 48 hours after burn. Four had hypophosphatemia; this was most prevalent at postburn day 7. Five had hypomagnesemia, with this finding most likely to present on postburn day 3. One patient demonstrated hypercalcemia and one hyperphosphatemia. No patients had hypermagnesemia. Elevated ionized Ca or PO_4 was always transient.

Regarding alterations in bone and mineral metabolism in adults, a 2016 study of 32 adult male patients with a median TBSA of 40% found significant changes in bone turnover markers.[18] In the first 7 days after burn injury, they found increases in bone-specific alkaline phosphatase (ALP), FGF-23, and intact PTH. Serum phosphate also increased in this first week postburn. These were accompanied by decreases in 25-OH vitamin D, albumin, and ionized

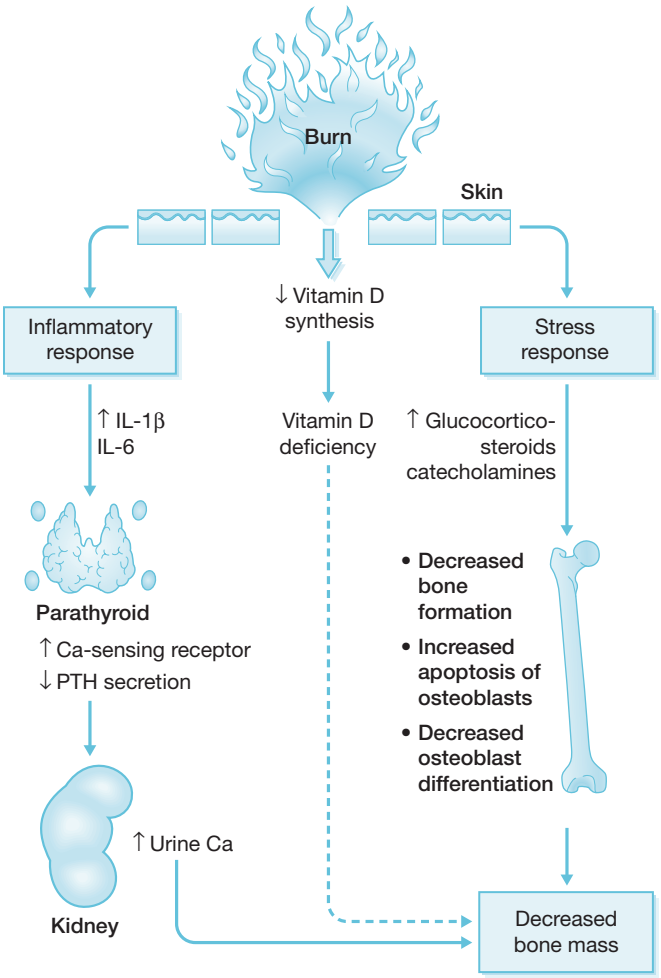

Fig. 25.2 Mechanisms of bone loss after severe burn. *IL,* Interleukin; *PTH,* parathyroid hormone

Ca. In the later phase (weeks 1–8 postburn), they found increases in Ca and ionized Ca; intact PTH, FGF-23, and phosphate all decreased in this period.[18]

Hypocalcemia cannot be diagnosed from total serum Ca concentration, owing to variability in serum albumin concentrations after burn. Blood ionized Ca concentration yields a more accurate diagnosis. Several mechanisms may underlie hypocalcemia. One is the extracellular–intracellular shift of Ca, supported by Ca accumulation seen in the erythrocytes of a burn patient.[19] Another is increased urinary Ca excretion, which occurs in burned children and is consistent with documented secondary hypoparathyroidism.[12] Ca loss in tissue exudates could also contribute to hypocalcemia. Although the amount of Ca in wound exudates is likely insufficient to account for postburn hypocalcemia,[20] few studies have measured Ca content in burn wound exudates.

Although fecal Ca losses can be high in burn patients[20] and burn-induced increases in endogenous corticosteroids may impair intestinal Ca absorption,[21] no evidence suggests that hypocalcemia is caused by corticosteroid-induced impairment of intestinal reabsorption of Ca secreted into the intestinal lumen. Other proposed mechanisms include reduced bone turnover.[17,22] However, upregulation of parathyroid CaR by inflammatory cytokines followed by a reduction in set point for Ca suppression of PTH production remains the most attractive hypothesis.[5,12]

Studies of 24 children with massive burns demonstrated a low serum concentration of 25-hydroxyvitamin D from as early as 14 months after burn[23] up to 7 years,[24] correlating with low bone density Z-scores.[24] Serum 1,25-dihydroxyvitamin D concentrations were normal 2 years after injury but were low at 7 years in 50% of patients.[24] This suggests that these patients became progressively vitamin D deficient.[24]

Possible explanations for postburn hypophosphatemia include intracellular PO_4 accumulation, inadequate intake, excessive excretion (unlikely in view of documented hypoparathyroidism), or loss into the extravascular fluid. In a review, Dolecek[20] found increased urinary PO_4 excretion only during the third and fourth weeks after burn in adults, but hypophosphatemia occurred earlier. Thus, increased urinary PO_4 excretion seen later may be more a function of increased tissue breakdown and filtered load than of inappropriate or excessive urinary PO_4 losses. There is little documentation of inadequate PO_4 intake after burns. We administer a minimum of 1.6 g PO_4 daily in enteral feedings alone.[17] What is clear is that the two major hormonal facilitators of phosphate excretion, PTH[12] and FGF23,[25] are both suppressed in burns in children during the first month postburn, suggesting a hormonal conservation of phosphate.

The cause of sustained hypomagnesemia after burn is unknown, although excessive urinary and fecal losses occur in adults,[20] and excessive losses occur in the burn wound.[26]

Rationale for Therapy

Table 25.1 describes treatments for hypocalcemia and hypophosphatemia. Hypocalcemia, especially during the resuscitation effort, can potentiate hypokalemia-induced abnormalities in cardiac muscle[27] and block responsiveness to fluid repletion in shock.[27] Parenteral Ca during resuscitation does not benefit patients without hypocalcemia[28-30] unless they have hyperkalemia, hypomagnesemia, or Ca channel blocker toxicity.[31] Similarly, although caution should be exercised during massive transfusion with citrate-containing blood, Ca therapy may not be necessary in normocalcemic patients and if hepatic and renal functions are minimally impaired. The liver will clear citrate, which may transiently chelate Ca at a rate of 1 unit of blood transfused every 5 minutes.[32] Treatment should be initiated only when clinical and electrocardiographic evidence suggests hypocalcemia. Ca infusions should be administered slowly because rapid Ca replacement can produce cardiac arrhythmias.[27,32]

Hypophosphatemia may cause tissue hypoxemia due to increased hemoglobin affinity for oxygen and decreased tissue ATP, metabolic encephalopathy, hemolysis, shortened platelet survival, myalgias, weakness, and possible impairment of myocardial contractility.[33] Hypomagnesemia, or Mg depletion with normal serum Mg, blunts the effect of PTH secreted in response to hypocalcemia on target organs and impairs secretion of PTH itself.[1] Mg deficiency

Table 25.1 Treatment Options

Disturbance	Decision Point	Recommended Treatment
Hypocalcemia	Symptomatic	Intravenous calcium: Adults 90–180 mg of elemental calcium over 5–10 minutes Infants or children: calcium chloride as 20 mg/kg dose or Ca gluconate in a 200–500 mg/kg/dose in four divided doses
	Asymptomatic	Oral calcium carbonate or intravenous calcium gluconate
Hypophosphatemia	Symptomatic	Infants or children: 5–10 mg/kg infused over 6 hours followed by 15–45 mg/kg given by infusion over 24 hours
	Asymptomatic	Oral administration of 20–25 mg/kg of elemental phosphorus in four divided doses each day.

also causes generalized convulsions, muscle tremors, and weakness.[1]

Treatments for Maintaining Mineral Homeostasis

Acute symptomatic hypocalcemia should be treated with IV Ca. Adults should receive 90–180 mg of elemental Ca over 5–10 minutes to reverse twitching. Infants and children should receive 20 mg/kg Ca chloride or 200–500 mg/kg Ca gluconate in four divided doses.[34,35] Parenteral chloride should be used carefully because it may cause phlebitis, acidosis, or both. While hypocalcemia is asymptomatic and patients can tolerate enteral feeding, milk or infant formula can provide as much as 3 g/day of bioavailable Ca.[17] Hypocalcemia can occur despite enteral provision of such large Ca quantities, making intermittent parenteral administration of Ca salts sometimes necessary. The amounts given must be determined individually and may vary significantly from patient to patient. Dosing in six of our patients with greater than 40% TBSA burns ranged between 0.9 and 15 g of 10% Ca gluconate/day over the first 5 weeks after burn. Treatments were given, on average, twice daily for 75% of the days.

Rickets secondary to PO_4 deficiency can be treated with 20–25 mg/kg elemental PO_4 in four divided oral doses per day.[35] Infants and children with symptomatic hypophosphatemia should receive 5–10 mg/kg infused over 6 hours and then 15–45 mg/kg infused over 24 hours or until serum PO_4 exceeds 2.0 mg/dL (0.6 mmol/L).[36]

Adult patients who tolerate enteral feeding and consume an average of 1.6 g/day PO_4 should have consumed enough to treat asymptomatic hypophosphatemia.[17] Prolonged hypophosphatemia has not been reported in burn patients; however, parenteral supplementation would be necessary in such cases. Patients who have signs or symptoms of Mg deficiency with serum Mg concentration less than 1.5 mEq/L (1.8 mg/dL or 0.8 mmol/L) usually require parenteral therapy.[37]

Hypercalcemia and Impaired Renal Function After Burns

Hypercalcemia with acute renal failure was reported in the May 2010 issue of *Burns*.[38] Adult patients with serum ionized Ca of 1.32 mmol or greater constituted 30% of patient admissions, and those with creatinine clearance less than 50 mL/min developing in the intensive care unit 48 hours after admission made up about 20% of admissions. Of the four hypercalcemia cases described, three responded to standard doses of bisphosphonates. The onset of hypercalcemia occurred from 6 weeks to 6 months after injury. Much remains to be learned about this complication of burn management.

Bone

Silent bone loss may occur for up to 1 year after burn. Linear growth and bone remodeling are adversely affected by burns. Linear growth at the epiphyses of the long bones usually occurs through cartilage cell proliferation with production of extracellular matrix; these chondrocytes and matrix undergo a series of biochemical changes, leading to the formation of ossification centers. As these centers expand, cartilaginous tissue is replaced by bone and a vascular system that allows the delivery of nutrients, hormones, and growth factors. Growth velocity in children is retarded for the first year after a 40% TBSA burn.[39] The underlying mechanism is unknown, but growth velocity does return to normal[39] even though long-term stunting may result.

The stress and inflammatory response contribute to bone turnover abnormalities that lead to bone loss. Urinary deoxypyridinoline excretion increases the first week after burn.[40] Deoxypyridinoline is a marker of bone resorption or one of the byproducts of bone collagen type I breakdown. Its increase in urine during the first week is because of a three- to eightfold increase in glucocorticoid production[41] and a three- to 100-fold increase in proinflammatory cytokines produced by the systemic inflammatory response.[24] In studies of sheep after a 40% TBSA burn, bone harvested 5 days postburn demonstrated an eroded surface and decreased Young's modulus consistent with bone resorption.[42] Both glucocorticoids and inflammatory cytokines stimulate bone resorption by increasing osteocyte and osteoblast RANKL production.[43] Normally, bone resorption is coupled to bone formation. In high-turnover situations (i.e., both resorption and formation are increased), bone loss occurs because after bone is laid down, it takes time for it to mineralize properly. Bone will be resorbed more quickly than it can allow the type I collagen to crystallize into hydroxyapatite with proper binding sites for Ca and PO_4.

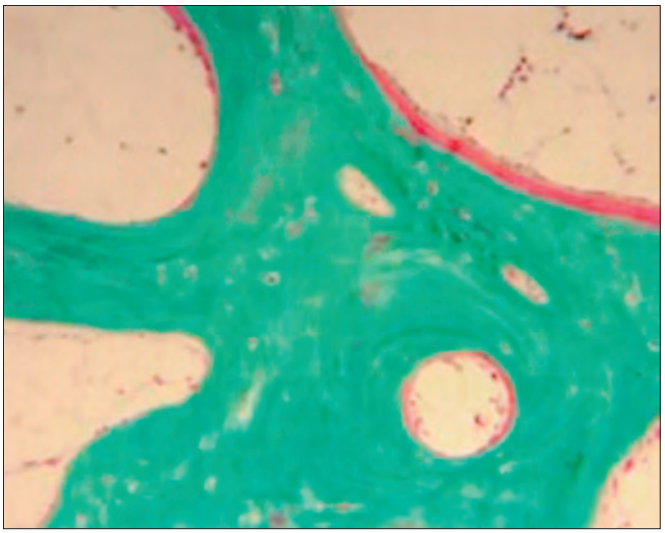

Fig. 25.3 Goldner trichrome stain of an iliac crest bone biopsy of a healthy person. The *blue-green area* represents mineralized bone. The *red area* represents unmineralized osteoid. Spindle-shaped cells from the osteoid surface are osteoblasts.

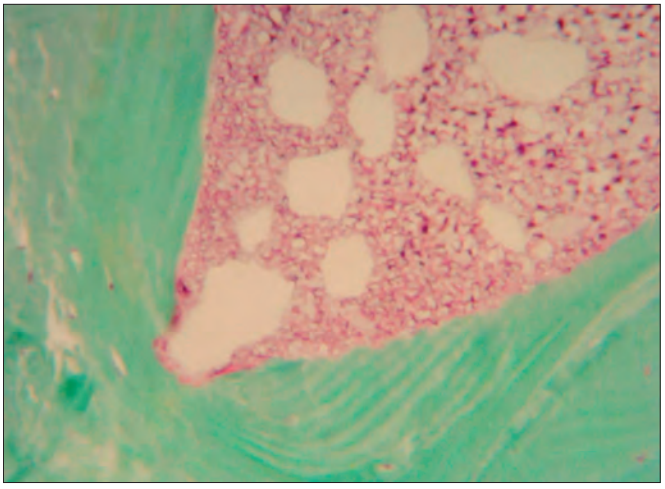

Fig. 25.4 Goldner trichrome stain of an iliac crest bone biopsy of a burned patient. The *blue-green area* represents mineralized bone. Compared with Fig. 25.3, note that osteoblasts are absent from the osteoid surface.

Osteoblasts (bone-forming cells) and osteocytes (terminally differentiated osteoblasts acting as mechanotransducers in the bone matrix) are key parts of normal coupling. They produce RANKL in response to cytokines (especially IL-1β and IL-6) and PTH. When stimulated by low serum Ca and downregulation of the parathyroid CaR, PTH increases bone resorption by binding to PTH receptors on osteoblasts. PTH also increases the number of osteoblasts on bone surfaces in humans[44] and animals.[45] However, by the second week after burn, glucocorticoids cause apoptosis of surface osteoblasts, and we even observe a loss of the ability for stromal cells to show markers of osteoblast differentiation.[11,46] This disappearance is apparent in iliac crest bone biopsies (compare normal bone in Fig. 25.3 with bone at 2 weeks after burn in Fig. 25.4). Similarly, when tetracycline is administered to children and adults before iliac crest bone biopsies, tetracycline uptake is markedly reduced, suggesting a reduction in surface osteoblasts and functioning of the surviving osteoblasts.[47] Finally, fewer markers of osteoblastic differentiation (a feature of glucocorticoid toxicity) are present in cultured marrow stromal cells from iliac crest bone of burned children than in cells from bone of age- and gender-matched control participants.[41]

Although endogenous glucocorticoids resulting from the stress response reduce osteoblast numbers and the differentiation of marrow stromal cells into osteoblasts, high circulating cytokine levels remain unabated. Therefore, cytokines would be expected to continue pushing the differentiation of marrow stem cells into osteoclasts. However, this does not occur. In fact, levels of urinary deoxypyridinoline (a bone resorption marker) remain quite low.[22] Thus, both bone formation and bone resorption fall dramatically in the second week after burn, leading to a low-turnover bone loss. This condition, known as adynamic bone, results from a lack of osteoblasts to process bone resorption stimuli.

IL-1β[14,15] and IL-6[16] stimulate upregulation of the parathyroid CaR in vitro. Moreover, both inflammation and stress produce oxidative stress, leading to a reduction in both osteoblastogenesis and osteoclastogenesis.[48] Thus, although the stress response explains the low-turnover acute bone loss after burn injury, the systemic inflammatory response explains upregulation of the parathyroid CaR in both humans and sheep. Parathyroid CaR upregulation provides continuous hypoparathyroidism after burn and renders the wasted urinary Ca unproductive in repairing demineralized bone.

In summary, 1 week after burn injury, the stress and inflammatory responses promote bone loss by increasing bone resorption and Ca wasting in the urine. By 2 weeks, osteoblasts are lost, markedly reducing bone replacement. This hypodynamic bone continues to thin, as resorption is reduced[22] and compensatory bone formation is all but shut off.

The silent events triggered by burn injury reduce bone density (Fig. 25.5) in the lumbar spine and appendicular skeleton (see radiograph in Fig. 25.6). The distribution of lumbar spine bone density Z-scores (standard deviation score) is shifted to the negative in children with greater than 40% TBSA burns (see Fig. 25.5) but not in those with less than 20% TBSA burns. Thus, more severe burns trigger the bone loss mechanisms discussed earlier. Obesity, an epidemic affecting children in the developed world, may also be implicated as a contributing factor because obese pediatric burn patients (defined as being in greater than the 85th percentile of body mass index [BMI]) had higher loss of bone mineral density (BMD) compared with their normal BMI counterparts.[49] This may be related to increased inflammation because these children also had higher C-reactive protein (CRP) levels in the months after burn injury than their normal BMI counterparts.[49]

Burn injury increases the annual extrapolated fracture incidence in boys and girls by 100% and 50%, respectively.[50] Thus, burn-induced bone loss increases the risk of fracture later on. Whereas bone remodeling recovers 1 year after burn,[51] the Z-score for at least lumbar spine BMD does not improve.[50,51] Given that peak bone mass is reached at 18 to

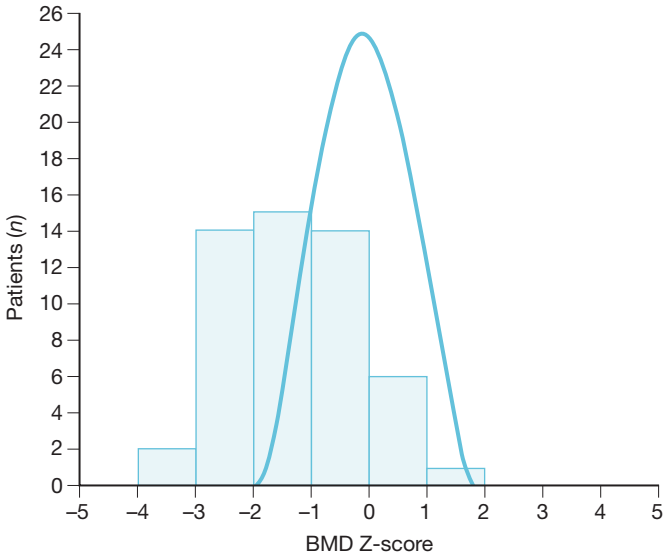

Fig. 25.5 Distribution of lumbar spine bone mineral density (BMD) Z-scores of severely burned children compared with a standard distribution curve. Note that the distribution after burn is shifted to the negative side.

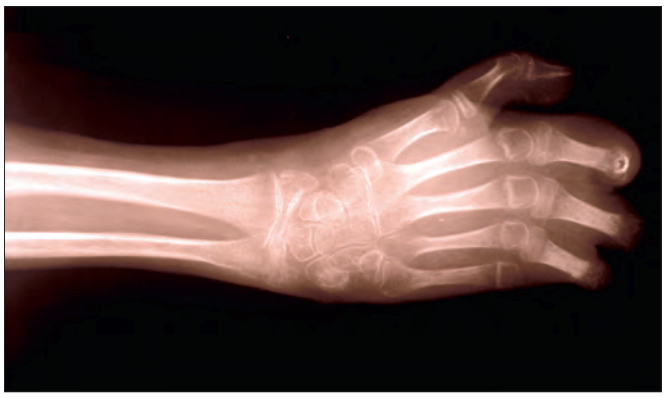

Fig. 25.6 Radiograph as an example of burn-induced osteoporosis 1 year after trauma.

30 years, failure of bone density to catch up to one's peers places burn victims at risk of entering adulthood with less than peak bone mass and may increase the risk of early-onset osteoporosis. In adults as well, we see markers of decreased BMD after prolonged follow-up. One study found that men with 30% TBSA burns, when tested at least 1 year postburn, had decreased femoral neck Z-score and femoral neck BMD, as well as bone-specific ALP, relative to non-burned control participants.[52]

Another obstacle to bone recovery is progressive vitamin D deficiency, which affects burn patients who are not discharged with vitamin D supplementation and related to a failure in skin production of vitamin D.[11] Sunlight exposure becomes limited because of heat intolerance due to sweat gland destruction, and the burn scar could become hyperpigmented. At 14 months postburn, biopsies have demonstrated that ultraviolet light converts only 25% of the normal quantity of 7-dehydrocholesterol into previtamin D_3, suggesting that skin is biochemically abnormal more than 1 year after injury.[23] Moreover, 7-dehydrocholesterol levels were significantly lower in burn scar and adjacent normal-appearing skin than normal control skin,[23] pointing to ongoing problems in cholesterol biosynthesis. In the previously discussed study of men after burn injury, they found a negative correlation between the modified Vancouver Scar Scale Score and serum vitamin D levels, suggesting that more clinically significant scars are also scars that affect vitamin D production.[52] In general, they found that burned patients had lower serum 25-OH vitamin D levels. The role of vitamin D deficiency in failed restoration of bone density is unknown. We found that 6 months after children were discharged on a vitamin D_2 (400 IU)-containing multivitamin, all but one of eight patients had vitamin D insufficiency.[53] In another study, children after burns were randomized to placebo, vitamin D_2, or vitamin D_3 supplementation and monitored for fracture; fewer fractures were observed in the vitamin D_3 group, suggesting that vitamin D_3 supplementation may decrease postburn fracture risk.[54] Thus, the vitamin D requirement for children during and after burn injury remains unknown.[53] A randomized controlled trial (RCT) of adults with severe thermal burns found that two-thirds of the patients (who were 2–5 years postburn) had vitamin D deficiencies and that more than half were osteopenic. Supplementing cholecalciferol and calcium orally improved serum vitamin D levels and quadriceps muscle strength but not BMD.[55] Thus, it remains unclear in adults as well what the optimal vitamin D supplementation regimen would be to prevent postburn bone loss.

Treatment of Bone Catabolism After Severe Burn

Several approaches have been studied to prevent, mitigate, or reverse burn-induced bone loss. Daily subcutaneous injection of 0.2 mg/kg of recombinant human growth hormone (rhGH) from admission throughout hospitalization immediately improves circulating insulin-like growth factor-1 (IGF-1) levels but does not raise serum osteocalcin levels to normal,[56] suggesting that rhGH fails to increase bone formation acutely. However, daily subcutaneous injection of 0.05 mg/kg rhGH for 1 year increases lean body mass (LBM) by 9 months after burn and increases lumbar spine bone mineral content (BMC), but not BMD, by 1 year.[57] This increased lumbar spine BMC but not bone density is notable for three reasons. First, the persistence of high glucocorticoid levels during the first year may block early efficacy of rhGH, a glucocorticoid antagonist. Next, this finding raises the question as to whether the absence of an increase in lumbar spine bone density reflects a failure of rhGH activity. Given that BMD is the quotient of BMC and bone area, an increase in BMC with no change in BMD would imply a proportional increase in bone area. Thus, a 1-year treatment with rhGH increases LBM; increases skeletal loading; and creates bigger, more biomechanically stable bone. Finally, one might ask whether the effects of rhGH on bone are only secondary, resulting from an increase in skeletal loading. This question cannot be directly answered based on available data. However, Branski et al.[58] recently showed that a 1-year treatment with 0.2 mg/kg/day rhGH (subcutaneous injection) reduces lumbar spine

BMC, increases LBM, and dramatically decreases circulating PTH. These findings suggest that high-dose rhGH directly stimulates bone resorption, with secondary suppression of serum PTH levels. Little evidence supports a direct effect at moderate rhGH doses.

The disadvantages of daily rhGH administration for at least 1 year include the high cost and the need for subcutaneous injections, which may reduce compliance. Another option is long-term use of the anabolic steroid oxandrolone. Similar to rhGH, a 0.1-mg/kg dose given orally twice daily for 1 year produced a rise in LBM succeeded by an increase in lumbar spine BMC by 3–6 months, increasing skeletal loading and bone size.[59] It is believed to work via IGF stimulation.[11] A more recent study has suggested that even longer-term treatment with oxandrolone may be even more beneficial.[60] An RCT of children with greater than 30% TBSA burns randomized participants to placebo or 24 months of oxandrolone and found that the treatment group saw increases in whole-body and spine BMC as well as lumbar spine BMD along with a greater height velocity. These improvements in bone mineralization were greater than previous studies of 1 year of oxandrolone therapy.[60] Oxandrolone is not costly and does not require subcutaneous injections, but it may produce clitoral hypertrophy. However, no premature growth plate fusion has been discovered on radiographs, and this clitoromegaly resolves when the drug is discontinued.

Another drug that has been studied is the bisphosphonate pamidronate. The current generation of nitrogen-containing bisphosphonates acts by adhering to the bone matrix, where they are taken up by osteoclasts and interfere with the cholesterol biosynthesis pathway, ultimately altering protein binding to the osteoclastic membrane and inducing apoptosis.[61] Bisphosphonates remain in bone for a prolonged period, raising concerns that they may interfere with growth or bone quality.[61] However, most bone resorption is thought to occur during the first week or two after burns, when inflammatory cytokines cause significant resorption of bone before osteoblast apoptosis. Thus, early use of bisphosphonates may prevent acute bone loss.

In a randomized, double-blind study, children with 40% TBSA or greater burns received 1.5 mg/kg of pamidronate intravenously (maximum dose, 90 mg) within 10 days of the burn and 1 week later. Pamidronate prevented the reduction in BMC in the lumbar spine and total body after 6 months of hospitalization.[62] By 2 years, BMC in the placebo group had caught up to that of the pamidronate group for the total body but not the lumbar spine.[51] This suggests that pamidronate effectively preserves the axial skeleton from bone loss and preserves the appendicular skeleton until bone replacement would otherwise "catch up." Pamidronate has glucocorticoid antagonistic properties similar to those of rhGH; however, the effects of pamidronate on bone are immediate.

Pamidronate use is not associated with hypocalcemia, growth delays, or changes in bone histomorphometry.[51,62] The next step in evaluating this drug is to determine whether the fracture rate in pamidronate-treated patients differs from that in the placebo group and from age- and gender-matched normal values.[50] Furthermore, some evidence suggests that bisphosphonates preserve muscle protein after burn, raising the question if there is some sort of communication, possibly a paracrine effect or effect in the microenvironment, between bone and muscle.[46]

Two other promising drugs bear mention. The first is recombinant human PTH (rhPTH). Daily subcutaneous injection of rhPTH for 1 year adds new bone in women with postmenopausal osteoporosis.[63] However, because rat studies have demonstrated an increase in osteogenic sarcoma,[64] the U.S. Food and Drug Administration does not allow its use in children. If this changes, rhPTH would be a potentially effective drug for adding bone mass in burned children.

Beyond pharmaceutical therapies, recent research also points to the possibility of exercise and other mechanical types of therapy playing a role in the management of post-burn bone loss. One study found that exercise, in combination with whole-body vibration therapy, helped maintain truncal BMC in children after burn injury relative to exercise alone.[65]

Heterotopic Ossification After Burn Injury

Another abnormality of bone and mineral metabolism observed after burn injury is the formation of heterotopic ossification (HO). HO is lamellar bone that forms ectopically via endochondral ossification. It is frequently seen after trauma and burns, as well as after spinal cord or traumatic brain injury and after orthopedic surgery. HO after burn injury can develop quite quickly even in the initial hospitalization. In a study of the Burn Model System National database, they found that the mean age of patients with HO by the time of discharge was 42.6, the mean TBSA was 18.5%, and the population was almost 75% male.[66] The same study found that TBSA and the need for grafting of the arm, head, neck, or trunk were risk factors for the development of HO.[66] In another study of patients from high-volume burn centers, they found that 3.5% of burn patients developed HO, almost all of whom had burns to the arms and skin grafting to the arms, with the latter translating to a 96.4 times higher odds of developing HO.[67] Patients with greater than 30% TBSA had 11.5 times higher odds of developing HO. More trips to the operating room and more days on the ventilator were also risk factors for HO development.[67] Interestingly, the prevalence of HO is low among elderly individuals. A recent website was developed to allow for further optimization of HO risk assessment (www.spauldingrehab.org/HOburncalculator)

Mouse studies suggest that the mesenchymal stem cells of younger individuals have more bone formation capacity than those of older invidiauls.[68] Additionally, younger patients are known to mount a more robust inflammatory response.

The early detection of HO is essential to its management with regards to how to manage occupational therapy. Additionally, an early diagnostic modality would allow for better directed treatment. Numerous studies have been performed to elucidate the optimal imaging modality to detect HO. Although plain radiographs and computed tomography (CT) are the mainstays of clinical HO diagnosis, mouse studies suggest that whereas near infrared imaging can detect HO as early as 5 days after burn injury, CT could

not detect it until 5 weeks after the burn.[69] Transcutaneous Raman spectroscopy can also detect HO as early as 5 days postburn injury in a mouse model.[70] Serum markers are not a reliable screening method for HO because elevated bone ALP is seen in fewer than half of patients with known hip HO, and CRP is elevated in 77% of patients with hip HO.[71] Recent studies have started to investigate the potential use of single-photon emission computed tomography (SPECT) imaging, which can detect increased pre-HO blood flow. Larger studies are needed to further validate its use. Furthermore, with increasing efficacy of high-frequency spectral ultrasound, this modality holds promise given the widespread and point of care use of ultrasonography.

The development of HO is a source of a significant amount of investigation. In one mouse study, it was noted that Adenosine Tri-Phosphate (ATP) hydrolysis as well as inhibition of the SMAD pathway both decrease HO formation, suggesting that both of these pathways play a role in the development of HO.[72] Similarly, both trauma- and burn-induced HO and genetic HO share a common pathway in hypoxia-inducible factor 1 alpha (HIF1α), and inhibiting this pathway can inhibit HO formation.[73] The early hypoxic wound is thought to stimulate HIF1α, which is a known mediator of chondrogenic differentiation, allowing for endochondral bone development. Inflammation has also been implicated in activating progenitors and stimulating osteogenic signals in the formation of HO.[74] Mouse studies also suggest that diabetic mice (i.e., leptin-deficient mice) have decreased HO formation and more HO resorption; this appears to be related to more osteoclasts noted on Tartrate-resistant acid phosphatase (TRAP) staining.[75]

The prevention and treatment of patients with HO have also been focuses of research. In patients who undergo arthroscopic surgery for femoroacetabular impingement, postoperative naproxen was exceedingly effective in preventing HO formation (4% HO incidence in the naproxen group vs 46% in the control group), so much so that they had to stop the study.[76] Another study of celecoxib found that the medication was a protective factor against the formation of HO and the development of limited Range of Motion (ROM) at 3, 6, and 9 months postoperatively.[77] Radiation is also efficacious in the prevention of HO in high-risk patients. This was demonstrated in a 1986 study of total hip arthroplasty patients.[78] Two prospective randomized trials have studied the optimal timing and dose of radiation for the development of HO; generally, pre- and postoperative radiation were both effective in preventing HO after hip surgery or arthroplasty, with either low- or medium-dose regimens that involved divided dosages of radiation.[79] Single-dose radiation therapy has also been noted to be effective in preventing HO formation after total hip arthroplasty.[80] Prospective trials studying nonsteroidal antiinflammatory drugs (NSAIDs) versus radiation in preventing HO have had mixed results, with studies showing similar efficacy or slightly more success with radiation than with NSAIDs but also noting that radiation is much more expensive and that NSAIDs have unwanted gastrointestinal side effects.[81,82]

For burn patients, bisphosphonates have also been used as early prophylaxis. However, no RCTs have been performed, and results from noncontrolled studies have had mixed results. Future treatments are currently under investigation including retinoic acid agonists, however, they should be approached with caution given their negative effect on wound healing. Additional drug development is underway to target bone morphogenetic protein receptors using kinase inhibitors because they have been shown to be effective in several animal studies. Although promising, kinase inhibitors also can have off-target effects that may impair wound healing and cause further osteopenia.

26 Micronutrient Homeostasis

METTE M. BERGER, LINDA E. SOUSSE, GORDON L. KLEIN, LUDWIK K. BRANSKI, and DAVID N. HERNDON

Videos available at www.expertconsult.inkling.com

Importance of Vitamins and Trace Elements

Essential vitamins and trace elements, which are globally known as "micronutrients," are fundamental to metabolism; they function as structures of enzymes or as their cofactors. Their requirements are influenced by the metabolic state and by increased nutritional needs after major burns.[1] The first publications about elevated vitamin requirements go back to the 1940s and of trace elements to the 1960s.[2] Their homeostasis in burn injury is summarized here.

Vitamins

Ascorbic acid (vitamin C), cholecalciferol (vitamin D), and α-tocopherol (vitamin E) have all been reported as depleted in burned patients.[3,4]

VITAMIN C

Vitamin C is not only an essential nutrient involved in many anabolic pathways and essential for would healing, but it also scavenges reactive oxygen species and improves microcirculatory flow impairment. Low plasma concentrations of vitamin C are very common in burned pediatric and adult patients.

Intravenous infusions of vitamin C have previously been shown to be beneficial in animal models. Dubick et al.[5] infused high doses of ascorbic acid in an ovine model of 40% total body surface area (TBSA) burn injury, which significantly reduced resuscitation fluid requirements of burned sheep after 48 hours. Plasma thiobarbituric acid reactive substances increased fourfold in sham-burned sheep; this was prevented by the use of the vitamin C infusion. Tanaka et al.[6] found that, using high-dose vitamin C, total tissue water content was reduced and negative interstitial fluid hydrostatic pressure was more positive in a rodent burned model when compared to unburned animals. Tanaka et al. showed in before-and-after trials that megadoses of ascorbic acid (66 mg/kg/h^{-1}) delivered during the first 24 hours after injury were associated with a significant fluid resuscitation requirement reduction and lesser weight gain,[7] suggesting a beneficial role in burn resuscitation. Randomized trials are still needed. Last, the use of vitamin C protected the seminiferous tubules and germ cell loss in burned rats compared to unburned rats,[8] but human data are not yet available.

VITAMIN D

Vitamin D is a fat-soluble micronutrient that has been implicated in a wide array of physiological systems, including skeletal muscle, bone health, cardiovascular health, immune system, and lung function. It has been shown to reduce inflammatory cytokines and reactive oxygen and nitrogen species, as well as attenuate cancer, osteoarthritis, schizophrenia, and depression. Notable risk factors for decreased vitamin D concentrations include decreased skin production, use of sunscreen, its decreased bioavailability and production, liver or kidney dysfunction, malabsorption disorders, the use of cholesterol-lowering agents, and increased glucocorticoids.[9]

Burned children develop a progressive deficiency of vitamin D as measured by circulating levels of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D_3. This result may be confounded by the acute reduction in serum vitamin D-binding protein[10] and albumin.[11] Fourteen months post burn, serum 25-hydroxyvitamin D levels are low[12] and remain low at 2 and 7 years post burn.[13] Whereas serum levels of 1,25-dihydroxyvitamin D_3 are normal at 2 years, about 50% of measured values are low at 7 years post burn, suggesting a progressive vitamin D deficiency.[13]

During the acute phase, the standard 200 IU/day is insufficient to maintain vitamin D status as shown in a Belgian cohort study.[14] Failure to provide vitamin D supplementation to burn patients at discharge from hospital may contribute to vitamin D deficiency. Fifteen adult burned patients were randomized into either a group that received quarterly intramuscular injections of 200,000 IU vitamin D_3 with daily oral calcium or into a placebo group.[15] After 1 year, calcidiol levels significantly increased in the vitamin D group. No change in bone health was observed between groups, but the vitamin D-treated group showed significantly improved quadriceps strength when tested at high velocity.[15]

In 2009, pediatric burned patients discharged from the Shriners Hospital for Children in Galveston received daily supplementation with a multivitamin containing 400 IU of vitamin D_2 for 6 months.[16] At that time, circulating levels of 25-hydroxyvitamin D were still in the insufficient to low range, without any improvement in lumbar spine bone density. This was further tested in pediatric burned patients at the Shriners Hospital for Children in Cincinnati with 100 IU of vitamin D_3 in a study that showed no significant differences in treated or untreated groups.[17] Thus the amount of vitamin D supplementation necessary to maintain normal circulating levels of 25-hydroxyvitamin D in pediatricburned patients is unknown. Chan and Chan cite 200–400 IU/day as required in healthy, nonburned children.[18] However there is no evidence supporting that

requirement in a burned population, and long-term vitamin D supplementation with levels exceeding 400 IU/day may be necessary to overcome the postburn deficiency.

Another major factor, however, is the profound change in skin structure and quality. Burn scar and adjacent areas of unburned skin can only convert roughly 25% of its 7-dehydrocholesterol precursor to vitamin D_3 on exposure to sunlight.[12] Moreover, the amount of 7-dehydrocholesterol substrate is significantly reduced in both burn scar and adjacent unburned skin.[12] This indicates that, after burn injury, the skin cannot synthesize normal amounts of vitamin D regardless of the amount of sun exposure received. Thus, progressive deficiency in vitamin D will result without supplementation.

VITAMIN E

It has been previously shown that adult patients with severe burns are characterized by increased free radical activity and very low levels of antioxidants; if the redox status of these patients was not restored, the patients died.[19] Vitamin E is a fat-soluble antioxidant that scavenges peroxyl radicals and prevents the radical-mediated chain reactions of polyunsaturated fatty acids. Recently, it has been shown that the tissue storage of vitamin E in burned children decreases by half as early as 3 weeks after injury.[20] Burned patients are entering the operating room with consistently low vitamin E status, and vitamin E intakes in pediatric burn patients are less than their requirements.[21,22] Furthermore, it has been shown in burned children that a combination of antioxidants (vitamin C, vitamin E, and zinc for 7 days; average of 900 IU/day, 400 IU/day, and 7 IU/day, respectively) increased circulating vitamin E and decreased malondialdehyde, which is a marker of oxidative stress.

Mechanistic studies in the ovine model of burn and smoke inhalation using deuterium-labeled vitamin E showed that the burn increased depletion of liver vitamin E, suggesting the tissue mobilization of vitamin E.[23] These studies suggested that, in addition to depletion of vitamin E from the lung and liver, other tissues were also depleted.[23] Given the hypermetabolic and hypercatabolic state and altered lipid metabolism in patients with burn injury, there is concern that depletion of adipose tissue vitamin E may reflect a significant level of oxidative stress, which then can cause secondary organ failure.[20]

The inflammatory response from excess oxidative and nitrosative stress in burn injury further impairs the healing process. Burned children who were supplemented with vitamins E, C, and zinc needed significantly fewer days to heal compared to unsupplemented children.[24] Increased wound healing using the nebulization of vitamin E in the 3-week ovine model of burn and smoke inhalation has also been demonstrated.[25] Furthermore, vitamin E has been shown to be beneficial in the treatment of wounds in a variety of models, including scar formation from acute surgical wounds[26] and in rats with skin lesions from diabetes.[27]

VITAMIN K

In a study of serum vitamin K levels in severely burned pediatric patients, Jenkins reported that 91% of children studied demonstrated low circulating levels in the first month post burn.[28] However, there was no relationship between serum vitamin K levels and prothrombin time, raising the question of clinical significance. It should be noted that osteocalcin, a gamma-carboxylated protein produced by osteoblasts, is vitamin K dependent. Osteocalcin is used as a standard index of bone formation and also has been shown to stimulate pancreatic insulin production and peripheral insulin sensitivity.[29] Circulating osteocalcin is reported to be low in the first month following burn injury.[30] Therefore, the possibility remains that low circulating vitamin K levels may contribute to the reduction in serum osteocalcin and hence to postburn insulin resistance and the reduction of bone formation.

Trace Elements

Facts about trace elements have been consolidated during the past decades. Among them, copper (Cu), iron (Fe), selenium (Se), and zinc (Zn) are involved in antioxidant and innate and adaptive immune defenses, and deficiencies largely contribute to the classical complications observed after major burns, such as persistent inflammatory state, multiorgan failure, and sepsis. Table 26.1 summarizes some of these specific alternations. Major burns differ from other trauma and critically ill patients by the magnitude of the changes and their mechanisms. Here, we address the changes affecting the blood compartment, exudative and urinary losses, their role in inflammation and antioxidant defenses, and, finally, some considerations about lesser-known and sometimes toxic trace elements.

BLOOD CONCENTRATIONS

Low blood concentrations (serum and plasma) of several trace elements in burn patients have been repeatedly reported since the 1970s[31–33] and support recommendations to determine and monitor blood levels after major burns and to orient repletion in cases of evident deficit.

Copper: Very low levels of Cu have been shown repeatedly in this category of patients. The circulating concentrations vary inversely with the size of burns.[34,35] This observation supports the diagnosis of deficiency because Cu and ceruloplasmin (Cp) usually increase during an inflammatory response, with Cp being upregulated by interleukin-1, but this increase does not occur in major burns. Further wound treatment is often carried out with silver products (silver-sulfadiazine and silver-containing hydrofiber dressings): silver penetrates in the body and antagonizes Cu, contributing to its decrease along with Cp.[36] It is important to note that Cu and Fe metabolism are tightly linked.[37]

Selenium: Blood levels of Se decrease very early after major burns due first to an inflammatory redistribution and then aggravated by large exudative losses. Se remains low for several weeks. This is associated with a nearly immediate depression of the activity of plasma glutathione peroxidase (GPX-3) (see later discussion).

Zinc: Blood Zn levels decrease within the first hours after major burns[38] and remain very low for weeks, also as the

Table 26.1 Micronutrient requirements and specific burn needs during the acute period (>10% TBSA)

	Vit A (IU)	Vit D (IU)	Vit E (IU)	Vit C (mg)	Vit K (mcg)	Folate (mcg)	Cu (mg)	Fe (mg)	Se (mcg)	Zn (mg)
AGES 0–13 YEARS										
Nonburned	1300–2000	600	6–16	15–50	2–60	65–300	0.2–0.7	0.3–8	15–40	2–8
Burned	2500–5000	NRE†	NRE†	250–500	NRE	1,000*	0.8–2.8	NRE	60–140	12.5–25
AGES ≥13 YEARS										
Nonburned	2000–3000	600	23	75–90	75–120	300–400	0.9	8–18	40–60	8–11
Burned	10,000	NRE†	NRE†	1,000	NRE	1,000*	4.0	NRE	300–500	25–40

Conversion based on the following: 1 μg of vitamin A = 3.33 IU of vitamin A; 1 μg of calciferol = 40 IU vitamin D; 1 mg of α-tocopherol = 1.5 IU of vitamin E.
NRE, no recommendations established.

result of the inflammatory redistribution associated with inflammation[39–41] and accompanying high losses.

Iron: After major burns, ferremia decreases nearly immediately and remains low for prolonged periods:[37] after the first week, other mechanisms will maintain the low ferremia, the principal being hemorrhage during surgery, but also exudative losses.[42]

Chromium: Animal studies[43] show that chromium (Cr) concentrations decrease in the liver of burned rats, becoming nondetectable after a few days and in muscle very early on and for several days. Simultaneously, urinary Cr losses increase. The changes in Cr concentrations were associated in animals with an early hyperglycemia, hyperinsulinemia, and increased secretion of stress hormones. Data from diabetic patients and patients on parenteral nutrition show that chromium deficiency contributes to insulin resistance. Preliminary human data from the Lausanne lab show that Cr is lost in exudates, along with molybdenum and manganese:[42] clinical significance must be confirmed.

Aluminum: The impact of aluminum (Al) remains debated; investigations are few but indicate potential serious consequences on bone metabolism. Large Al intakes from albumin were a problem for several years.[44] Al loading has been reported in at least one population of burned adults,[10] but no additional reports show Al uptake by either bone or liver. In pediatric patients suffering severe burns, aurin tricarboxylic staining of bone biopsies for Al accumulation at the bone surface have been negative.[11] The Al contamination of parenteral products has not been seriously addressed since the U.S. Food and Drug Administration (FDA) recommendation in 1986,[45] and because there is no real treatment in case of toxicity, suspicion should be maintained and blood levels checked in cases of neurological and bone pain, particularly in children. Preliminary data from the Lausanne Lab confirm that serum levels are above reference levels in adults and Al is detected in the exudates.[42]

EXUDATIVE AND URINARY LOSSES

In healthy subjects, trace elements are lost through urine (Se mainly) or feces (Cu, Fe, Zn), with extremely little being lost to sweat. Increased losses were suspected to occur after burns but have been difficult to measure precisely until recently.

Copper: In studies done urinary losses were shown to be above normal in the 1980s,[32,46] being particularly observed during parenteral nutrition, although excreted amounts were lesser than the infused quantities. The main losses of Cu have been shown to occur through exudates during the open wound phase after major burns: such losses occur similarly in children.[47]

Selenium: A 1984 study showed that urinary excretion of Se was decreased,[48] reflecting a deficiency status, with Se being retained. This deficit was explained by significant cutaneous losses, shown in the frame of a balance study.[49] These findings have been confirmed recently.[42]

Zinc: Urinary losses of Zn are initially above normal[50] as in other major trauma but then decrease. Significant losses occur through exudates, reaching about 10% of body content during the first week.[51]

Iron: Recently, a study investigating a large palette of trace elements showed that, in patients with 27% TBSA burns, Fe was lost in large amounts with exsudates even in the absence of active bleeding.[42]

It is important to note that, along with these four elements, other trace elements are also lost but do not seem to contribute to clinically detectable alterations. Magnesium and phosphorus losses are substantial and sufficient to explain the high requirements during the early phase of burns.[52]

ROLE OF TRACE ELEMENTS IN INFLAMMATION AND ANTIOXIDANT DEFENSES

The inflammation that starts nearly immediately after burn injury has a major impact on circulating trace elements. Already in the 1970s, in a study of rats with 20% TBSA, Van Rij et al.[39] showed that ^{65}Zn was rapidly taken up by liver, spleen, kidney, and wound, with a decrease in the brain, muscles, and bone: this type of redistribution would later be called *inflammatory-mediated redistribution of micronutrients* because it also affects Se and Fe. This type of redistribution pattern has been confirmed by several authors.[40,41]

Cu and Zn with Se are linked in cytosolic defense against reactive nitrogen and oxygen species:[53] iron adds to the complexity because it is also essential for immunity. In superoxide dismutase (SOD), Cu and Zn play major roles, enabling electron transfer. The plasma activity of SOD is decreased after major burns.[41] Furthermore, Cp plays a role as neutralizer of ferrous entities. Se is mainly active through the antioxidant family of glutathione peroxidase enzymes, which depend on Se for activity, but also through the large family of selenoproteins. Plasma GPX3 levels are the first to change, decreasing within hours after burn injury.[51] The redistribution of these trace elements to other compartments reduces their availability as first-line antioxidant defenses. Se depletion before the injury worsens the antioxidant defense, as shown in burned rats:[54] in animals made Se deficient, a nearly immediate Se supplementation did not restore their antioxidant defenses after burn.

Antioxidant and immune defenses are tightly coupled, and Cu, Se, and Zn modulate both the innate and adaptive immune response through their availability.[55] In particular, Zn deficiency will alter the activity of monocytes, polymorphonuclear, natural killer, B, and T cells: the latter are particularly susceptible to changes in Zn status.[55] Cu-dependent Cp is an acute-phase reactant protein that converts ferrous iron to its less reactive ferric form to facilitate binding to ferritin: its ferroxidase activity is important to iron handling. As recently demonstrated,[37] a low Cp favors oxidative reactions. Low Fe levels and inflammation are tightly associated, as recently shown by Dubick et al.[37] The body has developed strong defense mechanisms, including Cp, against this essential but potentially toxic trace element.[56]

TRACE ELEMENT THERAPY

In the late 1970s, combined Cu and Zn repletion was attempted in burned children by the enteral route[57] but failed to restore satisfactory blood levels due to the competition existing between Cu and Zn for absorption at the intestinal level. An animal study showed that a multi-trace element supply was required to achieve mucosal and carcass weight gains.[58] Successful treatment of deficiency requires the intravenous route, as shown by randomized studies. Low Se blood concentrations may be corrected by doses in the magnitude of 10 times RDA.[59] Intravenous therapy beginning the day of injury and combining Cu 3–4 mg/day, Se 300–400 mcg/day, and Zn 30–40 mg/day resulted in restoration of low but within-normal ranges of the three elements in 5–10 days and was associated with normalization of the activity of GPX3. The doses required in major burns are indeed higher than what can be delivered by the enteral route or that are required in parenteral nutrition. A recent study of exudates shows that there is a retention of the Cu, Se, and Zn in the body.[42] The just-listed adult doses[59,60] were adapted to children (normalized by body surface area) and also achieved restoration of blood values within reference range.[61] The clinical results of intervention trials delivering higher doses of trace elements are numerous: attenuation of oxidative stress;[24,62] improved wound healing (better graft take) probably by means of a modulation of protein metabolism;[63] improved immunity and reduced infectious complications, especially pulmonary;[64] and shortened length of stay.[59]

Conclusion

Burn injury is marked by a reduction in plasma levels of most vitamins and trace elements, which are redistributed mainly to the liver and kidney in order to maximize the antioxidant and anabolic response to injury. Antioxidant supplementation appears to have beneficial effects on both morbidity and mortality. While nutritional and antioxidant requirements of vitamins and trace elements are increased above RDA during the acute hypermetabolic phase of major burn injury, the duration and magnitude of the increased needs in the postburn state remain to be determined.

27 Hypophosphatemia

DAVID W. MOZINGO and ARTHUR D. MASON, Jr.

Certain humoral and metabolic responses to thermal and mechanical trauma that maintain homeostasis and prevent cellular dysfunction also produce alterations in electrolyte balance. An example is renal retention of sodium during the resuscitative phase of burn injury, which alters sodium balance in the course of preserving intravascular volume. Despite the markedly increased cardiac output and renal plasma flow that occur in the subsequent flow phase, a decrease in blood volume persists and results in sustained elevation of plasma renin activity, secretion of antidiuretic hormone, and sodium retention.[1] Conversely, the severe hypophosphatemia that often follows major injury occurs concomitantly with a 50–100% increase in resting energy expenditure, leading to a possible deficiency in the high-energy phosphate compounds essential for cellular metabolism. Thermal injury induces a precipitous decrease in serum phosphate concentration that reaches its nadir between the second and fifth postburn days. This phenomenon has been recognized for quite some time[2] and was recently confirmed by the authors in a large series of burn patients.[3] Despite aggressive phosphorus supplementation, normal levels of serum phosphorus are rarely reached before the 10th postburn day (Fig. 27.1). Of 550 patients studied, 175 had serum phosphorus concentrations below 2.0 mg/dL, and of these, 49 were below 1.0 mg/dL, with the lower limit of normal serum phosphorus being 3.0 mg/dL. Such hypophosphatemia is not exclusive to thermal injury, having been described after multiple trauma,[4] head injury,[5] and elective surgery.[6] The exact mechanism by which thermal injury or severe stress induces hypophosphatemia is unknown. Several events associated with burn injury, however, affect phosphorus metabolism, and these may combine to produce hypophosphatemia.

Etiology of Postburn Hypophosphatemia

Many of the pathophysiological changes and therapeutic interventions that occur during the first postburn week influence serum phosphorus concentration (Box 27.1). Hypophosphatemia does not necessarily imply phosphorus depletion; in the case of burn injury, most patients are healthy before injury and presumably have normal phosphorus stores. Nor do simple calculations of phosphate balance explain the dramatic decrease in serum levels; simultaneous reduction of urinary phosphate excretion is observed, suggesting an extrarenal mechanism. The fractional excretion of phosphate, however, increases during the early period of diuresis after burn injury (postburn days 2–4), potentially contributing to the decline in serum levels. The pathophysiological events and therapeutic interventions discussed here are associated with hypophosphatemia in other disease states and in certain experimental animal models, but the extent of their contributions to the postburn decrease in serum phosphorus has not been critically evaluated and is, at present, undefined.

STRESS RESPONSE

In the early postburn period, the classic "fight or flight" response occurs, with elevation of plasma catecholamines, glucose, glucagon, and cortisol. Exogenous epinephrine administration has been associated with the development of hypophosphatemia, and the profound catecholamine release accompanying thermal injury may contribute to the early decrease in serum phosphorus. The mechanism by which this occurs is uncertain but may be a consequence of the accompanying hyperglycemia, resulting in a redistribution of phosphorus from the extracellular to the intracellular compartment (see the later section on metabolic support). In acute clinical states of glucagon excess, tubular reabsorption of phosphate is impaired in both the proximal and distal nephron, leading one to expect renal phosphate wastage.[7] Because urinary excretion of phosphate is usually decreased in the early postinjury period, the importance of hyperglucagonemia remains uncertain. Administration of pharmacologic doses of glucocorticoids enhances phosphorus excretion and impairs phosphate absorption by the gut and reabsorption by the kidney. Whether the adrenocortical response significantly contributes to the hypophosphatemia after burn injury is not known.

RESUSCITATION AND TOPICAL THERAPY

Administration of large doses of sodium lactate for initial burn resuscitation may decrease the serum phosphorus concentration by several mechanisms.[8] Lactate is converted to glucose in the liver, a process requiring high-energy phosphate availability. Additionally, although it does not usually occur clinically, metabolic alkalosis induced by lactate infusion may result in depression of serum phosphorus concentration. Alkalosis is associated with an increase in glycolysis that promotes transfer of phosphorus to the intracellular space. During resuscitation, alkalemia is uncommon, and patients are more likely to manifest a mild metabolic acidosis, which is compensated by hyperventilation, resulting in a normal or mildly alkaline blood pH. Acidosis markedly inhibits renal phosphate reabsorption, resulting in phosphaturia. The contribution of this mechanism to postburn hypophosphatemia is probably minor; early renal phosphate wastage is not observed, perhaps being obscured by diminished glomerular filtration early in burn injury. In addition, the *p*-carboxy metabolite of mafenide acetate strongly inhibits carbonic anhydrase. Such inhibition diminishes proximal tubular reabsorption

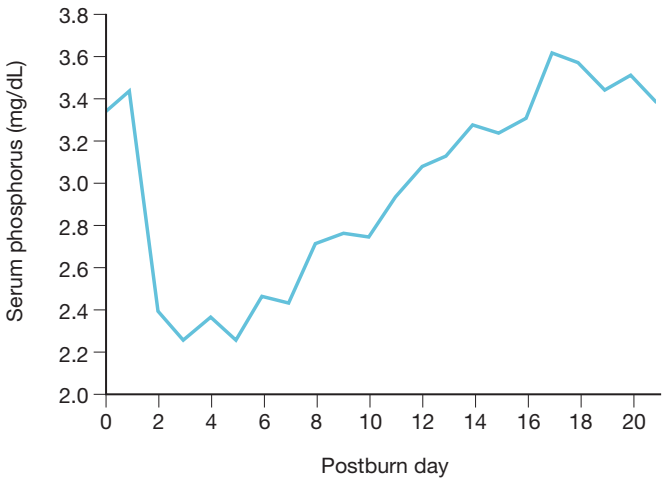

Fig. 27.1 Serum phosphorus levels abruptly decline with a nadir between postburn days 2 and 5. The data were obtained from 550 consecutive burn patients admitted to the U.S. Army Institute of Surgical Research.

Box 27.1 Possible Causes of Postburn Hypophosphatemia

Fluid resuscitation

- Volume loading
- Lactate administration

Carbohydrate administration

- Enteral alimentation
- Parenteral hyperalimentation
- 5% dextrose

Elevated catecholamines
Phosphate-binding antacids or sucralfate
Acid–base disturbance
Electrolyte imbalance

- Hypokalemia
- Hypomagnesemia
- Hypocalcemia

Carbonic anhydrase inhibition (mafenide acetate)

of phosphate and probably occurs after topical burn wound treatment with mafenide, but the magnitude of the effect is unknown.

Expansion of the extracellular fluid volume is also associated with inhibition of proximal tubular phosphate reabsorption. A tight coupling exists between sodium and phosphate transport across the renal epithelial cell. In patients with burns, mobilization and excretion of the large edema volume usually begins by the second postburn day and continues throughout the next week to 10 days. In contrast to the relative paucity of phosphate excretion during the first 24 hours after injury, when glomerular filtration is markedly reduced, a modest loss of phosphate may occur with diuresis of the edema fluid. In fact, the diuretic phase is associated with an increase in the fractional excretion of phosphate despite a concomitant reduction in the serum phosphate concentration.[9] Phosphorus excretion during the natriuretic phase of early burn injury is consistent with the tight coupling observed in other diuretic states.

ULCER PROPHYLAXIS

Effective prophylaxis against Curling's ulcers with H_2 antagonists and antacid buffering has been a mainstay of burn care for the past 2 decades. Significant degrees of hypophosphatemia and phosphate depletion occur during continuous or chronic administration of phosphate-binding agents containing magnesium, calcium, and aluminum. These agents bind not only dietary phosphate but also phosphate secreted into the intestinal lumen, often resulting in a net negative phosphate balance. The severity of such hypophosphatemia clearly depends on the dose of phosphate-binding agents, dietary phosphorus intake, and preexisting phosphate balance. To reduce alimentary scavenging of dietary and secreted phosphate, buffering with antacids containing aluminum phosphate salts (Al_2PO_4), which do not bind any additional phosphate, may be used. Sucralfate, which is also effective in preventing upper gastrointestinal stress ulceration after thermal injury, is not a buffering agent, but as a complex salt of aluminum hydroxide, is capable of binding phosphate. Its administration has also been associated with the development of hypophosphatemia in critically ill patients.[10]

HYPERVENTILATION

Respiratory alkalosis is often present during the first week postburn and may be enhanced by anxiety or pain and even by the inhibition of carbonic anhydrase induced by mafenide acetate burn cream. As fluid resuscitation progresses, the respiratory rate and tidal volume progressively increase, resulting in minute ventilation that may be twice normal. Mild hyperventilation induces only a slight decline of serum phosphorus levels; prolonged, intense hyperventilation, however, may result in serum phosphorus values less than 1.0 mg/dL.[11] During respiratory alkalosis, phosphorus virtually disappears from the urine, eliminating renal losses as the causative mechanism. Respiratory alkalosis induces a rapid movement of carbon dioxide from the intracellular to the extracellular space. Intracellular pH increases, activating glycolysis and increasing the formation of intracellular phosphorylated carbohydrate compounds. The readily diffusible inorganic phosphate pool supplies the required phosphorus, and serum phosphorus concentrations consequently fall abruptly. The extent to which this mechanism contributes to postburn hypophosphatemia is uncertain.

METABOLIC SUPPORT

Administration of carbohydrates may play a major role in the development of postburn hypophosphatemia. Infusion of glucose solutions or oral intake of carbohydrates produces mild hypophosphatemia in healthy individuals. This decrease in serum phosphate is associated with an increase of inorganic phosphate, adenosine triphosphate (ATP), and glucose 6-phosphate in muscle cells. The mechanism by which such carbohydrate administration induces hypophosphatemia is somewhat speculative. Experience with

phosphate-deficient total parenteral nutrition and subsequent development of hypophosphatemia has provided some insight into the etiology.[12,13] As carbohydrates are absorbed, insulin secretion increases, shifting phosphorus from the extracellular to the intracellular space. If phosphate reserve is low, ATP is poorly regenerated because hypophosphatemia inhibits glucose 3-phosphate dehydrogenase. Inorganic phosphates in the intracellular pool become further diminished because of incorporation, initially as newly synthesized ATP, but eventually as triose phosphates when the ATP is consumed in the hexokinase reaction. Glucose utilization by red blood cells (RBCs) requires ATP at the hexokinase and phosphofructokinase steps, but regeneration of ATP does not occur during phosphate deficiency or acute hypophosphatemia because of a block at the glucose 3-phosphate dehydrogenase step. In states of phosphate depletion, the scant phosphate that enters the RBC is incorporated into 1,3-diphosphoglycerate, but most is diverted to 2,3-diphosphoglycerate (2,3-DPG), also preventing complete glycolysis to regain the ATP consumed.

In thermally injured patients, infusion of dextrose-containing solutions usually begins 24 hours postburn, and enteral nutrition, in which most of the calories are supplied as carbohydrates, is initiated within several days of injury. These interventions are temporally correlated with the rapid descent of serum phosphorus concentrations. In other clinical states, severe hypophosphatemia after the initiation of enteral or parenteral nutrition is most commonly associated with the feeding of patients with advanced protein-calorie malnutrition. When total body phosphorus is depleted by starvation, serum phosphorus levels usually remain normal, but carbohydrate administration produces a rapid marked decline in serum phosphorus concentration. If untreated, this may result in multisystem organ dysfunction, respiratory and cardiac failure, or death. Thermally injured patients are usually well nourished before burn injury, and the clinical scenario of refeeding hypophosphatemia may not apply to them. Similar findings, however, have been described recently in previously well-nourished surgical intensive care unit patients in whom the initiation of isotonic enteral feedings resulted in a decrease of serum phosphorus from normal levels to approximately 1 mg/dL, a level that is considered to be dangerously low and to require prompt supplementation.[14,15] In addition, the authors have reported that hypophosphatemia in thermally injured patients is exacerbated by the initiation of enteral feeding and occurs regardless of the postburn day when feeding is initiated.[3] This further reduction of serum phosphorus during the first postburn week, when levels are already low, may be particularly hazardous and speaks for aggressive phosphorus supplementation before and during the initiation of enteral alimentation.

BURN WOUND PHYSIOLOGY

In patients recovering from thermal injury, the burn wound itself may act as a significant phosphorus sink. Despite the overall catabolism accompanying major injury and loss of lean body mass, healing burn wounds and skin grafts are anabolic and require phosphorus for normal repair. In addition, the continued loss of fluid and protein through the burn wound surface is a potential source of unquantified phosphorus loss and may contribute to hypophosphatemia.[16] In a comparison between burn patients and traumatically injured patients, it was shown that urinary phosphorus clearance, fractional excretion of phosphorus, and renal threshold phosphate concentrations were not different between the two groups; however, persistent hypophosphatemia persisted in the thermally injured patients. This may further implicate the wound as a source of early phosphorus loss.[17]

ACUTE-PHASE RESPONSE AND SEPSIS

Burn injury is characterized by an abrupt increase in acute-phase proteins as patients enter the hypermetabolic phase of burn injury. These same responses are similar to those observed in the sepsis syndrome. Recently, the development of hypophosphatemia has been characterized in patients with the acute-phase response syndrome.[17] Similar findings have been documented in patients with sepsis and infection, and correlation to increase in levels of cytokines such as tumor necrosis factor alpha and interleukin-6 has been made.[18] Similar findings were observed in patients with a variety of infectious diseases, and correlation of high levels of C-reactive protein and white blood cell (WBC) count was made with the magnitude of hypophosphatemia.[19] Although these reports did not include burn-injured patients, one may infer that activation of the inflammatory cascades such as occurs in major thermal injury may contribute to the development of hypophosphatemia.

OTHER ELECTROLYTES

Disorders of electrolyte balance may contribute to the development of hypophosphatemia. Experimental magnesium deficiency in animals may lead to phosphaturia and phosphorus deficiency, but intentional magnesium deficiency in man results in no change or a slight rise in serum phosphate.[20,21] In individuals with chronic alcoholism, however, hypomagnesemia and hypophosphatemia are coexistent. Hypokalemia, which is also exacerbated by magnesium deficiency, may result in phosphate wasting and hypophosphatemia. The mechanism is uncertain but may be related to coexistent metabolic alkalosis, diuretic use, or the underlying illness. Changes in calcium and phosphate homeostasis and in the regulating hormones calcitonin and parathyroid hormone (PTH) have been described after thermal injury.[22] Coincident with the early depression of serum phosphorus, the fraction of ionized calcium was shown to decrease and remain low, but within the normal range, for the 14 postburn days studied. Urinary calcium output was low, about 4.5 mmol/day, and urinary phosphate output was as high as 30 mmol/day despite a low serum phosphorus level. Serum calcitonin levels were significantly elevated for up to 2 weeks postinjury, but PTH remained within the normal range. The magnitude of the contribution of the classic regulating hormones of calcium and phosphorus homeostasis to the observed decrease in serum phosphorus after severe injury is not known with certainty. Catecholamines and glucagon are known to induce an increase in calcitonin secretion, and the administration of pharmacologic doses of calcitonin results in

phosphaturia. A direct effect of calcitonin on phosphate transport in the nephron has been demonstrated. In these burn patients, it was notable that ionized calcium decreased slightly but still within the normal range despite very high levels of calcitonin and normal PTH concentrations. A slight, although statistically significant, increase in PTH was observed around the fourth postburn day and may be related, albeit indirectly through calcium regulation, to the observed postburn decrease in serum phosphorus concentration.

SUMMARY

Clearly, multiple factors influence the serum phosphorus level after burn injury. Fluid resuscitation and subsequent mobilization of interstitial edema fluids, catecholamine excess, respiratory alkalosis, the use of phosphate-binding antacids or sucralfate, hypokalemia, hypomagnesemia, and the initiation of enteral nutrition have all been associated with hypophosphatemia in other illnesses and experimental models. All or most of these factors may be encountered in the early treatment of burn patients, and the contribution and relative importance of individual factors to the depression of serum phosphorus is difficult to analyze. Most likely, carbohydrate administration, respiratory alkalosis, and diuresis of edema fluid are the more important etiologic factors contributing to hypophosphatemia in the early postburn course.

Consequences of Hypophosphatemia

The clinical manifestations of hypophosphatemia (Box 27.2) are mainly those of organ system hypofunction. These responses have been defined through clinical observation and laboratory studies in circumstances in which hypophosphatemia occurred as a relatively isolated event. Phosphorus supplementation has been reported to reverse these abnormalities, suggesting a cause-and-effect relationship. Hypofunction of organ systems associated with phosphorus depletion has been attributed to a lack of available inorganic phosphate for synthesis of high-energy phosphorus compounds; breakdown of stored ATP occurs, and the inorganic phosphate is diverted to other intracellular pathways. Organ system dysfunction after thermal injury is characterized by early hypofunction and later hyperfunction of most organ systems. Whether hypophosphatemia contributes significantly to the early postburn depression of function that occurs in multiple organs is not known. Clearly, some of the clinical manifestations shown in Box 27.2 are commonly observed in thermally injured patients, but others are not usually associated with such injury. Most patients reported to have had complications of hypophosphatemia have also had a coexistent and severe illness. It is important to remember that prior cellular injury has been prerequisite in most instances in which hypophosphatemia has been implicated as a cause of organ system dysfunction. The following discussions of organ system abnormalities should be interpreted in light of the specific circumstances under which the observations were made.

Box 27.2 Clinical Manifestations of Hypophosphatemia

Central nervous system
- Lethargy, malaise, neuropathy, seizures, coma

Cardiovascular
- Impaired cardiovascular contractility
- Decreased response to pressor agents
- Hypotension
- Acute cardiac decompensation

Pulmonary
- Tachypnea
- Decreased vital capacity
- Respiratory failure

Gastrointestinal
- Anorexia, dysphagia

Renal
- Glycosuria, calciuria, magnesuria, renal tubular acidosis

Musculoskeletal
- Weakness, myalgia, arthralgia, rhabdomyolysis

CARDIAC DYSFUNCTION

Although the early depression of cardiac function after burn injury has been attributed to an initial decrease in circulating blood volume, the search for intrinsic myocardial depression after burn injury and for mediators of such depression continues. In experimental studies and in clinical material, a correlation between hypophosphatemia and cardiac decompensation has been reported. Cardiac output, measured by bolus thermodilution, was impaired in seven critically ill patients with hypophosphatemia and improved significantly with phosphorus supplementation.[4] In one experimental study, myocardial contractility was impaired by phosphorus deficiency and reversed by phosphorus repletion, suggesting that phosphorus deficiency may be a cause of heart failure in certain clinical conditions.[23] Hypophosphatemic cardiac depression has been described as occurring in 28.8% of surgical intensive care patients.[24] Despite these reports, there appears to be little evidence that hypophosphatemic cardiomyopathy is a frequently encountered clinical entity; most patients in whom this mechanism is invoked have already had a number of other causes for myocardial dysfunction.[25]

NEUROMUSCULAR DYSFUNCTION

Varying degrees of areflexic paralysis, paresthesias, sensory loss, weakness, and respiratory insufficiency have been reported to be associated with acute hypophosphatemia, usually induced with feeding malnourished patients.[12] A reduction in available ATP to support respiratory muscle contraction has been suggested as a mechanism for acute respiratory failure, and diaphragmatic contractility has been reported to improve with phosphorus repletion in mechanically ventilated hypophosphatemic patients.[26] Profound generalized muscle weakness associated with

isolated phosphorus depletion has been observed in both clinical and laboratory studies.[27,28] In a study of hypophosphatemia and muscle phosphate metabolism in patients with burns or mechanical trauma, no direct correlation was demonstrated between the serum phosphorus concentration and the high-energy phosphate content of muscle cells; all of these patients, however, were receiving phosphorus supplementation during the study.[29] If acute hypophosphatemia is superimposed on preexisting cellular injury, potentially reversible muscle cell dysfunction may extend to irreversible necrosis.[30] Several authors have reported severe rhabdomyolysis associated with severe hypophosphatemia after burns and major trauma.[31,32] This spectacular clinical event is rare but may occur to a lesser, subclinical, extent in critically ill patients.[30,33] Hypophosphatemia as the underlying etiology may often be dismissed because muscle cell destruction results in release of phosphate and elevation of serum phosphorus. In the absence of significant hemochromogenuria, the diagnosis may not even be suspected. Further investigation is required to determine whether this "asymptomatic" rhabdomyolysis is, in fact, an important clinical entity or merely an obligate manifestation of critical illness.

HEMATOLOGIC DYSFUNCTION

When untreated, severe hypophosphatemia may lead to RBC dysfunction by alterations in cell shape, survival, and physiological function. Lack of high-energy phosphate results in a decrease in erythrocyte 2,3-DPG and subsequent leftward shift of the dissociation curve, with a consequent risk of tissue hypoxia.[7] Clinical hypophosphatemia, with or without previous phosphate depletion, results in reduced production of 2,3-DPG, erythrocyte ATP, and other phosphorylated intermediates of RBC glycolysis. In a variety of experimental and clinical situations, including burn injury and mechanical trauma, RBC 2,3-DPG has been shown to be reduced in the presence of hypophosphatemia.[34,35] In thermally injured patients, it has been demonstrated that postburn disturbance of RBC phosphate metabolism may be prevented by administration of phosphorus in the early postburn course.[35] Hypophosphatemia has also been associated with decreased RBC survival and decreased RBC deformability, with impaired capillary transit and the potential for further deficiency of tissue oxygenation.

White blood cell dysfunction also has been observed as a result of hypophosphatemia induced by the initiation of phosphate-free parenteral nutrition and was associated with depressed chemotactic, phagocytic, and bactericidal activity of granulocytes.[35] A reduction in granulocyte ATP content was also documented and amelioration of these WBC abnormalities was coincident with phosphorus repletion. Any correlation between these observations and an increased risk of infection remains speculative for hypophosphatemic patients in general and burn patients in particular.

SUMMARY

Although it is clear that organ system dysfunction may be a manifestation of severe untreated hypophosphatemia, the relationship between these specific abnormalities and those observed in either the hypodynamic or hyperdynamic phases of burn injury remains unclear. Clinical experience dictates that even when severe hypophosphatemia is avoided, the scenario of early organ system hypofunction and later hyperfunction persists. This is not to say that the marked hypophosphatemia observed after burn injury is part and parcel of the disease process, without bearing on the postburn physiological response but that thus far, the pathophysiological milieu after thermal injury has not permitted definition of the contribution of hypophosphatemia to the overall postburn response. Until cause-and-effect relationships are defined through ongoing research, aggressive phosphorus repletion should be approached cautiously after thermal injury. Such therapy does, however, clearly ameliorate RBC 2,3-DPG depletion, which, in and of itself, supports treatment.

Prevention and Treatment of Hypophosphatemia

An unequivocal recommendation to treat hypophosphatemia in thermally injured patients should be supported by evidence that the treatment is of benefit. Such evidence is somewhat lacking in thermally injured patients, but in many analogous instances of hypophosphatemia from other causes, a direct benefit has been ascribed to repletion.

Serum phosphorus levels should be measured daily during the early phase of burn care and intravenous phosphate repletion initiated when levels drop below 2.0 mg/dL (Fig. 27.2). Most of the severe adverse effects of hypophosphatemia occur with concentrations below 1.0 mg/dL, and this replacement strategy should prevent the development of clinically significant hypophosphatemia. Correction of severe hypophosphatemia with serum phosphorus levels less than 1.0 mg/dL requires intravenous replacement, usually with solutions of sodium or potassium phosphate containing 0.16 mmol/kg body weight (5 mg/kg body weight) of elemental phosphorus over 6 hours. The dose may be halved for patients with serum phosphorus levels between 1.0 and 2.0 mg/dL.[36] After completion of the infusion, a repeat serum phosphorus determination should be obtained, and further treatment should be based on the postinfusion plasma concentration. A potential hazard associated with intravenous administration of phosphate salts is hyperphosphatemia, which may induce metastatic deposition of calcium phosphate salts and hypocalcemia. Additionally, when potassium phosphate salts are used, care must be taken to avoid excessive or too rapid administration of potassium. Phosphorus replacement should be carefully monitored; proceed with great caution in patients with impaired renal function or evidence of soft tissue injury or necrosis.

Prevention of hypophosphatemia may be facilitated by beginning oral phosphorus replacement before interventions such as the initiation of either enteral or parenteral carbohydrate administration, gastric acid neutralization with phosphate-binding antacids or sucralfate, and the administration of diuretics. The nadir of serum phosphorus

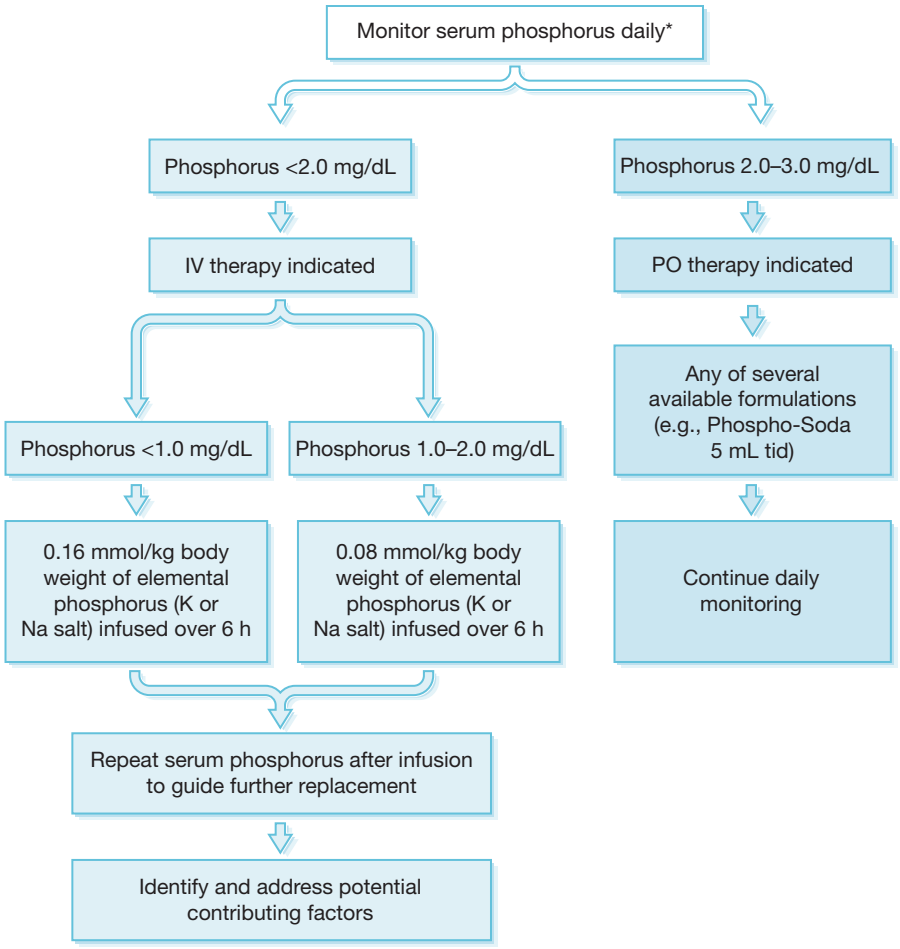

Fig. 27.2 The use of this algorithm permits prompt detection and timely correction of hypophosphatemia after burn injury. *IV,* Intravenous; *PO,* oral; *tid,* three times a day.

concentration typically occurs between 3 and 5 days postburn, during the period of edema mobilization, and the need to initiate phosphorus supplementation should be anticipated in this interval. Additionally, to temper the gastrointestinal losses caused by administration of phosphate-binding antacids, substitution of or alternation with antacids containing aluminum phosphate should be considered.

For mild asymptomatic hypophosphatemia and for prophylaxis when worsening of hypophosphatemia is expected, oral supplementation with any of several available formulations is recommended. Such oral regimens have been shown to be cost-effective.[37] Five milliliters of Phospho-Soda, containing 4.2 mmol/mL of elemental phosphorus, is commonly administered three times daily. Correction of other electrolyte abnormalities, most notably hypomagnesemia, hypocalcemia, and hypokalemia, as well as maintenance of acid–base normality, may prevent further renal phosphate losses and maintain the extracellular phosphate pool. In a recent publication by Kahn et al., continuous, preemptive repletion of phosphate by continuous infusion prevented hypophosphatemia after severe burn injury when compared with responsive repletion in historical control participants.[38] The protocol resulted in less hypophosphatemia without increasing the risk of hyperphosphatemia. Fewer cardiac and infectious complications were seen in the treatment group; however, the authors suggested that these findings needed further study.

After the 10th postburn day, the phosphorus delivered in standard liquid enteral formulas and hospital diets is usually sufficient to maintain serum phosphorus levels above 3.0 mg/dL.

SUMMARY

Thermal injury induces a precipitous decrease in serum phosphate concentration that reaches its nadir between the second and fifth postburn days. This phenomenon has been recognized for some time, but interest in the problem has been limited. The organ system dysfunctions induced by hypophosphatemia are in many ways similar to certain of the pathophysiological changes observed after burn injury. The contribution of hypophosphatemia to these manifestations remains undefined. Wound fluid losses, increased circulating catecholamines, intracellular phosphate redistribution, and increased fractional excretion of urinary phosphate, as well as iatrogenic induction of hypophosphatemia through various therapeutic interventions, have been implicated as contributing to postburn hypophosphatemia. There may be other pathways regarding phosphorus

regulation that have not been explored in this patient population. Frequent serum phosphate measurement and prompt phosphorus replacement when hypophosphatemia is recognized should minimize any sequelae of this potentially deleterious electrolyte deficiency.

28 Nutritional Needs and Support for the Burned Patient

JOSHUA S. CARSON, HOUMAN KHOSROZADEH, WILLIAM B. NORBURY, and DAVID N. HERNDON

Introduction

The massive burn is as much a metabolic insult as it is a tissue injury. Clearly resultant tissue defects represent the critical factor in long-term functional complications from massive burns. In the acute phase of burn care, a persistent, overwhelming metabolic response to thermal injury compromises the functional integrity of virtually every organ system. This response compromises wound healing capacity and the integrity of the body's defense mechanisms.

The massive burn represents a metabolic "double hit," a nutritional challenge of both supply and demand for the injured patient. The burn wound creates drastically increased demand for anabolic metabolism for wound healing while simultaneously triggering a systemic catabolic state. The resulting mismatch between high anabolic demand and negative anabolic supply (catabolism) leads to a profound state of functional malnutrition which, in turn, facilitates rapid debilitation and immunosuppression that place patients at profound risk for infectious complications. Addressing these nutritional challenges is thus critical to effective care for the burn patient.

Metabolic Pathology Associated With Burn Injury

Following all forms of major trauma, inflammatory and hormonal responses are activated and greatly influence metabolic pathways and mechanisms. Nutrient intake, absorption, and substrate assimilation are all affected during the different stages of the stress response. Nutrient requirements will increase but become more difficult to predict, and enteral or parenteral feeding will often be necessary to meet vastly increased nutritional requirements.

The physiologic response to trauma leads to activation of an array of processes, many of which increase immediate energy availability as part of the evolved flight-or-flight response. It is an evolved response to stress that assists the organism in overcoming a transient stress. However there is no adaptive response to the kind of sustained stress state seen with massive burns because these injuries were not survivable prior to the development of modern medicine. By supporting patients through what would otherwise be nonsurvivable states, modern medical care has created a novel physiologic state—a state of prolonged acute injury for which there is no adapted evolutionary response. In this state, powerfully adaptive responses to immediate stress become maladaptive when sustained for a timeline well beyond those encountered in the evolutionary context (Fig. 28.1).

The hypermetabolic response to stress is particularly exaggerated in thermal injuries. The severity of the catabolic response to burn injury cannot be overemphasized. Decades of clinical and animal research have demonstrated with increasing depth and detail the ways in which burn injury profoundly alters the host organism's metabolism to upregulate catabolic processes and inhibit anabolic processes. The net result is a substantial net loss of lean body weight with a distinctly exaggerated effect on protein stores. The pathophysiology of this protein wasting is notable for a diverse array of endocrine and metabolic factors from the cellular to the organismal level (Fig. 28.2).[1–3]

Adrenal hyperactivity in burn patients was well documented more than 50 years ago, with massive surges in serum and urinary catecholamine levels seen within hours of burn. Inappropriate catecholamine and cortisol production has since been found to persist for weeks to months following massive burns, with end organ effects reaching the metabolic, cardiovascular, musculoskeletal, and immune systems.[4–8] A sustained surge of catecholamines and inflammatory cytokines, along with massive wounds and profound dysregulation of thermal homeostasis, all combine and interact to yield enormous increases in resting energy expenditure.

Distorted thermal regulation plays a significant role in the increase in resting energy expenditures seen in burn patients. Destruction of a large portion of the primary thermoregulatory organ, the skin, leads to an ongoing drain of body heat via decreased insulation and the facilitation of evaporative heat loss. The primary central hyperthermia associated with the burn response compounds this energy drain. Alterations in thalamic temperature set-point, catecholamine-induced hypermetabolism, and shunting of mitochondrial energy to heat-producing pathways all drive the hyperthermia seen within 24 h of burn injury. As Wilmore and Pruitt et al. described in 1974, "Burn patients are internally warm, not [just] externally cold." Thus, the burn patient's metabolism is taxed with the challenge of generating sufficient heat to maintain a higher body temperature with less heat-conserving resources.[8]

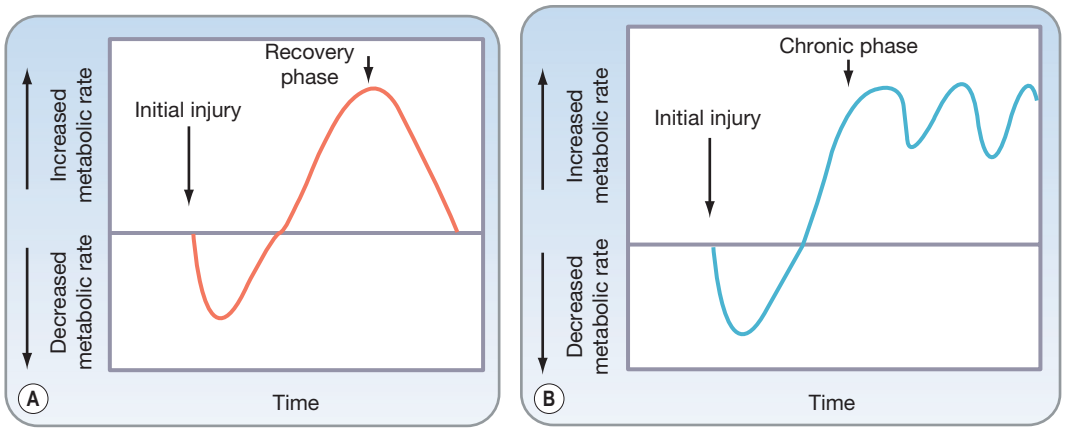

Fig. 28.1 Metabolic response to injury and trauma. Burn patients transition from the initial hypermetabolic response directly into a state of chronic hypermetabolism. (A) Classic ebb and flow phases of the acute stress response. The metabolic rate initially falls below normal and then increases to supranormal levels before returning to normal. (B) Ebb and flow revisited. In burn patients, the classic ebb and flow pattern is altered. Recurrent bouts of sepsis superimposed over a baseline of burn-induced proinflammatory stimuli result in a fluctuating metabolic demand, which remains chronically elevated. (From Ball S, Baudouin SV. Endocrine disorders in the critically ill: the endocrine response to critical illness. In Hall GM, Hunter JM, Cooper MS, editors. *Core topics in endocrinology in anaesthesia and critical care*. Cambridge: Cambridge University Press; 2010: 126–131.)

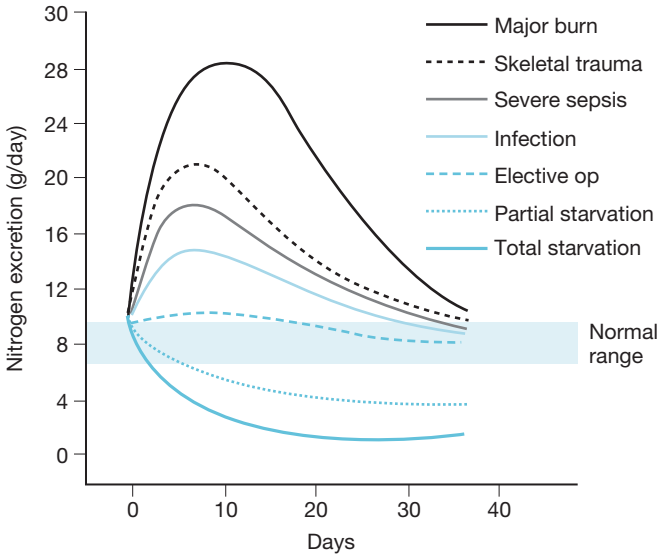

Fig. 28.2 Thermal injury induces a distinctly profound metabolic shift towards proteolysis. (From Long CL, Blakemore WS. Energy and protein requirements in the hospitalized patient. *JPEN J Parenter Enteral Nutr*. 1979 Mar–Apr;3(2):69–71.)

Nutritional Demand and Substrate Metabolism in Burn Patients

INCREASED TOTAL CALORIC DEMAND

Thermal injury triggers a marked increase in global energy expenditure, driven by a maelstrom of catecholamines, corticosteroids, and inflammatory cytokines.[2,9] In an earlier era of burn care—prior to the advent of early excision, pharmacologic interventions for hypermetabolism, and modern critical care—measurements of energy expenditure in patients with large burns were reported to range from 1.5 to 2.5 times those found in nonburn controls. While modern burn care has made significant progress in countering this hypermetabolic response, contemporary studies still report an average resting energy expenditure from 1.3 to 1.5 times those found in nonburn controls.[10–12]

SUBSTRATE-SPECIFIC REQUIREMENTS

See Fig. 28.3 for a simplified overview of the metabolic pathways involved in massive burn trauma.

Carbohydrates

The acute metabolic response to burn injury significantly alters carbohydrate metabolism and demands. Glucose/carbohydrate metabolism presents the burn physician with a rather vexing conundrum. On the one hand, failure to provide adequate carbohydrates results in additional compensatory protein catabolism.[13,14] And yet, on the other hand, the human body has a finite capacity for glucose oxidation. Multiple studies have demonstrated a limit to the amount of carbohydrate calories a burn patient can assimilate—approximately 5 g/kg per day in adult and 7 g/kg per day in children.[15,16] Providing glucose in excess of these limits will thus result in increasing hyperglycemia with resultant lactic acidosis (Fig. 28.4).

Unfortunately, with the enormous global energy expenditure of the massive burn patients, even a diet with a reasonably low percentage of carbohydrate-based calories can yield total carbohydrate loads well in excess of these limits when titrated up to meet full caloric requirements. Unfortunately administration of carbohydrates in excess of the patient's capacity for glucose oxidation will only result in increasing degrees of hyperglycemia, glucosuria, and hypertriglyceridemia. In such cases, the patient's nutritional demands simply reach a point where they exceed that patient's metabolic capacity.

Guidelines typically recommend providing 50–60% of calories as carbohydrates in the setting of trauma or burn injury.[17–19] However these same guidelines also recommend that total carbohydrate provisions not exceed 5 g/kg per

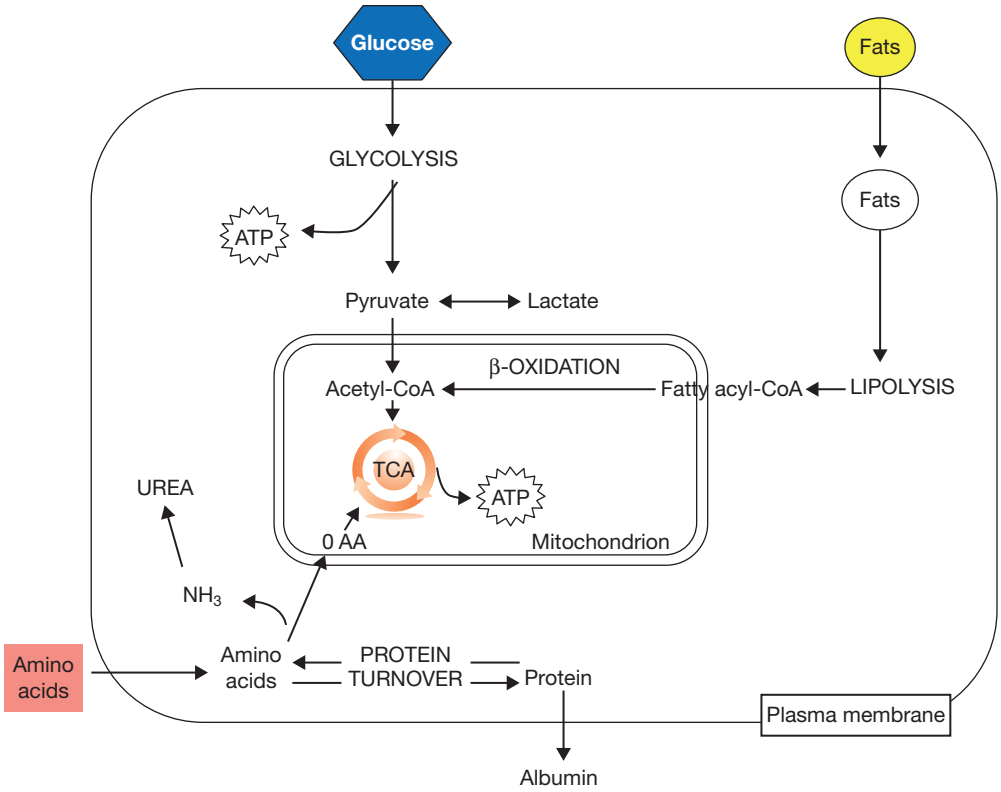

Fig. 28.3 Simplified overview of metabolic pathways.

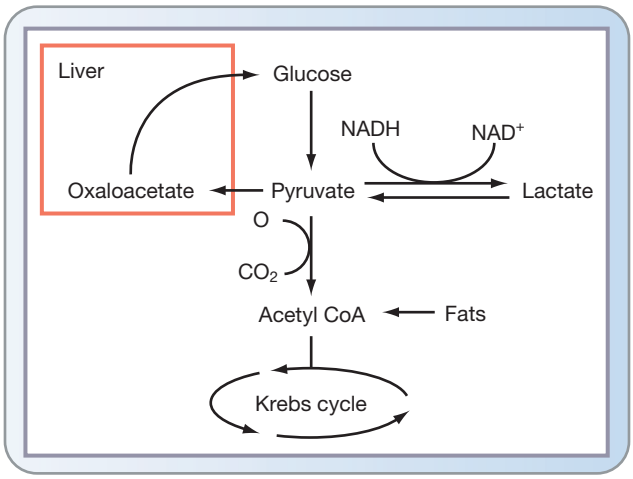

Fig. 28.4 Oxidative decarboxylation of pyruvate is a pivotal step in the overall oxidative metabolism of carbohydrates and fats. Overwhelmingly high levels of glucose may lead to lactate production, even in the presence of oxygen. (From Gore DC, Ferrando A, Barnett J, et al. Influence of glucose kinetics on plasma lactate concentration and energy expenditure in severely burned patients. *J Trauma* 2000;49:673–677.)

day (or 7 g/kg per day in children). Unfortunately providing 50–60% of calories as carbohydrate in the context of a nutritional therapy that meets the appropriately calculated total caloric needs of a burn patient will often result in doses of carbohydrates well in excess of these recommended limits.[11,12,16,18–20] There is no simple, clinically vetted solution to this challenge. A reasonable approach to this dilemma is to start by titrating enteral formula delivery up to a rate that delivers 5–7 g/kg per day of carbohydrates and then provide all further calories in the form of protein supplementation.

Fats

While lipids are unquestionably critical to effective basic homeostasis and wound healing, the amount of fat required to prevent essential fatty acid deficiency is remarkably small in patients with intact fat stores. Excess fat administration, on the other hand, can cause significant harm. The hypermetabolic response to thermal trauma upregulates lipolysis of circulating lipids. This surfeit of circulating free fatty acids is countered by increased hepatic esterification, with close to 70% of the free fatty acids accumulating in the liver. To minimize hepatic steatosis, the percentage of dietary calories from fat should be limited and carefully monitored. Multiple studies have demonstrated improved outcomes with lower fat nutrition therapy in burn patients.[21–23] Fat content should make up 3–15% of total calories. Patients receiving total parenteral nutrition (TPN) for a short period of time (e.g., less than 10–14 days) can generally be spared lipid infusion. In those requiring sustained TPN, 0.5–1 g/kg one to two times per week is sufficient. It should be noted that nondietary fat calories need to be taken into considerations as well: for example 1% propofol solution carries a proportional fat load equivalent to that found in a 10% intralipid emulsion.

It should be noted that the preceding discussion of the role of fat alimentation in nutritional therapy reflects a literature that largely predates the application of alternative
